5. *Chronic Joint Lesions.* Acute injuries to joints and cartilage are sometimes followed by such lesions as chronic synovitis, chronic traumatic arthritis, and joint mice. (*a*) *Chronic synovitis* is an ill-defined term applied to recurrent and persistent pain, swelling and fluid in the joint, particularly after exertion. When chronic synovitis develops after trivial injury, tuberculous disease of the joint is to be suspected. Often it follows trauma with injury to cartilage or because of malunion of an associated fracture. Occasionally an unsuspected joint mouse is responsible. In many cases, the cause is to be sought in repeated trauma or perhaps in insidious types of infection. Villous arthritis is a form of chronic synovitis in which the synovia proliferates to form numerous projections or villi into the joint. It may develop spontaneously without previous injury, is most common in older individuals, and may be present without symptoms or at most may cause "rheumatic" pains. It is manifested clinically by puffiness about the joint, commonly the knee, and a crepitation on motion and sometimes by fluid in the joint. (*b*) *Traumatic arthritis* is really a type of synovitis as just discussed except that the symptoms of pain, swelling, and disability clearly follow, and are due to a preceding injury (see also p. 540), and are aggravated by use of the part. (*c*) *Joint mice* are loose bodies in the joint which are composed of fragments of cartilage or bone which becomes covered with cartilage, and which move freely about inside the joint cavity (Fig. 13). They may give rise to pain, swelling, and disability (often in attacks) by their mechanical interference with joint movements. They are frequently the result of previous joint disease or injury. Loose bodies in the joints are also produced by spontaneous detachment of segments of the articular cartilage and underlying bone (osteochondritis dissecans) or by actual neoplastic growths from the synovial membrane (osteochondromatosis). X-ray usually reveals these loose fragments when they contain bone or calcified areas. Operation for their removal is often indicated when symptoms are sufficiently severe.

Fig. 13. Joint mouse of unusually large size in the knee. The patient was a 67-year-old man. Symptoms of mild pain in the knee were not sufficient to justify arthrotomy. There was no history of trauma.

Joint Infections. *The effect of pathogenic bacteria on joints is varied and depends on the causative organism. Since all parts of the joints are usually affected, the lesion is really an arthritis.* The influence of chemotherapy as discussed above (under Bone) is also true of joints.

1. *Acute Pyogenic (Suppurative) Arthritis.* The joint is not infrequently infected with pyogenic bacteria from without by penetrating wounds, from adjacent osteomyelitis, or most commonly *from the blood stream* as a *hematogenous infection.* In the latter case, evidence of disease elsewhere—such as a pneumonia, endocarditis, otitis media, and septicemia—is frequently present. However, the joint involvement may be the first manifestation and occasionally the only site of disease. Like osteomyelitis, the disease is most commonly encountered during childhood. The streptococcus, staphylococcus, and occasionally the pneumococcus are the organisms most frequently responsible for the infection. The gonococcus produces a special type of arthritis, which is considered separately. The inflammation begins as an acute synovitis, the joint filling with thin, slightly turbid fluid which contains many bacteria and leukocytes of the polymorphonuclear type. As the infection progresses, the cellular elements increase so that after a few days frank pus may fill the joint cavity. Of serious importance is the early involvement of the cartilage, which is attacked directly and destroyed. On some occasions, the loss of cartilage may include most of the articular surface. Pressure of the opposing surfaces aids in destruction of cartilage. As the inflammation subsides, these denuded areas become filled with granulation tissue and, since this cartilage does not regenerate, the raw areas eventually become united with each other across the more or less obliterated joint space with either fibrous or bony tissue. This end stage of repair leaves the joint in a state of immobility or ankylosis which, if bony, results in absolute immobility, but if fibrous may be only partial (Fig. 14).

Clinical manifestations are local and general, the latter being those of septicemia, as already described. The degree of fever and prostration may be great and often overshadows the local lesion. Pain is exquisite and localized to the joint, but is especially excruciating on the slightest attempt to move the joint. Tenderness is also marked and is sometimes so pronounced that the weight of the bedclothes cannot be borne. Associated with

Fig. 14. Complete ankylosis of the knee due to suppurative arthritis. X-rays (anteroposterior and lateral views) taken six months after the onset; the infection has completely subsided. The patient, a healthy 18-year-old schoolboy, was treated conservatively in a hospital for several weeks; late in the course of the infection several abscesses were opened above the knee, extensions no doubt of pus breaking through the suprapatellar bursas. Note the complete bony ankylosis; an arthroplasty was done with partial restoration of motion.

the pain is extreme muscle spasm of the adjoining muscle groups which splint the joint in a fixed position, usually in slight flexion. In the hip, flexion is accompanied by abduction and external rotation, a position which corresponds to the greatest relaxation of the joint capsule. Swelling, heat, and hyperemia are localized to the region of the joint. In superficial joints, the swelling is characteristically confined to the joint cavity which is easily apparent because of the obliteration of the bony landmarks. Frequently there is also a prominent superficial swelling due to edema of the subcutaneous tissue overlying the joint. Aspiration is important, especially in the deeper joints, such as the shoulder and hip, in order to establish the existence of joint fluid. Moreover, the examination of such fluid by smear and culture is essential for final diagnosis. Smears may reveal the presence of the organisms; segmented leukocytes also tend to brand the lesion as an acute pyogenic infection. Roentgenologic changes are late and due to destruction of cartilage obliterating the normal clear area between the ends of the bone.

Differential diagnosis of suppurative arthritis from acute rheumatic fever, acute osteomyelitis, and acute cellulitis is important because of the difference in the type of treatment required. *Acute rheumatic fever* is accompanied by acute joint manifestations for which operation is contraindicated; the joints are usually involved several at a time in this disease (but in a shifting pattern), and the general reaction, while marked, is not as severe as in acute pyogenic arthritis; the presence of cardiac signs and symptoms and the more subacute nature of the disease are also helpful. *Acute osteomyelitis* does not cause much joint tenderness or muscle spasm; there is no joint fluid or swelling; limitation of motion is less pronounced; the tenderness, while close to the joint, is located distinctly over the bone. *Acute cellulitis* over the joint may be confusing, but it is important to recognize since mechanical trauma, especially incision or even aspiration, may be

harmful. Usually the superficial location of the redness and swelling accompanying cellulitis is so localized as to be characteristic. Red streaks (acute lymphangitis), when present, point to acute cellulitis since they are absent in the deeper infections. Similarly, regional lymphadenitis, which practically always accompanies acute cellulitis, is absent in infections of the bone or joint, at least in its early stages. The typical joint effusion is absent in acute cellulitis; muscle spasm and limitation of movements are not apt to be present.

Treatment of acute pyogenic arthritis has been greatly influenced by the introduction of chemotherapy, which has permitted excellent healing without the necessity of operation in many patients whose treatment can be started early in the course of the disease. Antibiotics are used systematically as well as locally. The infected fluid is removed from the joint cavity and replaced with a solution of penicillin. This is repeated every day or two until the infection has subsided. Protection of the joint in a splint is appreciated by the patient to guard against movement, which is very painful. Slight traction with Buck's extension also relieves pain considerably and minimizes necrosis of the cartilaginous surface of the bones.

Now that antibiotics are available, arthrotomy is not necessary except in the rare, neglected cases when actual pus is found at aspiration or if suppuration develops in spite of treatment. Before the days of chemotherapy it was the procedure of choice. If considerable destruction of cartilage has occurred and ankylosis is inevitable, it is important to assure a good position for the fixed joint, i.e., one which gives a maximum of usefulness and a minimum of disability (see p. 551). Months or years after the infection has subsided, motion in the ankylosed joint may be restored by various types of arthroplasty.

2. *Gonococcal Arthritis.* There is usually a history of an acute urethritis or cervicitis preceding the joint lesion by several weeks. Because of modern therapy, the disease is only rarely seen now. While several joints may seem affected at the onset, serious manifestations generally localize in only one (Fig. 15). The disease is thus usually monoarticular, involving, in order of frequency, the

Fig. 15. Gonococcal arthritis of the elbow. A mild case with spontaneous recovery in a 26-year-old male. Onset two weeks previously; aspiration revealed thin serosanguinous fluid from which the gonococci were grown *in pure culture.* Patient discharged three weeks later with full function. This condition is no longer common.

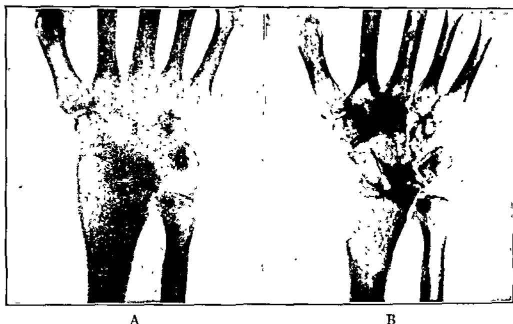

Fig. 16. Gonococcal arthritis of the wrist. The patient was a 27-year-old woman. There was a definite history of genital infection with identification of the organism from the cervix. A, x-ray seven weeks after onset of pain and swelling which was severe and disabling. Note the obliteration of joint markings indicating destruction of cartilage. Two periods of artificial fever each of four and one-half hours' duration produced prompt and lasting relief of symptoms; B, x-ray four months later; note the bony ankylosis, especially between the radius and lunate bone. The patient, while free from pain and swelling, has a partial limitation of motion. (Courtesy, Dr. Peter Heinbecker.)

knee, wrist, elbow, shoulder, hip, and ankle. Constitutional reaction is confined to fever and leukocytosis; prostration is rare. Tenderness and pain over the joint are exquisite so that sometimes even jarring of the bed is feared by the patient. However, great variations in severity are encountered, from a simple serous synovitis to actual suppuration with destruction of cartilage. In the former instance, satisfactory restoration of joint function may be expected; in the latter, bony or fibrous ankylosis is the rule (Fig. 16). The course of the disease may be prolonged for many weeks before subsidence of the acute manifestations. It may be difficult in the early stages to determine the course of the infection. This inconsistency in the progress of the disease undoubtedly accounts for the wide diversity in method of treatment. In many cases, especially the milder types, nonoperative therapy is adequate. However, in the suppurative type, incision and drainage may be indicated. Most forms of treatment used previously, such as fever therapy, have now been displaced by chemotherapy, especially with penicillin, as in other forms of gonorrheal infection, including salpingitis, and the like. Of great importance in cases ending in bony ankylosis is final fixation in a useful position of the joint (see p. 551).

3. *Tuberculous Arthritis.* This lesion is not uncommon in childhood and is a frequent cause of disability and crippling (Fig. 17). While constitutional signs and symptoms, such as loss of weight and afternoon fever, may be present, the disease not infrequently seems to present only local manifestations in a joint. Whether the bone or joint is the primary point of infection in joint tuuberculosis is still a considerably disputed question. A "cold abscess" occurs late in joint tuberculosis, but an effusion into the synovial cavity is usually present, which is often called "white swelling" because of the absence of acute signs. The hip and knee are commonly affected, but the ankle, shoulder, and elbow are also often involved. Years ago, before the days of dairy inspection and pasteurization, tuberculosis of bones and joints was much more common and was usually of bovine origin.

The onset is often gradual and insidious. Pain is always present, but may be slight, and is often referred to another joint. Thus the

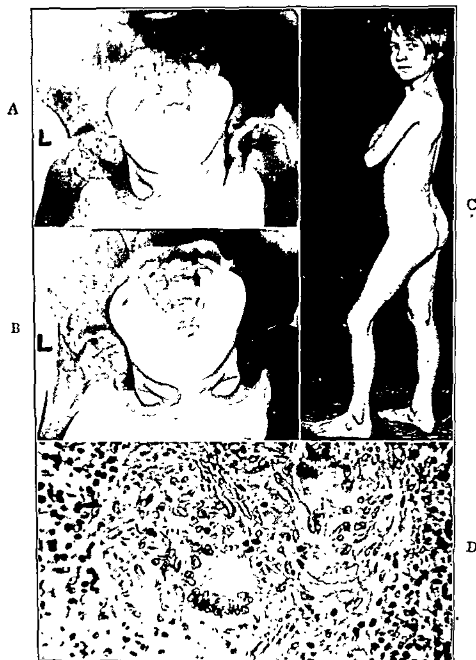

Fig. 17. Tuberculosis of the hip. For several months the patient, a seven-year-old girl, complained of pain and stiffness in the left hip followed by an increasing limp. A, the x-ray at this time was negative; nevertheless an operation was performed and a biopsy of the capsule revealed tuberculous tissue on microscopic section. The joint was immobilized in a cast; B, x-ray, one year later, shows marked changes and beginning ankylosis; C, photograph on admission; note the flexion at the hip and atrophy of the calf on the affected side; D, photomicrograph of the biopsy specimen showing typical giant cells.

pain associated with tuberculosis of the hip is often referred to the knee. Limping, however, may be the first apparent symptom. In the superficial joints, swelling is nearly always apparent. Aspiration will reveal fluid. There is a gradual atrophy of the adjacent muscles, which are tense and spastic. At night when they relax the pain may become severe and give rise to "night cries." After the disease has been present for some time, marked atrophy of bone becomes apparent. Eventually deformity may develop as a result of the

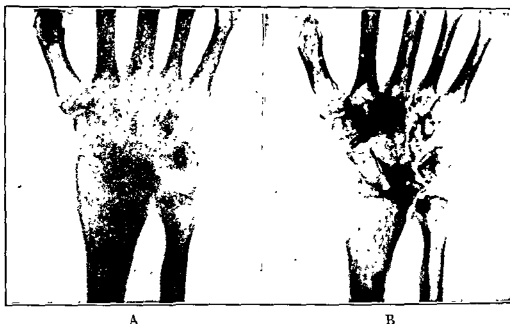

Fig. 16. Gonococcal arthritis of the wrist. The patient was a 27-year-old woman. There was a definite history of genital infection with identification of the organism from the cervix. knee, wrist, elbow, shoulder, hip, and ankle. Constitutional reaction is confined to fever and leukocytosis; prostration is rare. Tenderness and pain over the joint are exquisite so that sometimes even jarring of the bed is feared by the patient. However, great variations in severity are encountered, from a simple serous synovitis to actual suppuration with destruction of cartilage. In the former instance, satisfactory restoration of joint function may be expected; in the latter, bony or fibrous ankylosis is the rule (Fig. 16). The course of the disease may be prolonged for many weeks before subsidence of the acute manifestations. It may be difficult in the early stages to determine the course of the infection. This inconsistency in the progress of the disease undoubtedly accounts for the wide diversity in method of treatment. In many cases, especially the milder types, nonoperative therapy is adequate. However, in the suppurative type, incision and drainage may be indicated. Most forms of treatment used previously, such as fever therapy, have now been displaced by chemotherapy, especially with penicillin, as in other forms of gonorrheal infection, including salpingitis, and the like. Of great importance in cases ending in bony ankylosis is final fixation in a useful position of the joint (see p. 551).

3. *Tuberculous Arthritis.* This lesion is not uncommon in childhood and is a frequent cause of disability and crippling (Fig. 17). While constitutional signs and symptoms, such as loss of weight and afternoon fever, may be present, the disease not infrequently seems to present only local manifestations in a joint. Whether the bone or joint is the primary point of infection in joint tuuberculosis is still a considerably disputed question. A "cold abscess" occurs late in joint tuberculosis, but an effusion into the synovial cavity is usually present, which is often called "white swelling" because of the absence of acute signs. The hip and knee are commonly affected, but the ankle, shoulder, and elbow are also often involved. Years ago, before the days of dairy inspection and pasteurization, tuberculosis of bones and joints was much more common and was usually of bovine origin.

The onset is often gradual and insidious. Pain is always present, but may be slight, and is often referred to another joint. Thus the

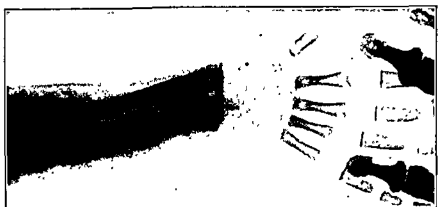

Fig. 18. Syphilitic osteochondritis. The patient was a Negro infant, three weeks old. Note the increased density along the epiphyseal line. The term "syphilitic epiphysitis" is often applied to the disease. The term "pseudoparalysis" is sometimes used because of the disability produced. The name of Parrott is also associated with this lesion. Although only one wrist is shown in the above photograph the same appearance was noted on the opposite side and in both lower extremities. The mother noted a swelling of the infant's wrists which were painful and tender; a history of a fall was suspected. The Wassermann was strongly positive and after two antiluetic treatments the pain and swelling disappeared.

This defect in the vertebra is known as spondyloschisis, and this is now thought more likely to be on the basis of posture than a congenital abnormality, as emphasized by Rowe and Roche (11). Clinical manifestations include pain and weakness in the lower back and inability to bend forward. Examination reveals a striking lordosis; diagnosis is aided by lateral roentgenograms to show the characteristic displacement and oblique films to show the presence of a spondyloschisis. Initial management should consist of a stout lumbosacral corset, a fracture board for sleeping, and instructions to the patient on how to protect the low back. When such conservative measures fail to give satisfactory relief of symptoms, spinal fusion frequently must be resorted to in order to stabilize the involved area. Resection of the neural arch, particularly in those individuals

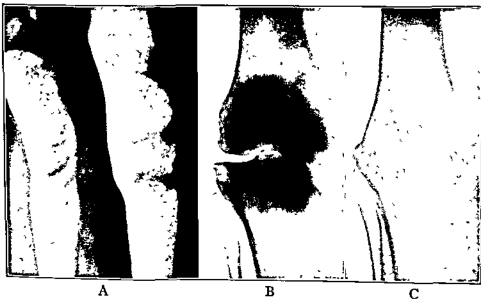

Fig. 19. Charcot joint. The patient was a tabetic, aged 57. A, note the enlargement of the left knee which was almost a "flail" joint, i e., movable in all directions without sufficient stability to avoid disability; B, anteroposterior x-ray of the joint; C, x-ray four months after arthrodesis, showing bony union between tibia and femur.

destructive process and/or dislocation. If drainage of a cold abscess is established, either spontaneously or by incision, the resultant sinus may drain for months or years. Because of the paucity of early clinical manifestations, diagnosis is often difficult but is aided by the following procedures: (*a*) tests to rule out other evidence of tuberculous disease—such as the tuberculin test, x-ray studies of the lungs, and examination of the genitourinary tract and urine—should be carried out. Also important is examination of the sputum; if there is no sputum, gastric lavage should be done to determine whether tubercle bacilli may have been swallowed in sputum coughed up from the lungs. (*b*) X-ray is negative early in the disease, but later shows generalized bone atrophy as compared with the opposite side and an irregular fuzzy appearance with ill-defined joint outlines. Destructive bone changes are seen only in the more advanced cases. In the spine, a lateral view will show erosion of the vertebral bodies and destruction of intervertebral discs. Characteristic of bone tuberculosis is the absence of new bone formation in the x-ray; in this respect it differs from pyogenic infections and syphilis. (*c*) The joint fluid may yield growth of tubercle bacilli on culture, or may produce the disease after injection into a guinea pig. It rarely shows bacilli on smear. (*d*) Arthrotomy with biopsy of the synovia may be the most reliable method of diagnosis. This may be justified in order to start therapy as early as possible. In attempting to establish the diagnosis in the hip in young children, biopsy of the deep inguinal lymph nodes may be helpful, as pointed out by Mercer (10).

In treatment, medicinal therapy is now very important. Since the development of the antituberculosis drugs—such as streptomycin, azoniazyd, and para-amino salicylic acid —great progress has been made in combating tuberculous infection. This progress applies not only to generalized disease but also to joint lesions. Great importance is, therefore, attached to a long-continued program of therapy with these drugs (6 to 12 months) as well as to prolonged immobilization of the diseased joint. Generally, streptomycin is administered intramuscularly two or three times a week in association with one of the other two drugs given by mouth. Under the protection of these drugs, it is possible to incise and clean out abscesses followed by primary healing and also to eradicate tuberculous foci by direct surgical attack without complication. If joint tuberculosis is diagnosed in the incipient stage before joint damage has occurred, and the patient is treated persistently with these drugs, and the joint protected by abstinence from weight-bearing, it is possible to anticipate recovery with preservation of joint function. In most cases of joint tuberculosis, damage to the joint is too far advanced to permit functional recovery, and arthrodesis of the joint is the best treatment. This procedure should be delayed until inactivation of the disease has been obtained by chemotherapy. Ankylosis of a joint in optimum functional fashion produces very little disability, and most patients can work and even participate in many sports. In Pott's disease, spinal fusion is practically always necessary and may be performed earlier than in the case of other joints because it is a completely extra-articular procedure.

4. *Syphilitic Arthritis.* Two forms are described; one is the osteochondritis of infancy, which is sometimes the first evidence of congenital syphilis (Fig. 18). A history of trauma is not infrequent and the joint is swollen and tender and clinically simulates an injury or an acute infection. The x-ray shows characteristic changes in the epiphysis; the Wassermann reaction is positive. The lesion responds to chemotherapy, though immobilization is necessary for symptomatic relief of pain. The second form of syphilitic arthritis is the painful joint encountered in the secondary stage and is often confused with tuberculosis. The Wassermann reaction is helpful. Treatment is also medical (chemotherapy). Charcot joints (Fig. 19), though of syphilitic origin, are discussed on page 550 under the heading of neurotrophic joints.

Spondylolisthesis. This lesion consists of a forward displacement of the body of one of the lumbar vertebra on the ones beneath; the most common is the fifth, which slips forward over the sacrum. One of the causes is a defect in the pars interarticularis, which allows the body to slip forward while the posterior element remains in its normal position.

ticularly in the hands and feet, become a cause of annoyance and must be removed surgically.

2. Hemophilics often have chronic stiffness and enlargement which may resemble a tuberculous joint. The swelling is due to the presence of blood which, on organization, gives rise to fibrous ankylosis. The history is important since the disease is hereditary, transmitted by females, but present only in males. Treatment is largely of a prophylactic nature. Transfusions are useful and endocrine therapy has been recommended. An antihemophilia fraction of the plasma proteins has been isolated and is easier to give than blood.

3. Hysteria is a term of exclusion used in joint disease when thorough examination is negative in a patient with stiffness and limp which, however, are characteristically varible. Contracture may develop from disuse. There may be a history of injury. Diagnosis is important, but often difficult. The finding of a psychogenic factor may help. Treatment requires careful local treatment and psychotherapy.

4. Intermittent hydrops is similar to chronic synovitis except that it is not connected with injury or activity, is not painful, and comes and goes without apparent cause. It may be of vasomotor nature (Allison). Treatment is symptomatic.

Congenital Deformities. The most important ones are clubfoot and congenital dislocation of the hip. *Clubfoot* is a congenital deformity due to maldevelopment of the bones and joints of the foot. The most common type of deformity is talipes equinovarus or reel foot, though other varieties are seen (talipes varus, valgus, equinus, and calcaneovalgus). The disease may be unilateral or bilateral. Treatment in early cases consists of manipulation and application of a plaster cast. Open operation is necessary in some patients when, after trial, conservative measures fail. *Congenital dislocation of the hip* is a not infrequent disease and, though present at birth, usually remains undiagnosed until the child begins to walk, when an abnormal gait or limp is observed. The condition is often allowed to progress into later childhood, during which the disability becomes more marked and the anatomic changes more pronounced. Diagnosis is confirmed by roentgenograms which show an abnormally shaped and displaced head of the femur and a deficient acetabulum. The disease may be unilateral or bilateral. Treatment consists of reduction by manipulation or open operation and immobilization by plaster cast. The method depends on the age of the patient and the experience of the surgeon. The best results are obtained when the condition is recognized and treatment is started before the age of one year. Today, with greater awareness on the part of pediatrician, cases are being diagnosed and treated even before the age of six months.

Ankylosis of Joints. Ankylosis is a frequent outcome of previous joint disease. As already mentioned, it occurs after destructive arthritis and tuberculosis. A severe fracture into the joint which involves both articular cartilages may result in bony union across the articular surfaces with complete joint immobility. In the operation of arthrodesis such a bony ankylosis is purposely produced. In all such cases, the degree of the resulting disability is minimized to a great extent if the joint is fixed in a favorable position and angle. It is important, therefore, that, whenever possible, healing be allowed to take place with the joint fixed in such a position. If the position is poor and ankylosis has not yet taken place, the joint should be manipulated under anesthesia, followed by immobilization at the proper angle in a plaster cast.

The angle of maximum usefulness is different for each joint as follows: ankle, at right angles with just enough equinus to permit wearing of a shoe with a heel; knee, in slight flexion to clear the ground easily when walking; hip, in moderate (15 degree) flexion and abduction for the same purpose; wrist, in partial dorsiflexion to aid in the grip of the fingers (Fig. 20); elbow, in flexion at an angle of 135 degrees, provided that the opposite elbow is normal and allows the hand to be brought to the face, with the forearm pronated enabling the hand to be used in most types of work; shoulder, at about 40 degrees abduction and 15 degrees flexion to enable as extensive motion of the scapula as possible, and to permit the hand to reach the mouth easily.

who have significant degrees of sciatica associated with their spondylolisthesis, may be helpful.

Arthritis Deformans. This term used to be applied indiscriminately to all forms of rheumatism and arthritis but, as the result of advances in the last 25 years, a great many different types of arthritic disease have been sorted out from this large wastebasket, have been classified, and their individual characteristics described. The following represents a somewhat simplified classification modified from that prepared by the New York Rheumatism Association (Hinch P. S., et al. Smith, Ninth Rheumatism Review: Am. Int. Med. 28:66, 1948).

A. Infectious arthritis of proven etiology
B. Possible infectious etiology unproven
  1. Arthritis of rheumatic fever
  2. Rheumatoid arthritis (atrophic, chronic infectious)
    a. Adult type
    b. Juvenile type (Still's disease)
    c. Ankylosing spondylitis (Marie Strumpell, etc.)
    d. Psoriatic arthritis
  3. Arthritis associated with various infections
C. Degenerative joint disease
  1. Osteoarthritis (hypertrophic, degenerative)
    a. Generalized
    b. Localized
      (1) Secondary to previous trauma
      (2) Secondary to joint abnormality
D. Arthritis associated with disturbance of metabolism
  1. Gout
  2. Others
E. Arthritis of neuropathic origin
F. Neoplasms of joints
G. Mechanical derangements of joints
  1. Traumatic arthritis
  2. Joint disturbance secondary to abnormal postural strain
H. Miscellaneous forms
  1. Manifestations of systemic disease
    a. Arthritis of serum sickness
    b. Arthritis of hemophilia
    c. Intermittent hydrarthrosis
    d. Pulmonary osteoarthropathy
    e. Hysteric joints
  2. Local joint disturbances
    a. Aseptic bone necrosis
      (1) Secondary to contusion, fracture, dislocation, or air embolism
      (2) Of unknown etiology (juvenile osteochondrosis of different bones and locations)
    b. Osteochondritis dissecans
    c. Osteochondromatosis

It is not possible in a textbook of surgery to discuss all these diseases and the student should consult the standard textbooks of medicine or the fifth revised edition of Comroe's Arthritis by Hollander (12) and collaborators, already mentioned. Pathologically, the disease exhibits hypertrophic forms in which there is proliferation of the fibrocartilage outside the joint (Heberden's nodes) as well as fibrous tissue and bone; in other cases, the joints become atrophic or ankylosed. Although various bacteria from time to time have been isolated from the joints of these cases, the cause is still undetermined. One group is called Still's disease and occurs largely in childhood. Further discussion of the various types of the disease and their treatment may be found in medical and orthopedic monographs on the subject.

Neurotrophic Joints. This term is applied to the so-called Charcot joint which occurs as a manifestation of tertiary syphilis, but may be seen in other diseases of the spinal cord, such as syringomyelia, or rarely in peripheral affections of the sensory nerves as in diabetes mellitus. It is a slowly developing, painless, degenerative lesion, although the manifestations may seem to appear acutely. Especially characteristic are the hypertrophic changes which most frequently attack the knee, but also the ankle, foot, hip, spine, shoulder, and elbow. When seen in the upper extremity, syringomyelia is more likely to be the etiologic factor. The earliest sign may be periarticular edema, but in the late stages the swelling, which is due to degenerated collapsing bone and overgrown fibrous tissue and cartilage, may be enormous. Pain is absent; instability of the joint is the usual complaint. Treatment may be conservative, i.e., support of the insecure joint by appliances if possible, or operative, i.e., resection of diseased tissue and production of a bony ankylosis.

Other Joint Diseases. 1. Gout is due to the deposition of sodium urate around joints (and also in the cartilage of the ear) as tophi. It is most frequent in joints of the great toe and causes episodes of severe pain and disability with relief of symptoms between attacks. Treatment is generally medical and dietetic, but occasionally tophus deposits, par-

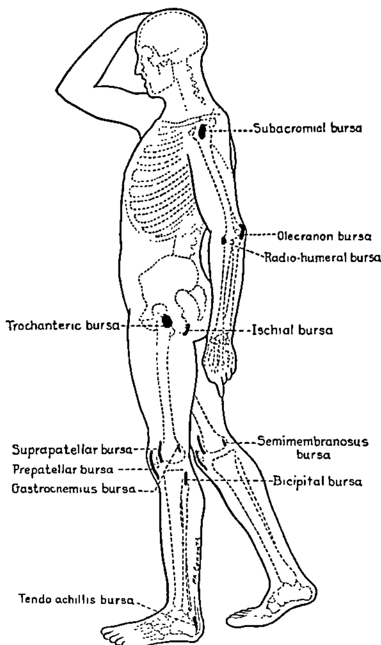

Fig. 21. The sites of the more common bursas.

Chronic Bursitis. This may follow an acute lesion, but frequently develops insidiously and is often erroneously diagnosed as neuritis, "rheumatism," or chronic arthritis. The pathologic changes in the bursa are similar to those in the joint, in that fluid is present and villous overgrowth of the bursal lining occurs. In addition, however, calcification of the wall of the bursa is not infrequent and can often be seen in a roentgenogram. Symptoms are pain, more or less severe, brought about or aggravated by certain movements which tend to compress or irritate the bursa. Tenderness is often localized to this area. Swelling may develop because of effusion which is always present, and may be demonstrated by aspiration. Treatment is often dramatically successful following the injection into the bursa of hydrocortisone with Novocain. For single attacks, even in calcified bursa, this often suffices. Occasionally it is necessary to recommend that the occupation or activities

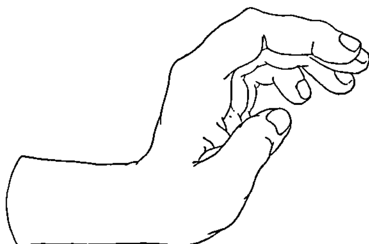

Fig. 20. Dorsiflexion. Slight dorsiflexion (less marked than that shown) is the most favorable position in ankylosis of the wrist; this gives satisfactory function with a useful grasp to all of the fingers and thumb.

BURSAS

Bursas are similar to joints in that they are cavities lined by modified fibrous tissue or mesothelium which secrete a mucoid lubricant and thus enable tendons or muscles which lie over them to glide smoothly against underlying bone or other structures. In superficial locations, the bursa protects underlying structures from trauma inflicted over them. Bursas likewise serve to facilitate skeletal movement. Some of them are present consistently at certain points; others may form in response to special needs when certain movements are repeatedly used, or when there is pressure over a bony prominence as, for example, with a bunion. Some bursas are not closed cavities but, like those about the knee, continuous with the joint cavity. They are similar to joints in their reaction to injury; they develop an effusion or swelling, may become painful and cause disability. Unlike a joint, however, a bursa may be destroyed or excised without causing disability, but often replaces itself by regeneration from neighboring connective tissue. Bursas are only rarely the site of an acute pyogenic infection; the most common lesions follow trauma which is sometimes direct and acute, but more often is the result of repeated slight injuries or continual external pressure.

Acute Traumatic Bursitis. This lesion may follow direct blows, but more often it results from the same type of forceful movement which gives rise to ruptured tendons or ligaments. These structures often form the floor or roof of bursas so that injury to them directly implicates the bursa. After such an injury, the differential diagnosis may be quite difficult and often impossible. A knowledge of the exact location of the various bursas is invaluable (Fig. 21). Often, acute bursitis develops rather suddenly, manifestations appearing after a relatively slight injury, repeated previous insults, or irritations to the bursa. Thus, a housemaid may injure her prepatellar bursa each time she scrubs the floor on her hands and knees but have no acute symptoms until, suddenly, an acute exacerbation follows some slight blow. Symptoms are local pain and swelling, the former aggravated by certain motions and the latter apparent only in the superficial bursas. Disability is usually quite severe on account of the pain, limitation of motion, and muscle spasm. Occasionally, infection develops in the bursa and progresses to suppuration, thereby demanding drainage by incision. Treatment of traumatic bursitis consists of rest in a comfortable position and local applications of heat until motion is possible without pain. The acute process may last for a week or two and subside without further difficulty. The injection of hydrocortisone into the bursa is often effective (see below). Unfortunately, further attacks are liable to occur. More troublesome is the development of more or less constant or chronic disability and pain.

The diagnosis is made on the demonstration of marked limitation of motion, pain in forcing motion in any direction, and on a negative x-ray examination.

Treatment requires restoration of motion by gradual and gentle active exercises. Formerly, forceful manipulation of the shoulder to rupture the adhesions under anesthesia was often done, but such complications as fracture of the humerus and dislocation of the shoulder were common and gentler methods are now in vogue. The patient is generally started with pendulum exercises with the body flexed at the hips and the arm hanging down like a bell clapper. These exercises should be carried out three or four times a day and combined with application of heat. Local injections of Novocain and hydrocortisone at weekly intervals are helpful. Pain at night is a frequent complaint, and it may be well to bandage the arm to the side in a sling to give relief. Sedatives are generally necessary. Progress is slow over several months and much patience and encouragement are necessary. In the end, most of these patients recover completely.

The *olecranon bursa* lies between the skin and the olecranon. Bursitis (miner's elbow) occurs at this point because of frequent injuries sustained over the bursa. The disease, however, is by no means confined to miners. Excision of the bursa is often indicated, when symptoms of pain and disability are sufficiently severe.

The *radiohumeral bursa* lies over the radiohumeral joint between the extensor carpi radialis and the supinator brevis muscles. Bursitis (tennis elbow) develops because the bursa is irritated by forceful movements of the elbow and wrist, associated with pronation and supination of the forearm. Local tenderness over and above the head of the radius is pronounced. The pain may be severe and disabling in some instances. It may be necessary to differentiate radiohumeral bursitis from myositis or epicondylitis involving the attachments of the extensor muscle group at the lateral epicondyle, which may cause similar symptoms. In both conditions, the injection of hydrocortisone into the tender area often gives relief. In intractable cases, the use of a cock-up wrist splint for a period of one to two months, to prevent tension on the extensor muscles of the wrist, will generally bring about a cure.

The *prepatellar bursa* is not as commonly injured in present days of mechanical appliances and machines for scrubbing floors. It is a superficial bursa lying between the patella and the skin or between the proximal end of the tibia and skin where irritation occurs from kneeling position (housemaid's knee). Rest and cessation of repeated injuries usually results in relief of symptons.

The *Achilles bursa* which lies between the gastrocnemius tendon and the os calcis is frequently the seat of inflammation and is commonly caused by improperly fitting shoes. Relief usually follows removal of the cause; only rarely is operation indicated.

The *ischial bursa* may be the seat of inflammation (weaver's bottom) in individuals who maintain the sitting position for long periods because the bursa lies between the ischial tuberosity and the overlying gluteal muscles.

TENDONS

Many but not all tendons move in sheaths which are structurally similar to joints and bursas but, in general, are not frequent sites of serious disease. Wounds, tumors, and acute infections of tendons have been described in previous chapters.

Traumatic tenosynovitis is a common, but rarely serious injury which produces an inflammation of the sheath with outpouring of an excess amount of the lubricating fluid. Local tenderness is present along the course of the sheath and use of the tendon produces pain. There may be palpable a creaking or crepitation on motion of the tendon. Later, fibrous tissue may replace the fluid and fibrin, thereby resulting in limitation of motion. In general, rest should be maintained as long as acute symptoms are present, but increasing active motion should follow as soon as subsidence of pain permits.

Other lesions depend on special injuries. *Rupture* of the biceps tendon, the tendon of Achilles, and of the extensors of the thumb and fingers produces characteristic manifestations which readily are recognized and treated. A dislocation of a tendon into a new abnormal site usually involves the long head of the biceps, the peroneal tendons, and the

of the patient be changed in cases due to irritation from certain specific muscular movements. In other patients, the decision as to the advisability of motion or rest is not an easy one. The application of penetrating heat is usually helpful. Excision of the bursa is often indicated and frequently curative, especially when the bursa is calcified and has not responded to nonoperative treatment (13, 14).

Specific Types of Bursitis. Although there are about 26 bursas in the human body, discussion will be limited to the few which are commonly diseased.

The subdeltoid (*subacromial*) bursa is located over the tuberosity of the humerus, underlying the acromion process and the deltoid muscle. Part of its floor is formed by the rotator cuff (chiefly made up of the supraspinatus and infraspinatus tendons). Its function is to permit the tuberosity to glide under the acromion and deltoid in movements of abduction and rotation of the shoulder. This bursa is commonly implicated by one of the following lesions: (*a*) calcifying tendonitis, (*b*) rupture of the rotator cuff, and (*c*) adhesive tendonitis.

(*a*) *Calcifying tendonitis* is caused by deposition of calcium salts in the tendinous tissue of the rotator cuff. The cause of this is not known, but it is thought to be due to degenerative changes induced perhaps by friction, and in some cases by trauma. Calcium is deposited in cicatricial tissue low in blood supply. The deposits are, in the beginning, chalky and granular, but later they tend to coalesce and become puttylike. They generally lie in the floor of the bursa where they cause pain when pinched by movement under the acromion. In some cases they may rupture into the bursa and cause an acute inflammatory reaction.

In the subacute stage, pain is caused by movements of abduction and rotation of the shoulder; in the acute stage, pain is exquisite on the slightest movement, and the clinical picture may resemble that of acute pyogenic arthritis.

Diagnosis is based on demonstration of local tenderness over the tuberosity by the production of pain on abduction and rotation of the shoulder, by limitation of motion, and by x-ray examination which demonstrates the calcium deposit.

Treatment is most successful when the calcium can be aspirated or washed out through two needles with salt solution. When the deposit is granular and diffuse, this is not possible, and other measures must be used. Some advocate x-ray therapy, others ultrasonic treatments, and others diathermy. Injection of hydrocortisone locally is often helpful, but may have to be repeated several times at weekly intervals. Most dramatic results are often obtained by aspiration and injection of hydrocortisone in the acute cases. In recurrent cases, when it has been impossible to get rid of the deposit by other means, it is necessary to open the bursa surgically and curette out the calcified mass.

(*b*) *Rupture of the rotator cuff* is caused generally either by a fall on the outstretched arm or by lifting effort of the shoulder. The injury results in pain due to hemorrhage into the bursa and shoulder joint, and also to inflammatory reaction. The examination reveals local tenderness and notable weakening or loss of abductor power, depending upon the extent of the lesion. X-ray examination is generally negative. When the diagnosis is doubtful, confirmation can be obtained by the injection of radio-contrast fluid into the bursa or shoulder joint following which x-ray examination will reveal direct communication between the bursa and the joint. Treatment, as in other types of tendon rupture, requires open surgical repair of the torn structure. Early diagnosis is important because the sooner the operation is carried out, the better are the results.

(*c*) *Adhesive tendonitis* is a condition in which adhesions develop between the rotator cuff and the adjacent structures, including the joint capsule, and the long tendon of the biceps both in the bicipital groove and in its intraarticular course. The bursal structure is often implicated. Two factors are generally present in varying degree; first, degenerative changes in some of the anatomic structures mentioned previously, and second, decreased use of the shoulder due to pain. The condition often follows a Colles' fracture or an attack of coronary thrombosis in which conditions the shoulder is kept in the adducted position for long periods on account of pain.

Fig. 22. Photograph of both hands and forearms showing a Volkmann's contracture on the left side, approximately three years after onset. (From Hill and Brooks. Ann. Surg.)

inability to move the fingers, and (*e*) tingling and numbness of the fingers. When the condition complicates fractures about the elbow the damage is presumably done by continued swelling after immobilization of the joint in flexion or damage to the brachial artery or veins. As a consequence, the venous return from the forearm is shut off. The arteries for a time continue to pump blood into the forearm, thus increasing the swelling which ultimately obstructs the arterial supply to some extent. It is important to realize that after six or seven hours the damage is done and no form of treatment will bring the muscles back to normal. The end result is the conversion of the contractile muscle fibers to fibrous tissue which produces an atrophied forearm and useless clawhand (main en griffe). The reader is also referred to the excellent article by Seddon (15).

Treatment is prophylactic, except when the swelling is due to vascular injury. In this case, the only efficient form of treatment is prompt and radical incision of the fascia overlying the tense tissues and inspection of the brachial artery. The greatest danger exists from swelling about joints immobilized with a cast or appliance in a flexed position. This is apt to occur most frequently after fractures about the elbow. After reduction and immobilization of such fractures, the surgeon must palpate the radial pulse since its absence is a sign of serious vascular obstruction. The patient should be either kept under observation for 24 hours or emphatically instructed to return at the first indication of severe pain, numbness, or paralysis of the parts distal to the lesion. In such an event, the constricting dressing or cast must be loosened or removed even at the expense of losing the position of the fracture.

Myositis ossificans is a remarkable post-traumatic condition in which osseous tissue develops in muscle. It may occur in hematomas of the muscle or may develop in muscles adjacent to a fracture. Tendons are oc-

posterior tibial tendon. Treatment consists of operative replacement of the tendon and rest for a week or two until movements without pain are possible. *Stenosing tenovaginitis* (trigger finger, snapping finger) is a lesion which produces a temporary impediment of flexion (or extension) of the finger which, on further movement, suddenly gives way and the finger snaps. Stenosing tenovaginitis of the radial styloid (de Quervain's disease) is common and is a painful condition involving the abductor pollicis longus tendon.

Tuberculous tenosynovitis manifests itself as a thickening of the tendon sheath which becomes filled with thick fluid and caseous material containing "rice bodies." The flexor and extensor tendons of the wrist, hand, and forearm are most commonly involved. Treatment may be nonoperative or surgical. At operation, all excessive tissue is removed and the wound closed carefully without drainage. A prolonged course of antituberculosis drugs should then be instituted.

MUSCLE

Unlike bone and joints, muscle is seldom the site of disease or serious injury, except by direct penetrating trauma. Involvement of muscle by war wounds is of great importance and is discussed on page 107. Of all the elements important to movement and locomotion, muscle is the most prone to atrophy, especially of disuse. Paralysis results from denervation; recovery depends on regeneration of the nerve.

Atrophy. There are several types of atrophy. Disuse alone, particularly following immobilization or when associated with ankylosis, will produce a rapid and severe muscular atrophy. The presence of infection aggravates the process. However, atrophy of disuse alone is usually relieved rapidly as soon as active motion is restored and leads, in most cases, to the return of the muscle to its normal state. Frequently, the stronger set of muscles contracts and results in a deformity, often called contracture, which is especially apt to follow atrophy due to paralysis of the muscles which follows interference with the nerve supply. Spontaneous subluxation (dislocation) of the joint may thus occur. Atrophy from severance of the nerve supply produces a paralysis as well as atrophy and is much more serious because recovery depends on regeneration of the nerve (see p. 615). Disease of the brain and spinal cord may also produce muscular atrophy; the paralysis which results is flaccid or spastic. *Cerebral palsy*, i.e., spastic paralysis of children (Little's disease) is produced by cortical injury sustained during childbirth, or to prenatal or perinatal cerebral defects. Mental deficiency to lesser or greater degree may accompany the muscular paralysis. Treatment is a complex neurological and orthopedic problem. *Poliomyelitis* is a serious cause of muscle atrophy which becomes permanent when the infection destroys the anterior horn cells which innervate the muscles. With the onset of paralysis it is very important that deformities be prevented and that a program of bracing and muscle re-education be carried out. The permanent paralysis is frequently accompanied by deformity due to the pull of the uninvolved muscles. The treatment of these deformities is an orthopedic problem and consists of muscle training, braces of various types, transplantation of tendons, and, if necessary, arthrodesis of the joints that are responsible for the deformity. A rare type of atrophy is *progressive muscular atrophy*, which is a slow chronic disease begining in the intrinsic muscles of the hand. *Birth (Erb's) paralysis* affects the muscles of the upper extremity and is due to injury to the brachial plexus during delivery. The diagnosis should be made as soon after birth as possible. Treatment consists of immobilization and relaxation of the injured structures; operative treatment of the nerves is only occasionally indicated.

Volkmann's contracture (ischemic contracture or paralysis) is a tragic and often preventable accident which occurs most frequently following a supracondylar fracture of the humerus or a fracture of the bones of the forearm (Fig. 22). It is caused by interruption of the circulation to the distal part of the extremity, either arterial injury or venous interruption. Soft tissue injury alone with extensive extravasation of blood about the elbow or forearm may also be the instigating factor. The first symptoms are (*a*) diffuse pain in the forearm and hand, (*b*) cyanosis, especially of the fingers, (*c*) swelling, (*d*)

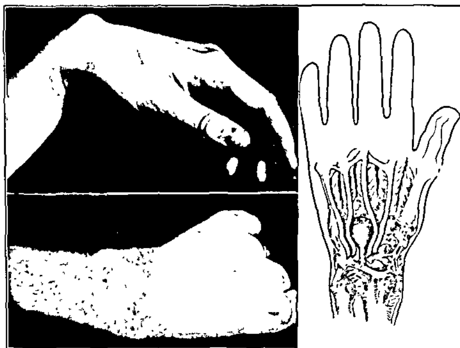

Fig. 24. Ganglion of the wrist. The patient was an 18-year-old school girl. Note in the photograph how the tumor is made more prominent by flexion at the wrist; it was tense but definitely cystic on palpation. The patient complained of constant rheumatic pain in the wrist and arm, aggravated by use. The sketch was based on a drawing made at operation and shows the mass attached to the joint capsule; it contained thick mucoid fluid. Excision of the entire cyst including its pedicle was performed; complete relief ensued.

ing mesothelial cells or to mucoid degeneration of the fibrous tissue. Its origin as a herniation of the joint or tendon sheath, a theory which is generally held, lacks definite proof. Clinical manifestations beside the presence of the tumor include pain or "rheumatoid" discomfort which may result in definite disability. Treatment, to be curative, necessitates complete excision, or recurrence may follow. Breaking the cyst with a well-directed blow is sometimes followed by cure. Aspiration and injection of sclerosing solutions has been used, but is obviously dangerous, especially if the lumen of the ganglion communicates with the joint cavity.

Corn or *clavus is a local hypertrophy of the* hornified layer of the skin which develops as a response to chronic pressure or irritation, usually from tight or ill-fitting shoes. The most important clinical manifestation is severe pain which is due to pressure over the lesion and can be relieved by shifting the contact with the shoe from the corn to the surrounding skin by means of a circular pad with a hole in the center, which protects the tumor. This is the principle upon which corn plasters are used. Eradication of the lesion *may be achieved by elimination of the source* of the chronic irritation or by actual excision. Occasionally, certain types of corns (particularly those between the toes) can be cured only by removal of the underlying bony prominence. Corns occasionally are the site of infection which is treated by the usual methods.

Hallux valgus is a common deformity of the great toe (outward deflection or abduction) which to a great extent, at least, is caused by wearing ill-fitting, short, and pointed shoes (Fig. 25). Its importance lies in the frequent *formation of a bunion which is often painful* and disabling. This knob or bunion consists of an overgrowth of the medial margin of the distal end of the metatarsal bone at the metatarsophalangeal joint *and is associated with* a true bursal sac which contains fluid and often becomes infected. Relief of pain is often achieved by correcting the normal position of the toe with an appliance, and the wearing of correct shoes. In severe cases, operation

Fig. 23. Congenital torticollis. The patient was a 12-year-old girl. Note the attitude and the tense sternomastoid muscle on the patient's right. This muscle was cut across and a cast applied; the result was excellent six months later. X-ray showed only a rotation of the cervical spine. (Washington U. Clinics.)

casionally affected also. Treatment consists of prolonged and complete immobilization; in a good many instances, partial or complete absorption of the bone in the muscle occurs. Occasionally, surgical removal of mature myositis ossificans is indicated.

Wryneck (*torticollis*) is a disfiguring disease of the cervical muscles (or their motor nerve supply) in which, by continuous muscular contraction, the head is maintained in a rotated and inclined position (Fig. 23). The condition develops generally in infants soon after birth. It is due to fibrous contracture of the sternocleidomastoid muscle. The exact cause is unknown, although there are various theories. An acquired type, often called spasmodic torticollis, occurs in adults and belongs to the group of nervous disorders known as "tics." When prolonged, torticollis produces changes in the cervical spine. Treatment of the congenital type is operative and manipulative and should be instituted as early in life as possible.

MISCELLANEOUS LESIONS

Ingrown toenail, a common lesion, especially in young women, is a frequent cause of suppuration about the large toe as described previously. Although with rest, elevation, and local heat, such an acute infection diminishes or subsides, it is apt to recur unless the ingrowing part of the nail finally clears the soft tissue of the toe or is removed and prevented from reforming by an appropriate operation. Tight shoes and too frequent clipping of nails probably do play some role in the development of this lesion. More important, however, is the presence of a congenital abnormality in the root of the nail allowing the lateral edge of the nail to grow out obliquely or downward and penetrate the soft tissue. This produces pain and frequently breaks the skin, thus introducing infection which persists because the ingrown nail acts as a foreign body.

Treatment in mild cases consists of excising a v-shaped wedge of the central portion of the nail, or of shaving the central surface from the distal edge back to the cuticle to relieve the lateral pressure and to encourage growth toward the center to such an extent as to relieve symptoms. Radical treatment consists of removal of a lateral or medial segment of nail, including its root, so completely that the removed portion will not regenerate. A simpler procedure, and usually as effective is the excision of a wedge of the hypertrophied toe adjacent to the ingrown nail (Winograd, 1929). Operation is done under local anesthesia with the aid of a rubber tourniquet.

Ganglion is a term applied to a smooth, rounded mass (0.5 to 1.5 cm. in diameter) which commonly appears in the distal portion of the wrist on the dorsal surface, and is made more prominent by flexion of the wrist (Fig. 24). It also occurs on the ventral or lateral surface of the wrist and around other joints, particularly the knee. It is found in women much more frequently than in men (3:1) and is especially common in young women. The tumor, when exposed, is found to lie among the tendons, but nearly always is attached to the joint capsule. It consists of a fibrous sac which contains mucoid material. The lumen of the cyst is commonly a closed cavity, but occasionally it communicates with the wrist joint or a tendon sheath. As to its pathogenesis, the most careful studies have shown that it originates from the fibrous tissue of the joint capsule as a small, benign, fibrous neoplasm. The cystic nature of the tumor is explained by the presence of secret-

Fig. 26. Dupuytren's contracture. The photograph indicates the maximum possible extension. Disability was insufficient to justify operation. The patient was a 45-year-old male.

tarsal scaphoid, which is most frequently the bone involved in the strain (Key and Conwell, 16). Occasionally adequate support to a low arch will relieve symptoms.

Scoliosis, or lateral curvature of the spine, is a disfiguring but not necessarily crippling deformity in which the spine develops more or less fixed lateral curves with rotary components (Fig. 27). It may result from congenital malformation of the vertebrae, or from poliomyelitis with imbalance of the spinal or abdominal muscles, or from other diseases of the central nervous system. The most common form, called "idiopathic" because of unknown etiology, develops during the growing period. Most curvatures tend to increase with growth but become arrested and static when skeletal maturity is achieved.

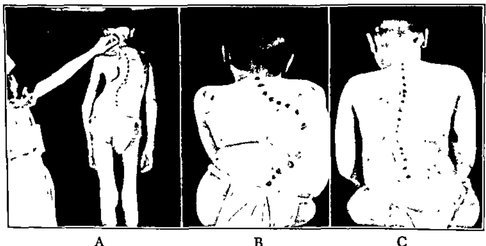

Fig. 27. Two types of scoliosis. A, idiopathic scoliosis with marked rotation of vertebral bodies. This type of scoliosis is very difficult to treat; B, total curvature of the spine without rotation due to infantile paralysis. No rotation of vertebral bodies. This type of curve is easily corrected and held by spine fusion; C, same as B, after fusion of the spine (Courtesy, Dr. C. H. Crego, Jr., Shriners Hospital for Crippled Children, St. Louis.)

Fig. 25. Hallux valgus before and after radical operation for its correction. The bunion and the *proximal two thirds of the first* phalanx of the toe were excised and the toe immobilized in its normal position. (St. Louis City Hospital.)

consists of removal of the bursa and trimming off the excess bone, thus allowing the toe to assume its normal position.

A *callus* sometimes forms under the ball of the foot at the points of pressure exerted by the heads of the metatarsals. Appliances to take pressure off the painful point will often be effective as will a "metatarsal bar" fitted into the shoe for the same purpose. Such calluses may become infected and simulate a perforating ulcer (mal perforans). However, the x-ray shows no osteomyelitis. The treatment consists of paring away the hypertrophied skin until the bottom of the sinus is reached. The adequate drainage of the tiny abscess thus achieved will result in healing.

Dupuytren's contracture is a rare, probably hereditary disease and of gradual and insidious onset (Fig. 26). This condition is not a contracture of the tendons but of the palmar fascia on the ulnar side of the palm, gradually causing a flexion deformity of the fifth and later the fourth finger. The fascia extending into the fingers, as well as the overlying skin, may also be involved. There is no pain or tenderness, disability being due to inability to extend the fingers. Treatment consists in the careful surgical excision of the hypertrophied bands of fibrous tissue. This is generally carried out through multiple small incisions corresponding to the palmar creases. Extension of the flexed fingers is obtained by dissection and removal of the hypertrophied bands. In extreme cases, it may be necessary to amputate an extremely flexed digit in order to improve function of the hand.

Foot strain is encountered under a variety of circumstances which bring the patient to the surgeon, largely because of foot pain, which may be severe or mild, and may be accompanied by swelling and other anatomic changes. Frequently no definite organic basis can be made out. Foot strain is a common disease, and is often aggravated by the wearing of improperly fitting shoes. It should be emphasized that the form of the arch has nothing to do with the painful symptoms of foot strain. The diagnosis and treatment of foot strain is largely an orthopedic problem; rest of the strained ligaments plays an important part in therapy, especially by the use of a Thomas heel, which gives support to the

pressure on the metatarsal head, but if the pain persists surgical removal of the neuroma is indicated.

Hammer toe is an acquired flexion deformity of the toes, most often the middle ones, due usually to tight fitting shoes. Severe cases may require a plastic operation (wedge resection of the interphalangeal joint).

Calcaneal spurs are sometimes the cause of pain localized to the heel (painful heel, policeman's heel). The pain may be due to an associated bursitis but is apparently primarily dependent upon the presence of the spur, which may be unilateral or bilateral. Diagnosis is readily made by the x-ray. If pain is very severe, and does not respond to conservative treatment, excision is justifiable.

Ainhum is a rare degenerative disease consisting of a circular constriction at the base of the toes, usually the little toe; it occurs largely in African countries but is encountered in this country in Negroes only. The etiology is unknown. The toe finally drops off; there is no effective treatment (Fig. 28).

Curvature of the spine causes little functional disturbance except in poliomyelitis where muscular instability necessitates spinal fusion, generally after correction of the curve. In other cases, the chief problem is that of disfigurement; when this reaches a stage that threatens to impair the prospects of a happy life, corrective treatment in a hinged plaster jacket furnished with a turnbuckle, followed by spinal fusion, should be considered. While braces and corrective exercises have been advocated in the past, it is doubtful whether these accomplish worthwhile results either in arresting progress of the curvature or in diminishing its extent.

Athlete's foot (epidermophytosis) is really a dermatitis of the skin of the foot, especially in and between the toes, caused by a fungus infection. Manifestation of cellulitis and suppuration may occur whenever secondary pyogenic invasion occurs; treatment is the same as that of infection in general. Eradication of the original ringworm may be achieved by cleanliness, and by the use of a nonirritating fungicide (resorcinol lotion, Whitfield's ointment, and the like). Infections about the feet, in general, may largely be prevented by ordinary cleanliness, as well as the wearing of properly fitting shoes; this is particularly important in patients suffering from peripheral circulatory disease and diabetes.

Foreign bodies, usually needles, are not infrequently introduced (accidentally) beneath the skin, especially in the hand, and often produce pain and disability, particularly if located over an area which is subject to trauma. Removal of the foreign body is usually indicated. When the needle is deeply seated, its removal may be difficult. The x-ray film should be taken just before operation inasmuch as considerable migration of the foreign body may occur even in a day or two. X-ray localization is often aided by placing a lead marker at a convenient point on the skin. Obviously two views are essential. If infection is present, the treatment is the same as that of an infected wound, as has already been described. An electronic device to aid in localizing metallic bodies may be helpful during operation.

Metatarsalgia (Morton's disease) consists of severe pain below and between the heads of the metatarsal bones, probably produced by pressure or impingement of the nerves between the heads of the metatarsal bones. Most commonly it is due to the development of a neuroma at the bifurcation of the digital nerves from the plantar nerve. Conservative treatment consists of rest and elimination of

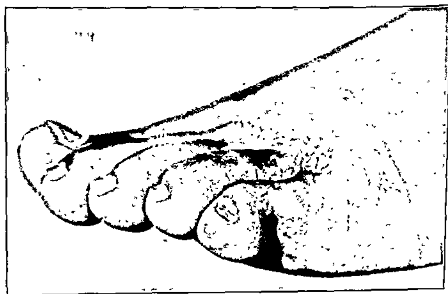

Fig. 28. Ainhum. The constriction at the base of the toe was first noted five years previously and has steadily progressed. The patient, a 35-year-old Negro, complained only of mild pain of three weeks' duration, due to a superficial infection which responded to local incision and bed rest. The remnants of the infection can be seen in the scaling of the skin.

lesions with this common basic malformation may be located in various regions of the body and may present a variety of clinical pictures. Numerous terms have been utilized in the past to denote this condition, e.g., pulsating venous aneurysm, arteriovenous varices, racemose aneurysm, angioma arteriole, arterial varices, and hemangiectatic hypertrophy of a limb. When these lesions occur on the scalp they have commonly been referred to as cirsoid aneurysms.

In the embryonic stage a vessel may function both as an artery and as a vein, and multitudinous communications may exist between arteries and veins. It is not surprising, therefore, that these congenital arteriovenous communications may persist beyond fetal life and occur in mature individuals. Trauma and infection have been cited as causes of the appearance and rapid growth of these lesions.

The condition occurs most commonly in the head and neck and secondly in the extremities. There are usually multiple arteriovenous communications between the smaller arteries and veins, in contrast to the acquired arteriovenous fistulas which are generally single and are found in larger vessels. Although not all are invariably present, the following characteristics have been noted of the typical congenital arteriovenous fistula: 1. pulsating compressible tumor; 2. enlarged tortuous afferent arteries; 3. systolic thrill and bruit over the tumor, or the afferent arteries or both; 4. enlarged tortuous efferent veins; 5. discoloration, resembling the so-called port-wine stain, in the overlying or surrounding skin; and 6. increased local skin temperature. Other effects, such as cardiomegaly, hypertrophy of the involved limb, and slowing of the pulse on compression of the artery, may or may not be present; their presence is generally related to the volume of blood being shunted through the arteriovenous fistulas.

The various clinical types of congenital arteriovenous fistulas have been grouped by Flynn and Mulder into three types.

Type I. Single or Multiple Gross Congenital Arteriovenous Fistulas. This type is the rarest of all. The arteriovenous communications occur between major arteries and veins, e.g., between the carotid artery and jugular vein, as in the case reported by Reinhoff (2), and may be treated successfully by direct ligation of the fistulas.

Type II. Extensive, Minute, Congenital Arteriovenous Fistulas. This type occurs more frequently. The communications are usually microscopic in size, and although numerous, they are difficult if not impossible to identify. Anatomically, they occur in the smaller distal branches of the arterial tree. Cases of this type (Fig. 1) generally have extensive involvement of an entire or a major portion of an extremity, frequently with gross hypertrophy and with marked superficial arterial and venous dilatation. There is at present no generally accepted method of treatment other than amputation, when indicated,

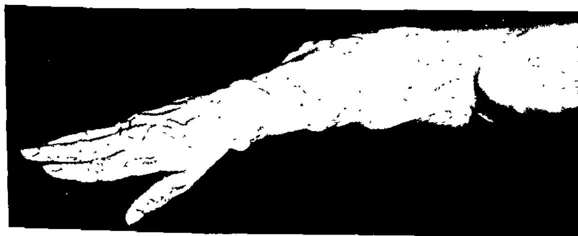

Fig. 1. Extensive minute congenital arteriovenous fistulas (Type II) involving forearm and arm of 28-year-old woman. Dilated veins and increase of size of hand and arm noted for many years. No history of trauma. Severe pains in fingers and ulceration of finger tips. Amputation subsequently required.

BLOOD VESSELS

William P. Longmire, Jr., and Jack A. Cannon

Early vascular surgery was related almost exclusively to the control of bleeding from traumatically severed or damaged blood vessels. The reintroduction of the ligature (first described by Celsus) by the French surgeon, Ambrose Paré, was the major contribution of this period. Later interest in the treatment of aneurysms and arteriovenous fistulas broadened the objectives of surgery of blood vessels from the mere arrest of hemorrhage to the correction of abnormalities of the vessels themselves and of the pathways of blood flow. The ligation technics of Antyllus and John Hunter for arteriovenous fistulas and the proximal ligation procedures for arterial aneurysms as practiced by Halsted were extensions of the use of ligatures in the treatment of diseases of the vascular system.

The direct suture of blood vessels was first utilized for the cure of an arterial aneurysm by Matas in his technic of endo-aneurysmorrhaphy. The introduction by Leriche and Adson of surgical procedures designed to alter the well-established influence of the autonomic nervous system on the caliber of the peripheral arteries and arterioles opened a new phase of vascular surgery.

In recent years, the early experimental technics and ideas of Carrel of direct vascular suture and the use of vascular grafts to reestablish circulation in traumatized and locally diseased vessels have seen wide application in clinical surgery. Thromboendarterectomy as first proposed by dos Santos has also been widely used.

ARTERIAL ANOMALIES

Abnormalities of the arteries are extremely common and consist chiefly of *malposition.* Common examples of significance in operative surgery consist of abnormalities in position of the hepatic and cystic arteries. When the former vessel is anomalously placed anteriorly, it may be injured or be mistaken for the cystic artery and erroneously ligated during cholecystectomy; this error gives rise to pathologic changes, resulting in hepatic insufficiency, and may well be fatal if the condition is not promptly recognized and the patient treated vigorously with antibiotics. Anomalies of the renal artery, particularly aberrant vessels, are not uncommon; they tend to give rise to symptoms, as the aberrant vessels may press on the ureters or pelvis of the kidney and produce obstruction with consequent infection.

Other abnormalities may be considered *structural* in type. The most commonly encountered example being the various types of hemangiomas. These are discussed in Chapter 20. Far less frequent are the congenital arteriovenous fistulas which, despite their rarity, deserve comment because they must be clearly differentiated from acquired arteriovenous fistulas in matters pertaining to diagnosis, treatment, and prognosis.

Flynn and Mulder (1) define congenital *arteriovenous fistulas* as all nontraumatic vascular abnormalities in which arterial blood passes into the venous system without going through a capillary bed. Congenital vascular

and systemic evidence of blood loss. Blood lost from an injured artery may pass directly into an adjacent opening in an accompanying vein and establish an arteriovenous fistula. The characteristic thrill and to-and-fro bruit may be absent at the time of initial examination but they will be present within a few hours when a normal arterial pressure is reestablished and the arterial spasm diminishes. In injuries to vessels of an extremity, there will usually be evidence of impaired circulation to the involved limb with loss of or diminished pulse and absent or diminished blood pressure.

Impaired circulation due to contusion of an artery may be difficult to differentiate from mere arterial spasm. With contusion, however, the impairment is more severe and persistent and is accompanied by signs of muscle, nerve, and skin ischemia—such as pain, paralyses, pallor, and coolness. Vascular occlusion due to spasm rarely persists to the point of causing distal pain and paralyses. If necessary, a regional block of the sympathetic nervous system by an injection of procaine will abolish arterial spasm and differentiate the two conditions.

TREATMENT. First-aid treatment has as its objective the control of blood loss without causing further injury until definitive treatment can be instituted. Active bleeding from a wound, even one involving an injury to a major artery, can, in most instances, be controlled by direct pressure over the bleeding area. In an extremity, this can be accomplished by placing padded gauze over the wound with a snug circular bandage. Elevation of the extremity aids in the arrest of hemorrhage. When bleeding is not controlled by compression, a hemostat may be carefully applied directly to exposed large vessels. A tourniquet should be used only for life-endangering hemorrhage not controllable by other means. It should be placed as low on the limb as possible and should be sufficiently tight to control arterial bleeding and not merely to produce venous obstruction and increase bleeding. Once a tourniquet has been applied, it should be remembered that it may be fatal to loosen it after massive hemorrhage until lost blood volume has been replaced. Major arterial injuries in the base of the neck, axilla, chest, abdomen, or groin can be treated adequately only in an operating room. Bleeding from iliac or common femoral vessels may be retarded by firm compression of the abdominal aorta against the spine.

If hemorrhage has been severe, blood volume should be restored as quickly as possible by transfusions. Other intravenous solutions, such as saline, glucose, or dextran, may suffice temporarily until blood is available. In every major arterial injury, the goal should be complete restoration of circulation through the damaged vessel. Various circumstances may at times thwart this goal, such as lack of proper facilities, unavoidable delay before treatment is instituted, or other life-endangering injuries of higher priority. Incised or divided arteries are treated by freshening the edges of the vessel and suturing the edges or ends of the vessel with fine silk suture on small-gauge atraumatic needles. Local heparinization is used to prevent thrombosis and every effort is taken to prevent infection of the wound. When segmental excision of a major vessel in a limb has occurred, it may be replaced with a plastic prosthesis or an autologous vein graft. The vein graft probably has the greater chance of remaining patent, but it may be subject to future aneurysmal dilatation. Larger vessels, such as the aorta or iliac vessels, may be replaced with arterial homografts or plastic prostheses as described on page 556. If the excised area is short, sufficient vessel length may be obtained for a direct end-to-end suture by wide dissection of the proximal and distal ends of the vessel, by rerouting the vessel, or by flexing the extremity.

If contusion of an artery is sufficient to produce persistent arterial occlusion, the traumatized area should be explored and an effort made to re-establish circulation by removing a thrombus at the site of injury. Should this procedure be unsuccessful, the vessel may be ligated proximally in an uninjured area. The contused area may be excised, if proper facilities are available, and the vessel anastomosed end-to-end, or the area may be replaced with a graft. When such procedures are attempted, it is essential that all of the damaged arterial wall be excised and the suture performed in a portion of the vessel that has a normal wall.

False Aneurysm. When a hematoma forms in the soft tissues following an incision or

because of ulceration, bleeding, or pain of the involved part.

Type III. Localized, Minute, Congenital Arteriovenous Fistulas. This is the most frequently encountered type. It is a more discrete lesion which generally occurs in the peripheral portion of an extremity or about the head or neck. The external ear is a frequent site for this type of lesion. Treatment is directed toward: 1. reduction of the afferent arterial supply by ligation of regional arteries; and 2. total or partial excision of the discrete lesion. Satisfactory results are usually achieved.

ARTERIAL TRAUMA

Acute Injury. One of the most exciting advances in surgical technic in recent years has been in the management of acute vascular trauma. Even under battlefield conditions, as was demonstrated in the Korean War, successful attempts have been made to preserve circulation in major vessels of the extremities by restorative vascular procedures rather than by ligation of the injured vessel (3). The employment of such procedures requires special skills and facilities as well as surgical judgment in the proper selection of cases, but the possibilities of such technics should be known and appreciated by everyone (4, 5, 6). Acute trauma to a vessel may take the form of incision, division, segmental excision, or contusion.

Any manipulation of or trauma to an artery will result in contraction of the wall of the vessel and dimunition of its diameter due to the contraction of the circular muscular fibers in the vessel wall. Such constriction in an incised or lacerated vessel which is only partially divided will diminish blood loss because the lumen of the vessel proximal and distal to the point of injury will become narrow. The opening in the vessel itself in the incised or partially divided artery, on the other hand, is actually enlarged and stretched open by this contraction resulting in continued loss of blood. Complete division of the vessel, however, permits vascular contraction to exert its complete protective power. The lumen of the vessel is maximally constricted, and the ends retract into the surrounding soft tissue. As the blood pressure falls, clotting about the end of the vessel is encouraged and the loss of blood stopped. In experimental animals, under identical conditions, blood loss from a partially divided artery is greater than from a completely severed vessel. Clinically, the total amount of blood lost under these two circumstances (i.e., partial division or complete division) will vary greatly depending largely upon other conditions of the wound—such as size, location, depth of vessels in the wound, and extent of the partial laceration in the vessel wall. The injury in which excision of a segment of an artery occurs is similar to complete division of the vessel but is generally more serious, inasmuch as there is usually greater associated injury to surrounding soft tissues, bone, other vessels, and nerves.

A high velocity missile passing in close proximity to an artery, a fractured bone, or a blunt force which compresses an artery against an adjacent bone, may result in *contusion* of the vessel of such magnitude as to interrupt the flow of blood without actually interrupting the continuity of the vessel. This type of injury is associated with disruption of the vessel wall and progressive formation of an intramural hematoma, which may enlarge sufficiently to occlude the vessel completely or to slow the flow of blood sufficiently to permit formation of an additional intraluminal thrombus.

Diagnosis. Any injury which occurs in the region of major vascular channels should immediately raise the suspicion of arterial injury. Evidence of external bleeding may or may not be present. If an artery has been incised or divided, there will be bleeding, either (*a*) externally; (*b*) into the soft tissues between fascial planes; (*c*) into a space or potential space, i.e., lumen of the bowel, bladder, or peritoneal cavity; or (*d*) into a simultaneously injured vein. External bleeding, of course, may readily be detected. A hematoma from extravasated blood in soft tissues can be detected by palpation although, if the wound is not examined soon after injury, generalized edema of the area may be difficult to differentiate from a hematoma. A pulsating hematoma is indicative of an arterial injury. Concealed hemorrhage into the lumen of the alimentary tract, pleura, or peritoneal cavities must be diagnosed on the suspicion of arterial injury plus local signs of blood in these spaces

pulse volume, blood pressure, or oscillometric determinations, is impaired.

The patient complains of pain in the region of the aneurysm from compression and irritation of adjacent nerves. When the peripheral circulation is compromised, there is intermittent claudication or resting pain due to ischemia of distal muscles. The usual course of the false aneurysm is one of gradual enlargement with increasing pain and discomfort. Rupture and exsanguination may occur in neglected cases.

Treatment is directed toward evacuation or excision of the aneurysmal sac and repair of the opening in the artery. The involved artery is isolated and occluded above and below the site of the aneurysm. The sac is then dissected out or opened and evacuated, and the opening in the artery is closed with fine silk sutures. If the vessel has been sufficiently damaged, excision and grafting of the involved area may be the indicated procedure.

Arteriovenous Fistula. The congenital type of arteriovenous fistula has been described previously. The traumatic variety follows a stab or small-caliber missile wound which lacerates both the artery and its accompanying vein. A hematoma forms about the vessels, external bleeding stops, and within the confined area of the hematoma the arterial blood finds its way back into the vein. Within a short time this channel becomes endothelialized, and a permanent arteriovenous communication is established. If the openings in the vein and artery are immediately adjacent to one another, they may become sealed together without the formation of an aneurysmal sac. On the other hand, if the hematoma has been large and the vascular openings not immediately contiguous, a large aneurysmal sac is formed. Vascular injuries of this type have been reported following surgical trauma: i.e., after the use of transfixion suture, at the superior pole of the thyroid during thyroidectomy, and in the broad ligament during hysterectomy. A number of vascular lesions of this type have occurred following injury to the terminal aorta and inferior vena cava or the iliac vessels during the removal of a ruptured nucleus pulposus.

The examination of any fresh wound suspected of involving major vascular structures should include careful palpation for the continuous thrill and auscultation for the continuous murmur characteristic of an arteriovenous fistula.

Manifestations. The signs and symptoms of this abnormal vascular communication, which develops days or weeks later, if it has been overlooked on the initial examination or early treatment has not been undertaken, will be related to the size of the communication, the volume of blood flowing through the fistula, its location, and the presence or absence of an aneurysmal sac. The patient may be aware of a pulsating mass in the region, and there may be local pain due to compression of adjacent nerves. If vessels in the neck or head are involved, the patient frequently complains of a buzzing noise in the head.

On inspection, dilated superficial veins are present, and a pulsating mass may or may not be visible. The area is warm, and a continuous thrill may be felt over the fistula. On ausculation a continuous murmur is present. Circulation distal to the fistula is usually impaired with a reduction of skin temperature, diminished or absent pulses, and in long-standing cases actual muscle atrophy and skin ulceration. A small communication in major vessels or a fistula involving smaller vessels such as the radial, dorsalis pedis, or superior thyroid arteries rarely produce any symptoms other than these local findings.

If the fistula is of sufficient size to shunt a large quantity of blood from the arterial directly into the venous circulation, there is a profound effect on the circulatory system. Blood volume and cardiac output are increased, the heart increases in size as the left ventricle dilates and hypertrophies, and acute heart failure with pulmonary edema may occur. Pressure over the area sufficient to interrupt the passage of blood through the fistula will cause a prompt bradycardia. This is called the Branham-Nicoladoni sign.

Treatment. Up until a few years ago, procedures were not often used that permitted closure of the fistula and re-establishment of circulation through the involved artery. The generally recommended surgical treatment was ligation of all vessels communicating with the sac, and ligation of the artery and vein above and below the fistula, followed by excision or obliteration of the aneurysmal sac. Circulation peripheral to this point was there-

laceration of an artery, the area may become sealed off, the external bleeding cease, and, over a period of time, a fibrous capsule will encircle the hematoma. If the opening in the vessel remains patent, there is a constant flow of blood into and out of the area of the hematoma. Laminated areas of clotted blood of varying thickness line the periphery of such a space, the interior surface becomes endothelialized, and the center is filled with fresh flowing blood from the artery. The entire mass pulsates with each cardiac systole. This is called a *false aneurysm,* for in contradistinction to a true aneurysm, which is surrounded by all, or a part of the wall of the vessel from which it originates, the false aneurysm has no true wall other than the layer of fibrous tissue which forms within the soft tissue space (Fig. 2).

The majority of such lesions are traumatic in origin resulting from a stab wound or a small missile, although at times a vessel with syphilitic or atherosclerotic changes may rupture spontaneously and form a false aneurysm.

The *diagnosis* is usually not difficult. As stated, there is usually a history of local injury. A mass can be palpated. The degree of pulsation will vary depending on the amount and tenseness of the overlying soft tissue and the thickness of the laminated clot. A systolic thrill may or may not be palpable but a systolic bruit is always heard over the mass. The bruit is present only during systole and is quite different from the to-and-fro murmur associated with an arteriovenous aneurysm. The vessel of origin is compressed by the mass and peripheral circulation, as determined by

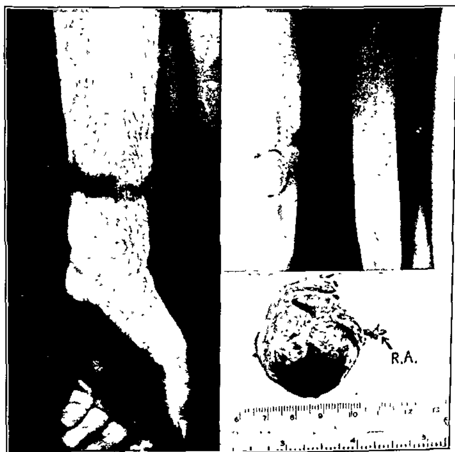

Fig. 2. Traumatic aneurysm secondary to an injury six years previously. A small fragment of steel penetrated the forearm, but healing was rapid without any special treatment. A small mass developed shortly after injury; a few weeks before entry it began to enlarge rapidly, aided perhaps by the development of an essential hypertension. The photograph was taken just before operation. The x-ray on the right shows the foreign body lying adjacent the radius, and calcification in the wall of the aneurysm. Below is a photograph of the aneurysmal sac after removal. The proximal end of the radial artery (R.A.), is indicated.

its further progress. Thus, most emboli lodge at a bifurcation of the common iliac, the femoral, or popliteal vessels. Less frequently, the embolus is detained at a point where the vessel may be compressed, such as the point where the superficial femoral artery passes through the adductor muscles.

The signs of pallor, coldness, paralysis, and pain do not extend proximally to the level of the embolus. In determining the location of the obstruction, the next major branch proximal to the level of these signs or, when it is possible to palpate a proximal pulse, the major division of the vessel between the level of coldness and pallor and the last palpable pulse will be the most likely location of the embolus. Oscillometric readings will also be of value in determining the site of the obstruction, as the readings will be greatly diminished below the point of arterial occlusion. The location of the embolus is usually not difficult.

Coincident with the impaction of an embolus in an artery, a reflex arterial spasm occurs in the regional vessels distally and to some extent proximally. This results in further decreased blood flow to the area. Shortly thereafter, thrombosis starts in the column of blood in the vessel above and below the obstruction. This is called the propagated clot.

The subsequent course of the circulation in the part distal to the obstruction is dependent primarily upon the degree and persistence of reflex arterial spasm, and the time of onset and extent of intraarterial thrombosis or propagated clot. Pronounced arterial spasm reduces markedly the effectiveness of the collateral circulation and, if persistent, will diminish the chances of success of nonoperative therapy in preserving viability in the involved part. Persistent severe arterial spasm also shortens the time interval during which the performance of an embolectomy may be expected to preserve viability distal to the obstruction.

Extensive thrombosis of the arterial tree distal to the embolus also decreases the effectiveness of both operative and nonoperative forms of therapy in preserving distal tissue viability. If nonoperative therapy is utilized, the life of the part distal to the arterial obstruction is dependent upon the collateral circulation; and for the collateral circulation to provide an adequate blood supply, the arterial system distal to the embolus must remain patent. Embolectomy cannot be successful if a major portion of the distal arteries is thrombosed. The rate and extent of thrombosis in the slowed circulatory flow distal to an embolus varies greatly in individual cases, due partially to unknown influences. Persistent distal arteriospasm causes further slowing of the flow of blood and encourages intravascular thrombosis. In general, the extent of propagated clot is directly related to the interval of time between the onset of the embolus and the institution of therapy (13).

TREATMENT. Prompt recognition and the institution of early therapy are essential for effective results in this condition. The two complications to combat are arteriospasm and intraarterial thrombosis. As soon as the diagnosis is made, systemic heparin and papaverine should be administered and the extremity should be placed in a position slightly below the level of the heart and protected from mechanical or thermal injury. If the occluded vessel is a critical one in the blood supply of the limb, prompt embolectomy should be performed, except in unusual conditions. Rarely, the associated cardiac condition is so critical as to contraindicate the most simple operative procedure under local anesthesia. In such circumstances, in addition to the measures outlined above, the injection of procaine solution to block the sympathetic nerve supply of the involved extremity may be considered. Contrary to some former recommendations, current reports emphasize the desirability of performing embolectomy in cases of upper extremity embolism (10, 12, 14). In the cases of Shumacker and Jacobson, amputation was required in four of six cases of upper extremity embolism not treated by embolectomy. Cerebral or visceral (i.e., splenic, renal, mesenteric) arterial emboli are treated by nonoperative means. Embolectomy of the superior mesenteric artery has been attempted recently in a limited number of cases. The procedure, however, will require further evaluation before its efficacy can be established.

Embolectomy in the extremities is performed with local anesthesia. Exposure of the terminal aorta or iliac vessels requires a general anesthetic. The site of the embolus is exposed. The vessel is isolated proximally

after dependent upon collateral channels. It was, therefore, important to delay definitive treatment for a period of approximately three months, as recommended by Reid (7), to permit adequate collateral circulation to develop. The disadvantages of such a delay were: 1. increased cardiac strain and possible cardiac failure, if the fistula were large; and 2. the development of the desired collateral circulation added greatly to the technical difficulties and hazards of subsequent operation due to the extreme vascularity of the tissues surrounding the fistula. Spontaneous closure of the fistula occurs in only approximately 4 per cent of cases as reported by Seeley (8), and the expectation that such might take place is not a sufficient indication to delay treatment.

Currently available technics of vascular suture, anastomosis, and grafting are sufficiently reliable that there is no reason to delay direct surgical repair unless there are existing contraindications, such as 1. other life-threatening injuries; 2. poor operability from the standpoint of hypovolemia, severe infection, myocardial decompensation; and 3. lack of adequate facilities and trained personnel.

The principles of immediate surgical repair consist of securing control of the artery and vein proximally and distally to the site of injury, evacuation of the hematoma, and direct suture of the laceration or lacerations of the artery. If the arterial wall is badly damaged, excision of the area with end-to-end anastomosis or grafting should be done. The laceration in the vein, if minimal, may also be sutured, provided the vessel is patent, or flow may be re-established by simple removal of a fresh clot; otherwise the vein should be ligated.

ACUTE ARTERIAL OCCLUSION

Nontraumatic acute arterial occlusion may be caused by 1. arterial emboli or 2. arterial thrombosis. In some cases it is difficult to distinguish between the two as causes of acute arterial obstruction. Generally, however, the suddenness with which the onset of symptoms occurs will suggest embolic occlusion. Arterial spasm associated with venous thrombosis may at times be so severe as to suggest the presence of an arterial obstruction.

1. Arterial Emboli. The most frequent site of origin of arterial emboli is within the heart of the patient with rheumatic heart disease (9). Rheumatic heart disease was present in 31 of 55 patients with arterial emboli reviewed by Shumacker and Jacobson (10). Other diseases of the heart associated with the formation of intracardiac thrombi and the site of origin for peripheral emboli in their cases were: arteriosclerotic heart disease, hypertensive cardiovascular disease, myocardial infarction, and toxic goiter with auricular fibrillation. The left atrial appendage is the most frequent site of intracardiac thrombus formation in patients with rheumatic heart disease, mitral stenosis, and auricular fibrillation. Garvin (11) found mural thrombi in 43.3 per cent of 60 patients in whom auricular fibrillation had occurred; 86.5 per cent of the thrombi were located in the atria. In the series of cases reported by Warren and associates (12), 12.5 per cent of the emboli occurred in patients in whom no source of the embolus was clinically evident.

The seriousness of arterial embolization and the cardiac disorders usually associated with this condition is indicated by the patient mortality in a series of 200 patients reported by Warren and associates of 28.4 per cent during a seven-year period and 38.7 per cent in the preceding ten-year period (12). The causes of death in the hospital in 67 of these 200 patients were as follows:

Cause of Death	*Number of Cases*	*Per Cent*
Cerebral embolism	20	30 0
Cardiac failure	19	28 5
Mesenteric embolism	11	16 5
Myocardial infarction	7	10 5
Cerebral and mesenteric embolism	1	1 5
Pulmonary embolism	2	3.0
Other	7	10.5

SYMPTOMS. With an arterial embolus there is a sudden onset of pain, coldness, numbness, and paresis. The pain at times is quite transitory, and numbness and loss of function of the part may be the patient's chief complaints. On examination the extremity distal to the embolus is pale, cyanotic, and cold, and there is anesthesia and loss of motor function. The embolus passes from the heart distally into the arterial system until it encounters a vessel of insufficient luminal diameter to permit

Fig. 3. X-ray of the abdomen. Extreme calcification of aorta and iliac vessels. Areas of calcification visible in upper left abdomen in an aortic aneurysm. While patient was in the hospital he developed severe pain in the upper abdomen with marked tenderness and muscle spasm. Early gangrene of entire small intestine found at operation due to atheromatous obstruction of superior mesenteric artery.

which may or may not be at fault; angiospasm; Raynaud's disease; erythromelalgia; acrocyanosis.

DISEASES DUE TO STRUCTURAL CHANGES IN VESSELS

Great strides have been made in recent years in the surgical treatment of the most common cause of chronic circulatory insufficiency, *arteriosclerosis obliterans,* involving large and medium sized arteries (Fig. 3). The exact cause of this process, and therefore its prevention, is not clearly understood (15, 16). Vascular changes similar histologically to those observed in humans may be produced in experimental animals by the simultaneous oral administration of an antithyroid drug and cholesterol (17, 18, 19) (Fig. 4). This process is typically encountered in the elderly male patient but is seen in both sexes. It may rarely occur in individuals under the age of forty. The presence of diabetes seems to predispose to this condition as it occurs earlier, and almost invariably the condition accompanies advancing age in diabetic patients. Although atheromatous vascular changes are usually generalized they may, particularly in younger patients, be localized, producing complete segmental obstruction of a major artery without evidence of significant disease elsewhere in the vascular system. The arteries of the lower extremity are particularly prone to involvement.

Fig. 4. Microscopic transverse section (low power) of an artery showing changes due to arteriosclerosis. Note that the hypertrophy of the intima partially obliterates the lumen. There is an extensive deposition of fat in the thickened intima, which can be seen better in sections specially stained to show fat (e.g., Sudan stain).

and distally and occluded at these points, while a longitudinal arteriotomy is performed to expose the embolus. After removal of the embolus, if there is not a free flow of blood from both ends of the vessel, the obstructing propagated clot is aspirated, first from the distal arterial tree and then proximal to the arteriotomy. For extensive propagation of the clot distally in the lower extremity, Dye and his associates (14) have cannulated the posterior tibial artery and flushed the thrombus in a retrograde fashion from the distal arterial tree with heparin solution. If an adequate blood flow cannot be obtained from the proximal end of the artery by aspiration, and the wall of the vessel does not indicate extensive atheromatous changes that are probably associated with primary thrombosis rather than embolism, the next higher major division or branching of the vessel should be exposed and treated in similar fashion. Under such circumstances, the level of the embolus has been misdiagnosed, and, although propagated clot may be aspirated from a vessel, an impacted embolus will resist removal by this means. The opening in the vessel is closed with a delicate running over-and-over silk suture. Heparin solution is instilled distally as the vessel is closed. Postoperatively, motion of the extremity is encouraged and systemic heparinization is maintained for a period of seven days. The decision must then be made with regard to placing the patient on prolonged anticoagulant therapy with dicumarol to reduce the risk of subsequent emboli since recurrent emboli are common.

2. **Arterial Thrombosis.** The signs and symptoms of acute arterial thrombosis are similar to those described above and, as stated, may at times be difficult to distinguish from an obstructive embolus. Frequently, however, they are more gradual in onset and there is usually a preceding history suggestive of vascular insufficiency, such as intermittent claudication in the lower extremities.

Thrombosis is associated with arteriosclerotic changes in the vessel wall with intimal thickening and gradual reduction in the caliber of the lumen. The development of collateral circulation is encouraged by this gradual occlusion, so that the final complete obstruction by the thrombus does not cause the severe ischemic symptoms that are associated with the occurrence of an embolus in an otherwise normal vessel. The sclerotic changes are frequently most severe at an arterial bifurcation, but may occur anywhere in a vessel; therefore, the location of the obstruction is made more difficult. This difficulty is increased by the presence of the collateral circulation, which may prevent ischemic changes for variable distances down the extremity.

The character of onset, the presence or absence of cardiac disease which would be compatible with the formation of mural thrombus and emboli, and the evidence of generalized arteriosclerosis are prominent criteria that are of assistance in the differential diagnosis. Gradual thrombotic occlusion is best treated by elective operation. This will be described in a subsequent section. The nonoperative treatment outlined above will be of value during the initial period of mild symptoms. For the acute obstruction with pronounced symptoms, which is usually indicative of a thrombus occurring in a vessel with a fairly adequate lumen, immediate exploration with thromboendarterectomy is indicated. The vessel is exposed at the supposed level of obstruction. Tapes are passed about the vessel above and below this point and a longitudinal incision is made through the wall. The thickened intima and thrombus are carefully dissected from the media and adventitia and the dissection is carried above and below the obstructed area. The distal thickened intima must be carefully sutured circumferentially to the media to prevent it from being further dissected by the arterial stream and folded inward to obstruct the lumen. Heparin solution is placed in the vessel as the incision is closed and the patient is maintained on systemic heparin for seven days.

CHRONIC ARTERIAL INSUFFICIENCY

Under this heading may be considered a group of disorders which interfere with the distribution of blood through peripheral areas. They may be classified as: (1) diseases due to structural changes in vessels: arteriosclerosis; thromboangiitis obliterans (Buerger's disease); and (2) diseases resulting from abnormal functional response of the arteries to various stimuli, including those mediated by the autonomic nervous system

Fig. 5. Aortogram demonstrating segmental obstruction of right common iliac artery. The external iliac and femoral vessels are well filled with the radiopaque solution indicating a patent peripheral system or "run off bed" below the obstruction.

Attempts may be made to re-establish circulation in the major arteries when the obstruction is in the terminal aorta, the iliac vessel, or femoral vessel by 1. thromboendarterectomy; 2. excision of the obstructed segment and replacement with a homograft or plastic prosthesis; and 3. bypass graft.

THROMBOENDARTERECTOMY. The thickened intima and obstructing thrombus are carefully dissected from the media and adventitia through a longitudinal incision in the wall of the vessel. If the segment of obstruction is short, the incision is extended and the core dissected under direct vision (22, 23, 24, 25). For more extended areas of obstruction, such as may be encountered in the femoral vessels, a loop stripper may be utilized to free the core blindly from the center of the vessel as suggested by Cannon and Barker (26, 27) (Fig. 6). At the distal end of the dissection, the intima must be meticulously sutured to the media and adventitia to prevent its infolding and occluding the lumen. The arteriotomy is closed with a delicate continuous suture of silk.

EXCISION OF THE OCCLUDED SEGMENT AND REPLACEMENT BY A GRAFT. This method of treatment has been most useful in the treatment of occlusive disease of the terminal aorta and the iliac vessels (28, 29, 30). After gaining control of the aorta and iliac vessel above and below the site of obstruction, the involved segment is excised and replaced by a graft which is sewn to the cut ends of the vessel with a continuous silk suture.

Although vascular homografts have been most widely utilized, various types of plastic prostheses have been found to provide adequate replacement material and are more readily available (31, 32).

BYPASS GRAFT. When treating obstructed vessels, such as the femoral artery, by grafting, it is preferable to bypass the clogged segment by anastomosing the graft end-to-side to the vessel above and below the obstruction rather than by attempting resection of the oc-

Although chronic arteriosclerotic obstruction of other arteries, for instance the coronary and carotid vessels, are of great clinical significance and efforts have been made (20, 21), some of which are quite preliminary, to improve the circulatory capacity of these vessels by surgical procedures, the major concern today is with the diagnosis and treatment of chronic circulatory insufficiency of the lower extremities.

Symptoms and Signs. The characteristic symptom of chronic arterial insufficiency in the lower extremities is intermittent claudication. This is a severe cramping pain in the muscles of the leg brought on by exercise. The location of the pain varies with the level of arterial obstruction. Pain in the gluteal muscles and hip is associated with terminal aortic obstruction; obstruction of the iliac vessels typically causes pain in thigh muscles; and with femoral artery obstruction the pain is in the muscles of the calf. The circulation is adequate to nourish the muscle at rest but unable to meet its metabolic requirements during exercise. The amount of exercise required to bring on these symptoms is a rough measure of the degree of circulatory insufficiency. Rest relieves the pain, but it reappears again with exercise.

A similar type of pain in the muscle groups during rest and a feeling of coldness in the extremity are indicative of a more severe degree of circulatory insufficiency, and, if the process continues, a more or less constant burning type of pain develops which is thought to be due to ischemia of the nerves. Some relief is afforded the patient by maintaining the extremity in a dependent position, although this position encourages the development of edema and interferes further with capillary circulation. The next stage is the development of skin ulcers about the toes, feet or ankles, an expression of ischemic gangrene usually initiated by mild or insignificant trauma.

Obstruction of the terminal aorta produces a characteristic series of symptoms, *Leriche's syndrome*. There is intermittent claudication in the gluteal and thigh muscles which is usually more severe on one side or the other, but is present bilaterally. Impotence is frequently present.

On examination, absent or greatly diminished pulsations are noted in the major vessels. The skin is cool and has a smooth atrophic appearance; hair growth is sparse. When the veins are emptied by stripping them upwards, they fill slowly. Pallor of the skin of the foot is noted on elevation and rubor in the dependent position. The test of *reactive hyperemia* gives considerable information in regard to the adequacy of circulation. Blood flow to the extremity is restricted either by elevation or by inflating a sphygmomanometric cuff for a period of three minutes. In the normal subject, there is an immediate light red flush which extends over the leg, foot, and toes on return of circulation. This is called reactive hyperemia. A lack of intensity or delay in appearance of the flush indicates a poor capillary circulation in the area.

Additional studies which may give confirmatory and, at times, more exact evidence of circulatory disorders are oscillometric readings, digital plethysmography, skin temperature determinations with thermocouples, and the disappearance rate of subcutaneously injected radioactive sodium solutions. Arteriograms, performed by the injection of a radiopaque solution into the artery proximal to the point of obstruction or performed at the time of operation by injection distal to the suspected point of major arterial obstruction, are of value to demonstrate 1. the exact site and extent of obstruction; and 2. the patency of the smaller distal vessels or "run-off bed" (Fig. 5).

Treatment. An extremity with impaired circulation and impending gangrene must be observed carefully to prevent minor trauma. It is best to maintain the extremity at a level slightly below the level of the heart and at room temperature. Both heat and cold should be avoided. Minor skin abrasions should be kept dry and protected from further trauma. Diabetes, if present, should be rigidly controlled. Autonomic blocking agents are not of value in the treatment of vascular insufficiency resulting from *arteriosclerosis obliterans*. Surgical treatment is directed toward 1. re-establishment of circulation in the major arteries; 2. vasodilation by sympathetic denervation; and 3. carefully considered amputation for gangrene.

Fig. 5. Aortogram demonstrating segmental obstruction of right common iliac artery. The external iliac and femoral vessels are well filled with the radiopaque solution indicating a patent peripheral system or "run off bed" below the obstruction.

Attempts may be made to re-establish circulation in the major arteries when the obstruction is in the terminal aorta, the iliac vessel, or femoral vessel by 1. thromboendarterectomy; 2. excision of the obstructed segment and replacement with a homograft or plastic prosthesis; and 3. bypass graft.

THROMBOENDARTERECTOMY. The thickened intima and obstructing thrombus are carefully dissected from the media and adventitia through a longitudinal incision in the wall of the vessel. If the segment of obstruction is short, the incision is extended and the core dissected under direct vision (22, 23, 24, 25). For more extended areas of obstruction, such as may be encountered in the femoral vessels, a loop stripper may be utilized to free the core blindly from the center of the vessel as suggested by Cannon and Barker (26, 27) (Fig. 6). At the distal end of the dissection, the intima must be meticulously sutured to the media and adventitia to prevent its infolding and occluding the lumen. The arteriotomy is closed with a delicate continuous suture of silk.

EXCISION OF THE OCCLUDED SEGMENT AND REPLACEMENT BY A GRAFT. This method of treatment has been most useful in the treatment of occlusive disease of the terminal aorta and the iliac vessels (28, 29, 30). After gaining control of the aorta and iliac vessel above and below the site of obstruction, the involved segment is excised and replaced by a graft which is sewn to the cut ends of the vessel with a continuous silk suture.

Although vascular homografts have been most widely utilized, various types of plastic prostheses have been found to provide adequate replacement material and are more readily available (31, 32).

BYPASS GRAFT. When treating obstructed vessels, such as the femoral artery, by grafting, it is preferable to bypass the clogged segment by anastomosing the graft end-to-side to the vessel above and below the obstruction rather than by attempting resection of the oc-

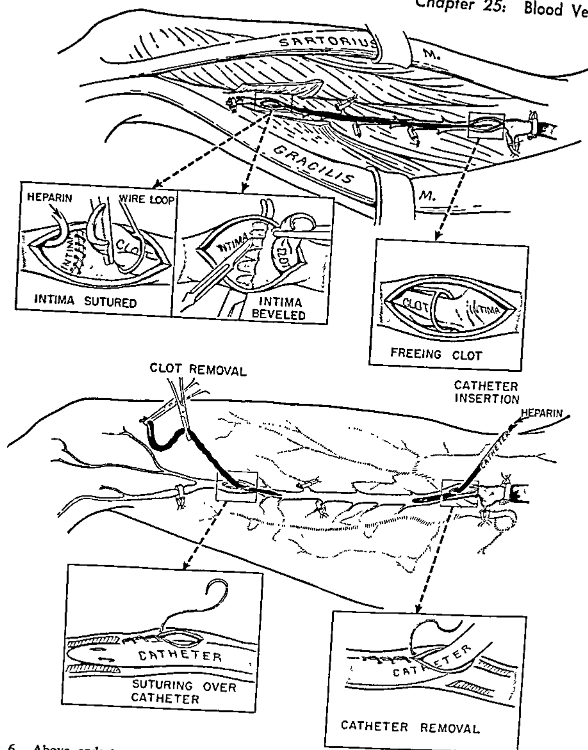

Fig. 6. Above, endarterectomy by semiclosed technic using wire loop stripper. Two arteriotomies are performed. Inserts show management of distal intimal edge either by suturing or beveling. Core removed consists of occluding atheromas plus secondary organized blood clot. Below, repair of vessel after semiclosed endarterectomy over catheter stent. (From Cannon, J. A., and Barker, W. F., Surgery.)

cluded vessel and replacement of it with a graft. Crawford and DeBakey (33) state that,

The most important advantage of this procedure lies in the fact that it not only permits restoration of a normal pulsatile blood flow into the peripheral arterial bed, but also is associated with minimal jeopardy to the existing circulatory and functional capacity of the extremity. The minimal dissection required in its performance reduces the risk of injury and thrombosis to the main artery and to its collateral vessels in the region of occlusion as well as above and below this process.

They were able, by this method, to restore a pulsatile blood flow in the peripheral arterial bed in all but three of 40 extremities so treated. Autogenous vein, arterial homografts, and plastic tubes have all been utilized as bypass vascular substitutes. Although the early results of such procedures have been gratifying, a question has been raised in regard to the continued patency of these grafts. Haye and Warren (34) reported that 70 per cent of their patients suffered closure of the graft after discharge from the hospital. At the present time, it seems difficult to define the procedure of choice for occlusive disease involving the femoral artery. The choice of the authors is thromboendarterectomy. For satisfactory results, however, the procedure must be carefully performed with strict attention to technical details beyond the scope of this chapter. Successful re-establishment of circulation by any of these methods cannot be expected unless the smaller peripheral vessels are patent and there is an adequate "run-off bed."

SYMPATHETIC DENERVATION. Patients with arteriosclerosis obliterans considered unsuitable for a direct attack on the major arterial channels, usually because the disease process is so extensive and because it involves the smaller vessels of the extremity, may, in certain instances, obtain symptomatic improvement by removal or interruption of appropriate portions of the sympathetic nervous system (35, 36). Although the principle effect of sympathetic denervation is vasodilatation of cutaneous vessels, the blood flow through other collateral channels may be increased, and circulation to regional muscles improved. The local anhydrosis produced by sympathectomy prevents maceration of the skin due to excessive sweating, lessens the loss of heat from the extremity, and thereby lowers the circulatory demand.

The degree of elevation of skin temperature over the innervated area, following a block of the sympathetic nerve fibers by the injection of procaine solution into the region of the appropriate sympathetic nerve ganglia, may give an approximate idea of the circulatory improvement to be anticipated from surgical interruption of the nerve fibers. Clinical experience indicates, however, that some degree of improvement may be anticipated in these unfortunate individuals when such tests give evidence of a minimal response. The effectiveness of sympathectomy will depend upon the total number of patent arteries in the extremity and the ability of these vessels to respond by vasodilatation.

The technic of the operation for denervation of the upper extremity (35, 37) involves division of the sympathetic chain between the third and fourth thoracic ganglia, division of the rami to the second and third thoracic ganglia, and division of the second and third thoracic nerves proximal to the sensory root ganglia. The mobilized sympathetic chain is elevated into the wound and sutured to the muscles to prevent nerve regeneration.

The lower extremity is denervated by removal of the second and third lumbar ganglia. This results in complete sympathetic denervation of the foot and lower leg except in its medial aspect. When it is desirable to obtain a maximal increase in circulation from the knee down, the first lumbar ganglion is included in the resection. If bilateral removal of the first lumbar ganglion is considered, it is important to recall that permanent loss of seminal emission has been reported to occur in 54 per cent of patients so treated (35).

AMPUTATION. Any patient with peripheral ulceration or gangrene resulting from inadequate arterial blood flow must be carefully evaluated, not only in regard to the selection of the proper local therapy but also in regard to the management of his general physical condition. The status of the cardiovascular system and the proper regulation of diabetes, if present, are of prime importance.

An effort is made locally to control the extent of gangrene by keeping the affected foot in the position of optimum blood flow, slightly below the level of the heart; the foot is carefully cleansed and kept on a sterile towel, a foot board is used to prevent the bedclothes from rubbing or pressing on the foot and toes, and necrotic material is carefully excised. Sterile saline compresses at body temperature may be alternated cautiously with intervals of exposure to the air to prevent maceration. Penicillin or other antibiotics are indicated, if infection is present. If gangrene is extensive, packing the extremity in ice may markedly reduce the sys-

temic reaction and allow the general condition of the patient to improve.

For minor areas of gangrene in younger patients, amputation of digits may suffice. Healing is rare in elderly patients with arteriosclerosis obliterans following toe amputations. McKittrick, et al. (38) have advocated transmetatarsal amputation in the following conditions: 1. gangrene of all or part of one or more toes, providing that the gangrene and accompanying infection have become stabilized and the gangrene has not involved the dorsal or plantar aspect of the foot; and 2. a stabilized infection or open wound involving the distal portion of the foot, when total excision of the infected area with primary or delayed closure can be accomplished. Success in this type of amputation requires skill in selection of patients and selection of the proper time for operation. The technic of the operation must be meticulous and postoperative care painstaking. These authors report 215 transmetatarsal amputations with two hospital deaths; 33 of the patients failed to heal and required a higher amputation. Satisfactory results were achieved in 135 of the 174 patients followed after discharge from the hospital.

Shumacker and Moore (39) report 61 leg amputations and 53 supracondylar amputations in their series of 121 primary definitive amputations. There was no difference in the mortality between the leg and thigh amputations, although wound complications were encountered slightly more frequently in the leg amputations. They express a preference for the leg, or below the knee, amputation whenever possible. At operation, the extremity is draped so that amputation can be carried out either through the leg or thigh. The gross vascularity noted on trial incision into the leg is used as the principal guide to adequacy of circulation. They feel this method is superior to any method of preoperative evaluation. All eight deaths (6 per cent) in their over-all series were apparently the result of cardiovascular difficulties.

Thromboangiitis Obliterans (Buerger's Disease) (40). This disease is a progressive process involving whole arteries or segments of arteries of medium or small caliber, characterized by thickening of the intima, thrombosis, and periarterial inflammation which may involve the accompanying vein and nerve (Fig. 7). The initial pathologic changes and the etiology are unknown. It occurs most often in young men with the onset of the disease occurring between the ages 25 and 40. Involvement of the lower extremity is much more frequent than the upper. It rarely occurs in the vessels of the viscera. Tobacco smoking is considered a factor in the etiology of the dis-

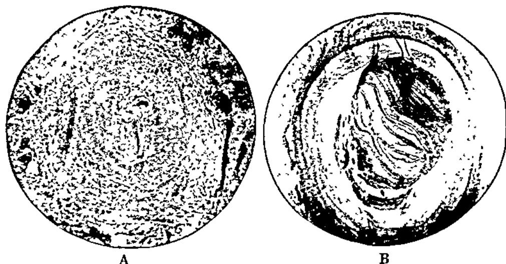

Fig. 7. Photomicrograph of arteries in Buerger's disease; specimens obtained from an amputated leg. A, the entire artery has been obliterated by a thrombus which is fairly well organized. Note the marked inflammatory reaction, with dense fibrous tissue, surrounding the wall of the artery; B, this artery is likewise occluded by a thrombus, but recanalization is taking place. An unusually large amount of proliferation of the intima is present in this specimen.

ease, although rare cases have been reported in nonsmokers.

Clinical Manifestations. The initial symptoms vary. With sudden thrombotic occlusion of the hitherto patent, but narrowed, artery, the onset may be sudden and painful with all the manifestations of an acute circulatory deficiency, *including gangrene (Fig. 8)*. Most often, however, the symptoms, like the pathologic process, develop gradually. In many cases, the first sign will be a peculiar, localized phlebitis of the superficial veins of the leg which subsides after a few days only to recur in some other vein or other area of the same vein. This condition is called *migrating phlebitis* and should lead one to an investigation of the state of the arteries. *Intermittent claudication* may be the first symptom when gradual arterial occlusion occurs. The slowly developing, circulatory deficiency promotes the development of a collateral circulation in the vessels of the skin. As signs of circulatory insufficiency progress, the skin of the foot may become blue or dusky red in color, shiny, and stiff. Changes in the position of the foot will result in marked color changes.

In the later stages slight edema, indolent *ulcers, and eventually gangrene of the toes* may develop. However, gangrene is not extensive; rarely does it involve more than a portion of the toes. The periarterial, inflammatory process which involves the accompanying vein and nerve gives rise to the most characteristic and distressing symptoms. The foot becomes deep red or blue, the pain intense, and the skin hyperesthetic to a degree which will not permit the bedclothes to rest upon it. For some reason, most relief is obtained with the foot hanging over the side of the bed and the hands grasping and encircling

Fig. 8. Buerger's disease. Onset one year ago with tingling and pain in the toes. Pain increased and became very severe. Six months after onset, the lateral three toes became gangrenous at the tip and were amputated. The incision healed, but later broke down, resulting in the ulcer as noted in the photograph. Note the cyanosis of the skin over the distal part of the foot. Pain is still present and now located in the remaining toes and distal part of the foot.

the ankle. Fortunately, the inflammatory process recedes spontaneously in many patients; but in some, when it persists, the patient will beg for amputation. There is almost always a vasospastic element in the circulatory deficiency.

TREATMENT. The most important step in the treatment of Buerger's disease is to prevail upon the patient to stop smoking. The exact etiologic relationship of tobacco smoking to thromboangiitis obliterans is unknown; but there is sufficient clinical evidence to support the view that tobacco smoking exerts a deleterious effect on patients with this disease. Silbert (41) has emphasized that patients who continue to smoke invariably show a progression of the disease despite vigorous treatment, whereas, if they discontinue smoking, the disease tends to remain quiescent, and exacerbations and new vascular occlusions are rare.

During acute exacerbations, bed rest and sedation for pain are indicated. The extremity should be protected from trauma and temperature changes. Every effort should be made to minimize edema by keeping the extremity in a dependent position as little as possible. Drugs to produce vasodilatation may at times be helpful. As soon as they can be tolerated, Buerger's exercises, alternately elevating and lowering the legs to empty and fill the collaterals, are helpful. Sympathectomy is usually indicated to improve collateral circulation after the acute stage has subsided. As the disease tends eventually to be self-limited, and further progression can in most cases be prevented by cessation of tobacco smoking, a conservative attitude should be maintained in regard to amputations, and the procedure reserved for areas of established gangrene. All measures should be utilized to improve the general health of the patient as much as possible.

DISEASES DUE TO VARIOUS STIMULI

Angiospastic Conditions. Spasmodic contraction of the smooth muscle in the wall of an artery or in one segment of a vessel may come about in a number of circumstances as a result of vasoconstrictor impulses reaching the muscle through autonomic nerves. There is frequently a large element of vasospasm in organic disorders such as thromboangiitis obliterans and even arteriosclerosis. Thrombophlebitis, injury of a nonpenetrating type, or rough handling of an artery at operation may also give rise to reflex angiospasm.

The best-known clinical entity of this type is a vasomotor disturbance giving rise to bilateral symmetrical attacks of arterial spasm called *Raynaud's syndrome*. This was described, in 1862, as a disease process which frequently resulted in bilateral symmetrical gangrene (Fig. 9). Occasionally, long-standing cases are seen today in which fibrosis of the arterial wall produces a permanent narrowing of the lumen and atrophic changes in the peripheral part, or even gangrene. The disorder most commonly occurs in women, with its onset in youth or early middle life, and usually affects the hands, only occasionally being encountered in the feet. The first attack is often precipitated by some disturbing emotional experience, and subsequent attacks may be preceded by some psychic upset; however, the history after the initial spasm is generally that cold produces a painful, persistent blanching of both hands with a rather slow return of circulation, sometimes with an abnormal degree of redness, numbness, or paresthesia and pain. Gangrene may develop, but is always superficial and confined to the tips of the fingers. More often, an atrophy of the pulp of the tips of the fingers develops, with a dry, scaly skin. The nails may be distorted. The attacks may be minimized by preventing exposure to extreme cold, wearing warm gloves, or immersing the exposed hands in warm water. When such measures are of no avail, dorsal sympathectomy as described in the preceding section should be considered.

Other types of vasospastic conditions have been said to demonstrate *Raynaud's phenomena* with local signs quite similar to those which characterize Raynaud's disease. Such signs may occur in the hands of workmen who use a pneumatic drill or other vibrating tool; they may also occur in patients with a cervical rib or the scalenus anticus syndrome, with certain nerve lesions, or with poisoning from ergot or such metals as lead. It is important in the examination of the patient with these symptoms to rule out the presence of such etiological factors before concluding that the patient has a true Raynaud's disease.

Fig. 9. Advanced Raynaud's disease. The process is bilateral. Skin of finger is shiny. There is loss of substance in the terminal finger pads and superficial gangrene of multiple finger tips.

Mild vasospastic conditions of the hands and feet are relatively common, particularly in young people. The chief complaints are coldness and hyperhydrosis with occasional attacks of numbness and cyanosis. The symptoms are most severe in cold weather and when the patient is under particular emotional or nervous strain. Treatment entails abstinence from tobacco, avoidance of excessive chilling, attempts to lessen general emotional and nervous strain, and dressing warmly. Systemic autonomic blocking agents are useful. Under severe conditions, sympathetic denervation may be indicated; however, these conditions usually improve as the patient becomes older.

Erythromelalgia (Weir Mitchell's Disease). This disease, as originally described by Mitchell (42), is rare, but its manifestations are dramatic because of its contrast to the manifestations of many other circulatory disturbances. The patient complains of attacks of frequent, constant pain in the feet, particularly when they are held in the dependent position. Examination reveals swelling, redness, and hyperesthesia of the skin, which is usually warm, presumably because of a vasodilation. The disease is perhaps slightly more common among men than women. There is no known satisfactory treatment.

Acrocyanosis. The characteristic feature of this disease is a persistent, bluish-red discoloration of the fingers and hands. Occasionally, the feet are involved; coldness, cyanosis, and excessive sweating are common. The disease occurs most frequently in young women. It is aggravated by exposure to cold. The cyanosis tends to disappear when the extremity is elevated or warmed. Usually, protection from cold is the only treatment indicated. Sympathectomy may be considered in severe cases. *Livedo reticularis* affects both sexes in all age groups. It is characterized by a prominent, reticular, reddish-blue discoloration of the skin of the extremities. *Most frequently, the feet and legs are involved.* Although the discoloration is persistent, it is aggravated by cold. The condition is associated with a narrowing, either organic or spastic, of the local arterioles with dilatation of the capillaries and venules. Ulceration of the skin may occur in affected areas. In the mild case, no treatment is indicated other than protection from cold. More severe

cases, particularly if ulceration is present, may be treated by sympathectomy. Satisfactory results from operation may usually be anticipated.

Arterial Aneurysms. Rupture of *aneurysms of the cerebral vessels* is one of the common causes of subarachnoid hemorrhage. Improved methods of diagnosis by cerebral angiography and treatment by direct surgical attack with closure of the neck of the sac or involved vessel have been developed in recent years. The majority of these aneurysms are thought to be congenital in origin, although they do not produce symptoms until adult life. Mycotic and arteriosclerotic aneurysms of the vessels also occur.

Peripheral arterial aneurysms may be classified as 1. true aneurysms and 2. false aneurysms. False aneurysms have been discussed in a preceding section; they usually result from direct trauma to an artery. Infection and necrosis of the vessel wall from an infected embolus or infection in the vasovasorum may cause rupture of the vessel and the formation of a false aneurysm. A vascular lesion produced in this manner is called a *mycotic aneurysm*. A similar process may occur from an abscess outside the vessel which causes necrosis and disruption of the arterial wall. The aneurysmal sac in these conditions is formed from fibrous tissue which develops about the hematoma surrounding the point of rupture.

The aneurysmal sac of the *true aneurysm* is formed by tissue of the vessel wall itself which has become dilated and expanded. Aneurysms may be called *fusiform* or *saccular* depending upon their shape and their relation to the vessel from which they originate. An aneurysm is considered fusiform when the entire circumference is weakened, thereby allowing a more or less symmetrical dilatation. A saccular aneurysm projects from the artery as a globular mass because of a localized weakness in the vessel wall at one point.

One of the most common aneurysms seen today is a fusiform aneurysm arising in an arteriosclerotic area of the distal aorta. This condition is discussed in Chapter 38. Local pain, swelling, or pulsation may be the first symptoms of an aneurysm; the mass may increase in size slowly or rapidly. Pain at the

Fig. 10. Syphilitic aneurysm of the left popliteal artery. The patient is a Negro, aged 40, who contracted syphilis at the age of 17. The mass, accompanied by pain in the thigh and popliteal region, was noted only during the past six months.

site of the aneurysm or along the course of an adjacent nerve is experienced because of pressure of the mass. The pain is more severe if bone is being eroded. The involved extremity may become cold and pale and, on rare occasions, gangrene may develop. Rupture of the vascular mass with serious or fatal hemorrhage may occur (Fig. 10).

One of the most diagnostic features of aneurysm is the presence of expansile pulsation as detected by careful palpation or by fluoroscopy. This must not be confused with transmitted pulsation, which is noted frequently when solid tumors lie against large arteries.

Treatment. Occasionally, spontaneous cure may occur in saccular aneurysms by thrombosis. This occurred in eight of 119 cases reported by Shumacker (43). Fusiform aneurysms (of such arteries such as the femoral or popliteal), when of sufficient size to produce symptoms, or when there is evidence of rapid enlargement, may be treated by excision and grafting, usually with an autogenous vein graft. In cases of saccular aneurysm, the defect in the wall of the parent vessel may be closed by direct suture. In smaller vessels, such as the anterior tibial or radial,

the vessel may be ligated proximally and distally, and the lesion excised.

VENOUS SYSTEM

Diseases of the veins occur as the result of one or a combination of three basic derangements: valvular incompetency, venous thrombosis, and/or venous insufficiency. Venous disease in the lower extremities is one of the most common ailments suffered by man, and its treatment frequently is inadequate or even detrimentally unsatisfactory because of a failure on the part of the physician to understand the nature of the disease and the mechanisms whereby symptoms are produced.

Anatomy and Physiology. It is important first to understand the basic anatomy and physiology of the venous system of the lower extremities. Of the blood reaching the lower extremities, 85 to 90 per cent is returned to the heart via the deep venous system. The popliteal vein receives tributaries from the deep veins of the leg, becomes the superficial femoral vein in the thigh, and is joined by the deep femoral or profunda femoris vein which drains the muscles of the thigh to become the common femoral vein at the groin. All these veins are normally supplied with valves which, working in conjunction with the constrictive action of the muscles in the lower extremity in ambulation; force the venous blood up the extremity toward the heart. Heart action, per se, contributes nothing to the *mechanism of venous return of blood* from the extremity.

The superficial venous system of the lower extremity, the saphenous system, drains blood from the skin and subcutaneous tissue. It is comprised of the long saphenous system, which drains the superficial tissues of the medial and posterior aspect of the leg and thigh and empties into the common femoral vein at the groin, and the short saphenous system, which drains the superficial tissues of the lateral aspect of the leg and drains into the popliteal vein in the upper portion of the popliteal space. Both systems are normally supplied with valves, and valved, communicating veins join the superficial and deep systems of veins in the lower extremity, normally permitting blood to pass in one direction from superficial to deep system. It should be remembered that, as long as the deep system of veins in the lower extremity is relatively sufficient in its state of patency, the main trunks of the superficial system can be obliterated without evidence that any significant venous insufficiency, superficial or deep, is thereby imposed.

Varicose Veins. The most common venous disease of the lower extremities is varicose veins, manifested by both dilatation and elongation of the veins of the saphenous system (Fig. 11). It is of importance to remember that superficial varicose veins may be primary, i.e., exist in the presence of a normal deep venous circulation, or secondary to deep venous disease. Distinction between primary and secondary varicose veins is sometimes difficult but is of importance in determining proper treatment of the disease. Nevertheless, both primary and secondary varicose veins occur as the result of valvular incompetency in the affected veins.

VALVULAR INCOMPETENCY. The valves in the peripheral veins are extremely delicate,

Fig. 11. Tortuous varicose veins of the legs. Marked varicosities involving tributaries of greater saphenous system bilaterally.

cases, particularly if ulceration is present, may be treated by sympathectomy. Satisfactory results from operation may usually be anticipated.

Arterial Aneurysms. Rupture of *aneurysms of the cerebral vessels* is one of the common causes of subarachnoid hemorrhage. Improved methods of diagnosis by cerebral angiography and treatment by direct surgical attack with closure of the neck of the sac or involved vessel have been developed in recent years. The majority of these aneurysms are thought to be congenital in origin, although they do not produce symptoms until adult life. Mycotic and arteriosclerotic aneurysms of the vessels also occur.

Peripheral arterial aneurysms may be classified as 1. true aneurysms and 2. false aneurysms. False aneurysms have been discussed in a preceding section; they usually result from direct trauma to an artery. Infection and necrosis of the vessel wall from an infected embolus or infection in the vasovasorum may cause rupture of the vessel and the formation of a false aneurysm. A vascular lesion produced in this manner is called a *mycotic aneurysm.* A similar process may occur from an abscess outside the vessel which causes necrosis and disruption of the arterial wall. The aneurysmal sac in these conditions is formed from fibrous tissue which develops about the hematoma surrounding the point of rupture.

The aneurysmal sac of the *true aneurysm* is formed by tissue of the vessel wall itself which has become dilated and expanded. Aneurysms may be called *fusiform* or *saccular* depending upon their shape and their relation to the vessel from which they originate. An aneurysm is considered fusiform when the entire circumference is weakened, thereby allowing a more or less symmetrical dilatation. A saccular aneurysm projects from the artery as a globular mass because of a localized weakness in the vessel wall at one point.

One of the most common aneurysms seen today is a fusiform aneurysm arising in an arteriosclerotic area of the distal aorta. This condition is discussed in Chapter 38. Local pain, swelling, or pulsation may be the first symptoms of an aneurysm; the mass may increase in size slowly or rapidly. Pain at the site of the aneurysm or along the course of an adjacent nerve is experienced because of pressure of the mass. The pain is more severe if bone is being eroded. The involved extremity may become cold and pale and, on rare occasions, gangrene may develop. Rupture of the vascular mass with serious or fatal hemorrhage may occur (Fig. 10).

Fig. 10. Syphilitic aneurysm of the left popliteal artery. The patient is a Negro, aged 40, who contracted syphilis at the age of 17. The mass, accompanied by pain in the thigh and popliteal region, was noted only during the past six months.

One of the most diagnostic features of aneurysm is the presence of expansile pulsation as detected by careful palpation or by fluoroscopy. This must not be confused with transmitted pulsation, which is noted frequently when solid tumors lie against large arteries.

TREATMENT. Occasionally, spontaneous cure may occur in saccular aneurysms by thrombosis. This occurred in eight of 119 cases reported by Shumacker (43). Fusiform aneurysms (of such arteries such as the femoral or popliteal), when of sufficient size to produce symptoms, or when there is evidence of rapid enlargement, may be treated by excision and grafting, usually with an autogenous vein graft. In cases of saccular aneurysm, the defect in the wall of the parent vessel may be closed by direct suture. In smaller vessels, such as the anterior tibial or radial,

the deep venous system is uninvolved and remains satisfactorily functional even when the main trunks of the saphenous systems are removed.

SYMPTOMS. The symptoms of primary, uncomplicated varicose veins are usually minimal. The patient complains at first only of their appearance. Such a complaint in the female patient may be very significant and may demand careful, considered, therapeutic effort. As the condition progresses, the patient may note a heaviness in the legs especially along the course of the varicosities, sometimes a burning of the skin over the veins, a vague aching and tired feeling in the legs, occasionally some puffiness in the feet or ankles, and, at times, premenstrual soreness in the involved veins. Neglected varicose veins may give rise occasionally to a small localized rupture through the skin and frightening but rarely serious hemorrhage, thrombosis and thrombophlebitis of a varicosed vein segment, and, as a very late manifestation, stasis dermatitis and/or stasis ulceration on the skin of the leg in the region of the medial malleolus and on the skin of the lower medial aspect of the leg above the malleolus.

Probably because varicose veins are obvious at a glance, it is common for both the patient and physician to ascribe various symptoms, arising from some unrelated condition, to the varicosities. A word as to some of the symptoms which varicose veins *do not* produce is consequently indicated and has been well summarized by Dr. Geza de Takats (44):

> Greatest caution must be exerted, however, in interpreting a variety of symptoms as being connected with the presence of varicosities. From flatfoot to arthritis of the small joints and ankles, from muscle hernias to arthritis or internal derangement of the knee joint, from chronic inguinal lymphadenitis to arthritis of the spine, slipped disc and spondylolisthesis, from saphenous neuritis caused by a thrombophlebitis exudate in the femoral sheath to an alcoholic polyneuritis, a multitude of conditions should be thought of and excluded before one can attribute the patient's complaints to obvious varicosities.
>
> Varicose veins unless they are visibly inflamed do not hurt day and night; they do not cause cramping on walking unless arterial insufficiency supervenes. They do not produce sciatic type of pain on raising the leg; they do not manifest themselves by shooting radiation along the lateral cutaneous nerve and they do not cause absence of ankle jerks in diabetics. All this is stressed to indicate the necessity of a thorough examination and a proper interpretation of the patient's symptoms. The number of patients with vein ligations and stripping procedures whose symptoms continue or are aggravated by insufficient indication for surgery is considerable.

The major sign of primary varicose veins is essentially the presence on inspection of tortuous, dilated cords of veins occurring along the course of the involved system. The long saphenous system is usually involved alone. Involvement of the short saphenous system alone is rarely seen; it rather tends to occur as an added factor in more severe involvement of the long system. In long-standing varicosities, there may be brownish pigmentation over the malleolar and lower medial aspects of the legs.

DIAGNOSTIC AIDS. In the past, much attention has been given to various tests to determine the functional status and source of filling of varicose veins. Thus, in the *Trendelenburg test* (Fig. 13), the veins are emptied by elevating the extremity, applying a rubber tourniquet high on the thigh, and observing the degree of filling which occurs when the patient stands. If no filling or very slow filling results, the perforating veins between the superficial and deep systems can be considered competent. If the varices fill with the tourniquet in place, the perforating veins are incompetent and, if engorgement occurs, the deep system is probably insufficient. Competency of the perforating veins can also be tested by the *Perthes test*. The tourniquet is applied with the veins full and the patient standing. The patient raises up on his toes several times, and the varicosities are then observed for emptying, which should occur in the presence of competent, perforating veins to the deep system.

From a practical viewpoint, these tests are of most importance in aiding a critical evaluation of the status of the deep venous system. An array of elaborate tests involving radioactive solutions, x-ray venograms, and manometric determinations are available. Such tests are expensive, sometimes misleading,

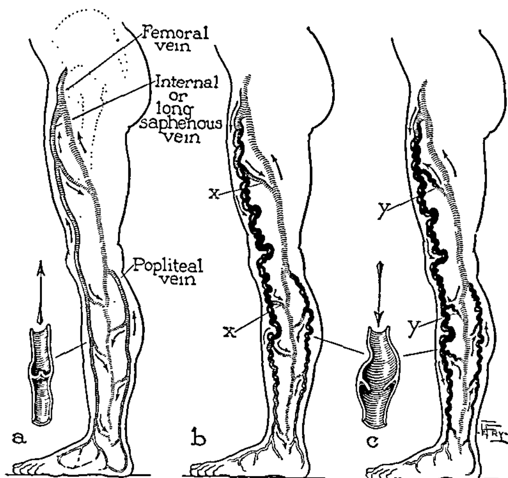

Fig. 12. a, diagrammatic drawing showing the relative relationship of the deep to the superficial veins of the lower extremities. As shown by the arrows, the direction of blood flow in the superficial and deep veins is upward, whereas the direction of blood flow in the communicating veins is from the superficial to the deep veins. This is possible because of competent valves in the deep, superficial and communicating veins. b, diagrammatic drawing showing varicosities of the superficial veins with incompetency of the valves in these veins. There is a reversal of blood flow in the superficial veins, i.e., from above downward. Because, however, the valves in the communicating veins (X) are still competent, the direction of blood flow is normal, i.e., from the superficial to the deep veins. c, diagrammatic drawing showing varicosities of the superficial and communicating veins with reversal of blood flow in both sets of veins. Because of incompetency of the valves in the communicating veins, as shown in Y, the direction of the blood flow is from the deep to the superficial veins instead of from the superficial to the deep as normally occurs. (From Ochsner. Lewis-Walters, Practice of Surgery, W. F. Prior.)

thin, fragile, precision-fitted, bicuspid structures. Once adult growth is reached, there is no evidence that these valves are capable of further growth. Any condition which leads to an increase in venous diameter in the region of a valve will result in leakage in the valve so that a vicious circle is set up and the condition becomes progressive. When a given valve becomes incompetent, increased pressure is placed on the next valve below so that its competency is jeopardized. The result is progressive dilatation of the entire venous system, thus producing *varicose veins* (Fig. 12). Only the long and short saphenous systems are significantly involved in this disease. Undoubtedly the most common etiologic factor is repeated pregnancy; in the last trimester, venous hypertension and dilatation in the extremities is apt to develop because of the intrapelvic growth of the fetus. Occupations which require prolonged standing and walking also foster development of this condition. There is some indication that persons of the thin, aesthetic, "loose-tissued" build are also more prone to develop varicosities than others. It is, under the circumstances, enumerated above that *primary varicose veins* are produced. In this instance,

such secondary varicosities may be indicated for various reasons, but it should be undertaken only with the full realization that further venous insufficiency and, hence, enhanced leg swelling may be imposed.

TREATMENT. The preferred treatment for saphenous varicose veins consists basically of vein ligation and stripping. Subsequent injection of sclerosing agents into residual, varicosed tributaries or even their secondary surgical interruption may be necessary. The use of the procedures of high saphenous ligation alone, ligation plus distal injection of sclerosing agents, or multiple ligations has not shown a satisfactory incidence of long-term improvement. On the other hand, the application of long saphenous vein ligation and stripping to the average case of long saphenous varicosities can be expected to result in a highly satisfactory, relatively permanent improvement both in symptoms and appearance.

The object of vein ligation and stripping is not only to interrupt the saphenous vein at the junction with the common femoral vein but also to remove the entire saphenous trunk from groin to ankle, thereby disconnecting not only the major tributaries from a source of engorgement but also obliterating the communicating veins between the superficial and deep systems. This latter objective is accomplished by removal of the trunk, since the bulk of the communicating veins issue from the main saphenous trunk. The operation can be performed quickly and with great facility by using a Zollinger-type (45) vein stripper. This instrument consists of a long flexible cable with a threaded end to which tips of various sizes may be attached.

At operation, the distal end of the long saphenous vein is exposed at its constant position anterior to and just above the medial malleolus. The vein is isolated and divided. The distal end is ligated, and the stripping cable with the thinnest tip attached is inserted into the proximal end of the vein and threaded up the entire length of the extremity to where the tip can be palpated in the saphenous vein at the saphenofemoral junction just below the groin crease. The saphenous vein is then exposed at this level and divided. The proximal end is traced to the saphenofemoral junction, dividing and ligating all tributaries which are encountered. The tip of the stripping cable is then delivered through the distal end of the saphenous vein at the thigh. The thin tip is exchanged for a large one and the vein is securely ligated about the stripping cable. A traction handle is then attached to the other end of the cable at the ankle, and the cable is withdrawn. The saphenous trunk telescopes on the cable, and all communicating and tributary veins are disconnected by tearing them from the main trunk as it is removed. During the procedure, the extremity is maintained in an elevated position and pressure is applied along the stripping tract until clotting in the torn tributory veins has occurred. Pressure bandages are applied, and the patient is ambulated beginning with the day of operation.

Secondary ligations and occasional injections may be necessary, but frequently complete relief is obtained by the single procedure. If the short saphenous system is involved, it can be similarly treated by removal of the short saphenous trunk from the external malleolus to the saphenopopliteal junction.

Venous Thrombosis. The occurrence of spontaneous clotting of blood in the veins of the lower extremity is much more common than is generally realized. Thrombosis is most apt to occur in the deep system of veins but can be encountered in the superficial system as well. The pathological manifestations which ensue produce signs and symptoms which are often confusing and are frequently misinterpreted. The factors which lead to deep venous thrombosis are not always apparent. However, any situation which results in relative stasis of blood flow in the deep veins of the legs, a change in the intimal lining of the vein, or an alteration in the clotting mechanism of the blood can also result in deep venous thrombosis. Consequently, the condition is commonly seen in trauma, especially that which involves fractures of the lower extremities, cardiac disease, the postoperative or postpartum period, certain blood dyscrasias, and possibly in patients suffering from certain carcinomas.

SYMPTOMS. Once thrombosis occurs in the deep venous system, a highly variable array of signs and symptoms may ensue. If the

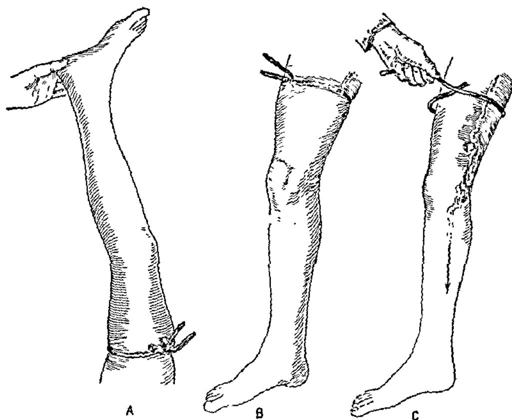

Fig. 13. Principles in the performance of the Trendelenburg test. A, with the patient lying supine and the extremity elevated, the blood is forced out of the veins by stroking the leg from above downward; a tourniquet is then applied, but only tight enough to constrict the superficial veins and not the femoral. It is easier to determine the correct amount of pressure by holding the ends of the tourniquet in the hands. B, negative *constriction test:* the patient was asked to stand and the rapidity of filling of the saphenous system noted. In this case these veins did not fill during thirty seconds observation: the test is therefore negative. C, positive *release test;* the tourniquet is released and the fall of the blood column in the saphenous vein observed. In this case the column fell immediately; the test is therefore positive. If the saphenous system is already filled before the tourniquet is released, it must be emptied by again placing the patient on the table. For interpretation of results see text.

and not without an incidence of morbidity. Rarely do they yield more information than can be obtained from a properly elicited history and carefully performed physical examination.

As will be indicated in more detail below, disease of the deep venous system usually begins as the result of deep venous thrombosis. Although subsequently the patient may become asymptomatic, there will usually be an elicitable history of an episode of pain and swelling in one or both lower extremities. The swelling in the extremity may persist as a chronic complaint. Over the course of time, superficial varicose veins are apt to develop in an attempt on the part of the system to improve venous return from the extremity by collateral circulation. For the most part, increased flow in collateral veins can only be obtained by dilatation of the vein, which promptly results in valvular incompetency and progressive varicose veins. Such a patient may well seek treatment because of the varicose veins or more often he will seek surgical treatment for chronic edema of the lower extremities. Both the patient and the referring doctor will often believe the latter to be the result of varicose veins rather than of a long-past episode of deep venous thrombosis which had resulted in deep venous insufficiency from which, in turn, was produced both the chronic leg edema and the secondary saphenous varicose veins. A diagnosis of *secondary varicose veins* can be strongly suspected on the basis of a history suggestive of a previous episode of deep venous thrombosis and a presenting complaint of leg swelling plus varicosities. Surgical treatment of

mechanism whereby blood clots. Furthermore, heparin is almost instantly effective. In addition, an antidote, protamine sulfate, is available which neutralizes the effect of heparin in minutes. In venous thrombosis, when heparin therapy is begun promptly in adequate dosage and over a sufficient length of time, the therapeutic result is usually quite dramatic, effective, and adequate. Because heparin is expensive and must be administered parenterally, there has been a tendency to use it in small amounts and for short periods of time and to rely basically on the cumarin drugs, such as dicumerol (47), to produce an anticoagulative effect. Unfortunately, the cumarin drugs act at only one point in the clotting reaction; namely, they depress prothrombin production by the liver. Consequently, the action is anticoagulative only to a limited degree and is reliably effective only if the prothrombin level is suppressed below 30 per cent of normal. A prothrombin level below 10 to 15 per cent of normal is dangerous.

Neutralization of the curmarin effect is a time-consuming process. Hence, use of the cumarin drugs in the treatment of venous thrombosis is unreliable, dangerous, and basically effective only to a limited degree. On the other hand, these drugs, when used in the prophylaxis of venous thrombosis have a definite place and value.

With the advent of anticoagulants, surgical therapy of acute deep venous thrombosis has been neglected. Nevertheless, it has an undeniable place in the treatment of this condition (48, 49). If a sublethal pulmonary embolus has occurred in a patient with venous thrombosis, the only reliable protection from further, possibly lethal, emboli is surgical interruption of the vein which is the source of the embolism at a level above the site of the primary venous thrombosis. This closes the route whereby the offending clot can reach the pulmonary circulation. The use of heparin still remains the basic therapy for this condition, but it should be remembered that venous interruption may be combined with heparin therapy with only a momentary, incomplete interruption in the latter while surgery is performed. Furthermore, it is to be remembered that there is no evidence that interruption of a vein involved with venous thrombosis will significantly affect the status of venous sufficiency or valvular competency later manifested by the venous tree involved. There is, indeed, some indication that vein interruption has a beneficial effect on the subsequent subsidence of acute deep venous thrombosis.

Postphlebitic Complications. Once the acute manifestations of deep venous thrombosis have subsided, the venous circulatory status of the afflicted extremity gradually enters a chronic state which, within a few weeks, may leave no detectable residual or may show certain permanent chronic manifestations of a very serious nature. Such an extremity is known as a postphlebitic extremity. The disease which such an extremity will manifest depends on several factors. On the one hand, if an episode of deep venous thrombosis is detected early, when involvement is limited to the veins of the calf, and the disease is treated vigorously and adequately with heparin, even the long-term residual manifestations, in the absence of further episodes of thrombosis, may be minimal or lacking. On the other hand, an extremity in which clotting in the entire deep venous system has occurred is apt to handicap the patient for the remainder of his life.

The reparative processes which occur are remarkable, but frequently inadequate. Veins in which thrombosis has occurred tend to recannalize. Nevertheless, their valves are permanently destroyed and the total effective drainage which can be restored through such a vein by recannalization is very limited. There is a remarkable tendency for collateral venous drainage to develop, but this too is limited; and, since circulation through collateral veins can be increased only by the occurrence of dilatation of these veins, their valves are automatically made incompetent. Consequently, such an involved extremity enters into a permanent condition of venous valvular incompetency and venous insufficiency. Neither of these conditions will result in very significant symptoms as long as the involved extremity is maintained at the same hydrostatic level as the heart; i.e., as long as the patient remains in a horizontal position, his extremity will manifest no significant detectable signs or symptoms. However, once the upright position is assumed, the

formation of the clot is slow and does not irritate the wall of the vein, a condition referred to as *phlebothrombosis* occurs. In this situation, the clot is soft, loosely adherent to the vein wall, and prone to break loose and travel into the lungs, resulting in *pulmonary embolism* and *pulmonary infarction*. Thus, the first inkling of deep venous thrombosis that the patient may manifest is sudden death from massive pulmonary embolism. More commonly, the patient may complain of chest pain which is relatively sudden in onset and usually severe. Hemoptysis may then occur. Chest x-rays taken 24 hours or more after an embolus has lodged in the lung may show findings consistent with a diagnosis of pulmonary infarction. Repeated pulmonary infarctions may occur in the complete abscence of detectable signs or symptoms in the involved extremity. The earliest detectable manifestation of so-called *bland phlebothrombosis* in the extremity may be a slight swelling of the foot and ankle, a relative dilatation of the superficial veins of the foot and ankle, a relative warmth of the foot and leg, mild cyanosis, minimal calf muscle tenderness, or a combination of some or all of these signs. The patient may have no complaints or may note muscle soreness in the calf on ambulation.

It should be remembered that signs and symptoms in the extremity occur in direct relation to the amount of reaction to the clot which occurs in the wall of the vein and perivenous tissues. In the instance discussed above, where the reaction to the clot is minimal, signs and symptoms may be absent or minimal, but the risk of pulmonary embolus is very great. This condition has been designated as bland phlebothrombosis. The local reaction to the venous clot is bland, but the distant lethal potential is very much the opposite.

In other instances, the thrombosis in the entire deep venous system seems to occur with great rapidity. The clot suddenly occludes the entire main deep venous trunk. The clot is firm and sticky. It tends to adhere and, at the same time, irritate the vein wall. The result is a combination of the effects of sudden, massive, deep venous occlusion and a massive, sterile inflammatory reaction in the entire deep venous system. It is this type of reaction which is recognized as *thrombophlebitis*. The extreme of this situation is known as *phlegmesia alba dolens*, the classical example of which is the so-called milk-leg of pregnancy. In this condition, the onset is relatively sudden. The involved extremity from toes to groin becomes swollen, painful, cold, and blanched. In these cases, pulmonary emboli are rare, since the clot is tightly adherent to the vein wall. Early in the course of the disease, the inflammatory irritation results in vasospasm which involves the arterial tree. Hence, the extremity is cold and pale. Frequently, no popliteal or pedal pulses are initially palpable. As the disease progresses, the sterile inflammatory reaction becomes more manifest: the extremity becomes warm and erythematous, dilatation in the superficial veins appears, and the patient runs a febrile course. For this inflammatory reaction, it is a common practice to administer antibiotics. Since no infectious agent, especially no bacterial infectious agent can be demonstrated, the use of antibiotics has no value whatsoever and, indeed, is contraindicated.

In the past, the two extremes in the manifestations of venous thrombosis mentioned above, i.e., bland phlebothrombosis and thrombophlebitis, have been designated as separate entities. Actually, depending upon the extent of the clotting phenomenon and the amount of sterile inflammatory reaction incited thereto, this condition may manifest itself in any possible combination of the two extremes.

Indeed, in a given case, bland phlebothrombosis may be seen to progress on an acute or chronic basis to a fulminating thrombophlebitis. Furthermore, an acute thrombophlebitis may gradually subside down the scale of local severity to a bland phlebothrombosis and somewhere along the course may discharge one or more pulmonary emboli.

TREATMENT. The basis of treatment for deep venous thrombosis in any form consists of administration of an anticoagulant. The only truly effective anticoagulant available is *heparin* (46). By its action, heparin is effective in blocking the blood clotting mechanism at every one of the numerous reactions which are involved in the complex chemical

ulcer. Here, excision and grafting or simply grafting the ulcer may occasionally be indicated to hasten healing. Frequently there are numerous varicosed veins which seem to "feed" the ulcer. Radical elimination of all superficial veins in the area proximal to the ulcerated area, after healing has first been obtained, will be helpful in the later management of the extremity in avoiding recurrent ulceration (50). The place of ligation of any segment of the deep venous system to eliminate the effects of valvular incompetency is highly dubious, even though recommended by some. Frequently the vein in question is already a fibrosed cord. If the vein to be ligated is patent then, at the very best, by ligation one is trading some theoretical prevention of the effects of valvular incompetency for a superimposed degree of increased venous insufficiency. So far, no satisfactory or reliable surgical method of correcting deep venous insufficiency and valvular incompetency has been devised. Consequently, all efforts at the treatment of the postphlebitic extremity are palliative at best. It is important that these efforts follow rational physiological principles.

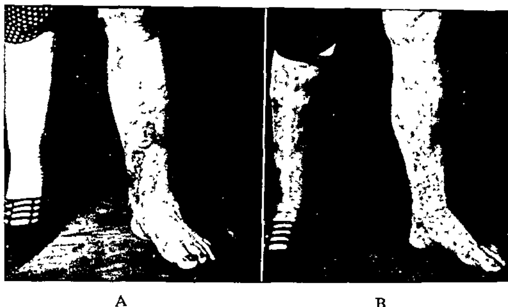

Fig. 14. Varicose ulcers of the leg. A, ulcers due to varicosity are usually single, not multiple. B, appearance of leg several months later, after obliteration of the veins by injection of a sclerosing agent. Note that the ulcer has healed and that the varicosities are obliterated. (Washington University Clinic.)

effect of gravity becomes apparent. Untreated, the extremity will manifest chronic edema, at least from toes to knee, and frequently of the thigh as well. Dilated secondary varicose veins will gradually appear, and over the course of time a brown pigmentation in and around the lower leg will be seen which is usually most marked on the medial aspect of the lower third of the leg, including the malleolus. The pigmentation is frequently circumferential in the region. The skin becomes thickened and edematous. It may undergo episodes of inflammation known as *stasis dermatitis,* and finally indolent ulceration of the skin in the region occurs. Such ulceration is referred to as *stasis* or *stasic ulceration* (Fig. 14). As long as the patient spends any significant time on his feet each day, such ulcerations will not heal and will tend to enlarge. They will be refractive to *any* treatment which permits continued daily ambulation. The imposition of bed rest, elevation of the extremity and the simplest of local cleansing measures will invariably result in slow, but definite healing of such an ulcer by secondary intention. Nevertheless, as soon as the patient again assumes the upright posture the swelling and ulceration will recur.

Prevention of this recurrent ulceration and swelling in the postphlebitic extremity is extremely difficult and usually possible only if certain handicaps are imposed upon the patient. Numerous operations and therapeutic regimens have been reported, but none are really satisfactorily effective. The best that can be offered such a patient is a plan of palliative management which consists of three main modalities: 1. application of external elastic support; 2. counteracting the effects of gravity; and 3. extirpation and ligation of superficial veins in the region of the skin area which is ulcerating.

Using external elastic support means wearing properly fitted elastic stockings whenever the patient is ambulatory. Counteracting the effects of gravity means that the patient must interrupt his activities during the day for at least three or four 15- to 20-minute periods; during this time he should lie down with the extremity elevated higher than the level of the heart. In addition, the foot of his bed should be elevated four to six inches. Furthermore, it may be necessary for the patient to change his work so that prolonged standing and walking can be avoided.

Numerous operations have been described for the management of this syndrome but it should be realized at the outset that there is no known operation that will alleviate postphlebitic leg edema. Surgery is of occasional value only in the management of chronic leg

ulcer. Here, excision and grafting or simply grafting the ulcer may occasionally be indicated *to hasten healing. Frequently there are* numerous varicosed veins which seem to "feed" the ulcer. Radical elimination of all superficial veins in the area proximal to the ulcerated area, after healing has first been obtained, will be helpful in the later management of the extremity in avoiding recurrent ulceration (50). The place of ligation of any segment of the deep venous system to eliminate the effects of valvular incompetency is highly dubious, even though recommended by some. Frequently the vein in question is already a fibrosed cord. If the vein to be ligated is patent then, at the very best, by ligation one is trading some theoretical prevention of the effects of valvular incompetency for a superimposed degree of increased venous insufficiency. So far, no satisfactory or reliable surgical method of correcting deep venous insufficiency and valvular incompetency has been devised. Consequently, all efforts at the treatment of the postphlebitic extremity are palliative at best. It is important that these efforts follow rational physiological principles.

THE LYMPHATIC SYSTEM

The tissue spaces between capillaries and cells are bathed by a fluid or lymph which is continuously collected by the lymphatic system and delivered into the veins of the neck. This system consists of channels called the lymphatics, which pass through a series of tiny lymph nodes located at various parts of the body (Fig. 1). The lymphatic system may be called part of the circulation inasmuch as much of the lymph originates from the blood stream as a cell-free filtrate across the capillary walls. However, the lymph also contains elements resulting from cellular activity and tissue metabolism. Analysis of normal lymph reveals one important difference from blood plasma, it contains much less protein, usually less than 1 per cent except when draining from areas of inflammation where the value may approach that of plasma. Nevertheless, it normally often contains enough fibrinogen to coagulate, although it does so much more slowly than blood. Its composition differs from the area of the body drained. For example, chyle is a milky mixture of emulsified fat and lymph which is found in the lymphatics draining the small intestines. Small lacteals in the villi of the intestine collect the emulsified fats from the intestines and conduct them to larger trunks in the mesentery. During starvation, however, this fluid will obviously contain but little fat. Chyle is of surgical importance as it escapes during injury from the thoracic duct or its tributaries into the peritoneal or pleural cavity.

Although lymph channels were described three centuries ago, our present knowledge has followed the investigations carried out during recent decades, particularly those of Florence Sabin (1) and Drinker (2). Lymphatic channels drain all tissues in the body except the brain, forming a number of re-

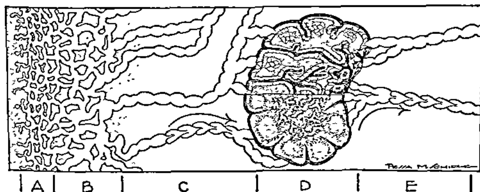

Fig. 1. The structural basis of the lymphatic system (semidiagrammatic). A, the irregular, blindly ending lymph capillaries. B, the reticular network. C, the afferent tubular lymphatics containing valves. D, the lymph node, presenting (above) the lymph sinuses and (below) the histologic picture. E, the efferent lymph vessels, showing above the arrow numerous valves. (From Curtis. Christopher, Textbook of Surgery, W. B. Saunders.)

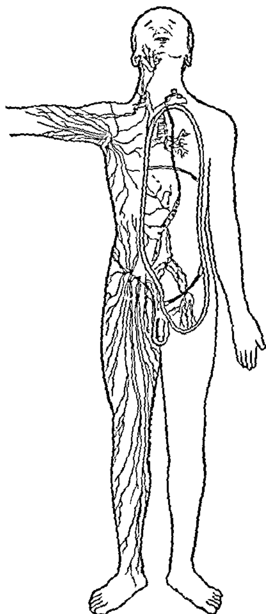

Fig. 2. Diagrammatic sketch of the lymphatics to show both deep and superficial systems as well as the main regional groups of lymph nodes. Note that the superficial lymphatics of the leg converge and enter the saphenous opening to join the deep lymphatics which then ascend along the iliac vessels to the thoracic duct.

gional networks, each passing through fixed groups of lymph nodes (Fig. 2). These nodes are composed of lymphocytic cells arranged along a labyrinth of channels, through which the lymph flows on its way centralward in gradually enlarging vessels, finally entering the thoracic duct which empties at the junction of the left jugular and left subclavian veins in the neck. A second, smaller duct drains into the right side and carries lymph only from the right upper extremity, right side of the neck, the heart, and the lungs. The lymphatics are thin endothelial lined channels equipped, as the veins, with valves.

The primary function of the lymphatic system is drainage of fluid from the tissue spaces. Especially significant in surgery is the drainage of fluid from areas of acute inflammation, and the transporting of bacteria and of cancer cells, thus playing an important part in the extension of infection and of cancer. The lymph nodes protect the body because they halt, for a time at least, further invasion. In the case of cancer, they act merely as a sieve, holding back the malignant cells for a while. With infection, however, their function is more useful; the cells lining the lymph spaces actively fight the invaders, and, indeed, in most cases succeed in killing them, thus protecting the rest of the body. In the process, the nodes always enlarge and sometimes soften and suppurate. The lymph vessels, although usually passive agents, are not infrequently involved in infections and become evident clinically by lymphangitis, lymphedema, and elephantiasis. The neoplastic diseases of lymphatic vessels and nodes are described in Chapter 20; the following discussion will therefore be confined largely to the inflammatory lesions.

THE LYMPHATIC VESSELS

Lymph flow from tissue spaces is always active but is slight in the resting limb. During acute inflammation it is often tremendous. Experimental studies by Field, Drinker, and White (3) have cast much light on lymph flow after immersion of the extremity in very hot water. Not only is the lymph pressure increased, but the protein content, normally under 1 per cent, rises to a value four times greater. The inability of the lymphatics to drain all of this exudate rapidly enough is probably responsible for the swelling in and even outside the actual field of inflammation (i.e., collateral edema) as discussed in more detail on page 597.

The lymphatics, like the veins, in the lower extremity at least, are composed of a deep and superficial group, separated by the deep fascia. Unlike the veins, lymphatics have no communicating channels through this barrier, although they do converge and join at

the saphenous opening below the inguinal ligament.

Trauma to Lymph Vessels. Such injury is probably frequent but is usually nonevident, for even if a large channel is cut, the lymph clots at once or the flow is so slow as to escape detection, especially if much bleeding is present. Detailed experimental studies by McMaster and Hudack (4), however, indicate that the tiny lymphatics severed by incisions remain open for as long as 48 hours and may absorb infectious material for this length of time. Later, however, they proliferate extensively into the inflammatory area (as described in a previous chapter) and play an important role in healing and repair. On rare occasions, clear fluid pours out of a wound profusely and for many days or weeks. Such an event is called *lymphorrhea* or *lymphorrhagia.* It is apt to be especially severe if the *thoracic duct* itself is torn as it enters the subclavian vein in injuries or operations in the left lower part of the neck. The escape of lymph into the pleural cavity or through the base of the neck (in the case of injury) may stop spontaneously; however, it usually requires such a long time that severe malnutrition may start before it ceases. Accordingly, operation is usually advisable to ligate the leaking lymph duct. Complete relief is afforded by ligation, and recurrence of leakage is uncommon. *Chylous ascites* is produced when the large lymph vessels of the mesenteries are injured, permitting their contents to escape into the peritoneal cavity.

After complete division of lymphatics to a limb, normal flow is soon restored as shown by the studies by Reichert (5). He found that regeneration of new channels is a rapid process, taking but a week in absence of infection.

Infection of Lymph Vessels. Even in severe infections the larger lymphatics usually play but a passive role in carrying exudate and occasionally bacteria from the inflammatory area. On some occasions, bacteria may gain access through a slight wound and be carried to the lymph node without provoking significant inflammation in either the skin or lymphatic channels. In such a case, the first defensive reaction takes place in the node.

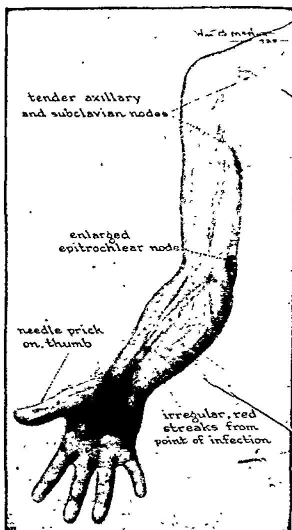

Fig. 3. Acute tubular lymphangitis. Streptococcus lymphangitis and lymphadenitis in a physician following a needle prick during an operation for appendiceal peritonitis. (From Babcock. Textbook of Surgery, W. B. Saunders.)

Acute Lymphangitis. Acute inflammation of the major lymphatics is called *acute tubular lymphangitis* (Fig. 3). It must be distinguished from the diffuse lymphangitis of the smaller channels. It is evident clinically as red streaks which extend up the arm or leg from the local portal of entry. It may be seen following relatively mild infections, and usually it is indicative of a serious invasion; it is frequently accompanied by the signs of systemic infection, i.e., chills, fever, and prostation. In such a case, the visable lymphatic vessels are intensely red, swollen, and often surrounded by an area of edema.

Tenderness is slight. Except in the severe or fatal cases, the process usually subsides in two to five days. However, the regional lymphadenitis, which so frequently follows lymphangitis, usually subsides more slowly. Occasionally the involved lymph nodes suppurate. Treatment of lymphangitis is strictly one of *noli me tangere* as far as operation is concerned; application of hot moist packs along the involved extremity will be helpful. The extremity, however, should be completely immobilized. Incision is used *only* if a local abscess forms along the course of the lymphatic; this rarely occurs. Chemotherapy has all but eliminated this formerly common condition.

Acute Diffuse (Reticular) Lymphangitis. This term is applied to a variety of infections. Its most specific and characteristic, though perhaps least common, form is a type involving the entire subcutaneous system of an extremity, which may occur in patients with lymphatic obstruction (lymphedema). Matas (6) has been influential in describing and emphasizing the importance of this type of lymphatic infection. It is ushered in by chills, fever, prostration, and a tender red swelling of the entire limb. A streptococcus has been found in many cases. After the infection has subsided completely, the swelling decreases, but a permanent enlargement persists due to the deposition of fibrous tissue and a continuing mild chronic lymphangitis (see below). Repeated attacks eventually lead to elephantiasis.

A more common type of reticular lymphangitis is that produced by a spreading infection which involves the smaller local lymphatic channels. Clinically, the redness, swelling, induration, and so forth, is differentiated with difficulty from acute cellulitis. Indeed, there undoubtedly is always a certain degree of diffuse reticular lymphangitis present in acute cellulitis. Entirely different is the reticular lymphangitis called erysipelas (see Ch. 7). Erysipeloid, however, is a mild type of reticular lymphangitis which occurs most commonly following injury to the skin of individuals who work with oysters or other types of sea food. Treatment is simple inasmuch as the infection usually subsides spontaneously, although chemotherapy is often helpful.

Another form of acute lymphangitis, still different, is the inflammation noted by Homans (7) around the iliac and femoral vessels in a patient with thrombophlebitis femoris, as already discussed (see Ch. 25).

Chronic Lymphangitis. Indolent, longstanding ulcers of the lower leg, often called stasis ulcers are usually associated with chronic lymphangitis. The skin surrounding the ulcer is thickened, inelastic, and discolored. These changes frequently precede ulceration. Occlusion of the cutaneous lymphatics has been demonstrated (8). The subcutaneous tissue is the site of edema and fibrosis which is believed to be due to chronic infection of the lymphatics through the open lesion. Chronic inflammatory changes about lymphatic vessels are occasionally due to the presence of a fungus (e.g., sporotrichosis) or of parasites (e.g., filaria) in the vessels. More commonly such changes are believed to be due to recurrent episodes of acute lymphangitis.

Chronic lymphangitis is seen, without obvious portals of entry for infection, in localized chronic swelling or enlargement, usually of the leg, often called lymphedema. Similarly chronic lymphangitis is also found with more pronounced swelling called elephantiasis. Histologically, there is primarily an extensive round cell infiltration of the finer subcutaneous lymphatic channels (Fig. 4). In addition, there may also be edema and fibrosis; the former, strictly speaking, is marked only in lymphedema, the latter only in elephantiasis. Unfortunately, microscopic study is possible only when the Kondoleon operation is performed and tissue is excised for examination. This is partly the reason, as indicated below, why there is confusion between lymphedema and elephantiasis. As might therefore be expected, the relation between chronic lymphangitis and its clinical manifestations are similarly difficult to establish.

Lymphedema. Lymphedema is a general term meaning a localized diffuse deposition of lymph in the skin and subcutaneous tissues, especially an extremity which is painless and which characteristically pits on pressure (Fig. 5). It occurs in a great variety of forms, acute and chronic. Acute lymphedema is common as an acute swelling, transient, usually associated with acute infections and

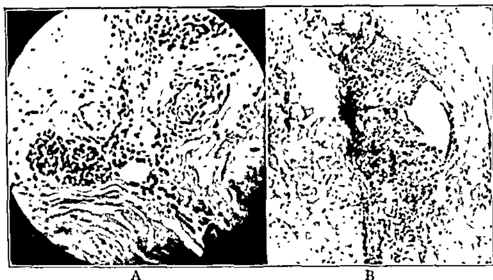

Fig. 4. Chronic lymphangitis. Photomicrographs from two cases of unilateral swelling of the leg in which the Kondoleon operation was done. A, note the round cell infiltration; only moderate fibrosis is present. The inflammation present in this case was not due to infection entering through ulcers of the leg for this patient had none. The onset of the swelling was insidious but there was a definite history of several attacks of acute infection (subcutaneous cellulitis) involving the entire affected leg; these attacks are characteristic of elephantiasis. B, note the dilated lymphatic vessel and extensive round cell infiltration; only moderate fibrosis was present. The inflammation in this case is probably similar in nature to that in A; there was a history of episodes suggesting acute infection of the subcutaneous tissues of the entire leg. The photograph of the leg is shown in Figure 8.

already described as collateral edema. Transient more or less acute lymphedema may also occur following insect bites and may be confusing if no history is obtainable and no wound discernible. The swelling, however, is apt to be somewhat harder and less apt to pit on pressure. This is also true of the lymphedema seen following thrombophlebitis femoris (see p. 587), in which the swelling also may only pit slightly on pressure, possibly because of the presence of lymphatic infection. Although the swelling in acute lymphedema is transient and of little clinical significance, it may, if extensive and acute enough, produce shock by dislocation of sufficient extracellular fluid into the swollen extremity.

Chronic lymphedema also occurs in a variety of forms (Fig. 6). The localized swelling is obviously different from the symmetri-

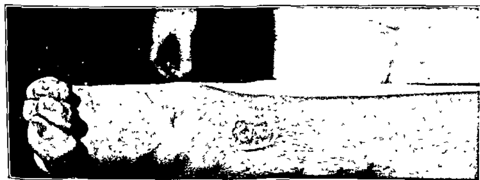

Fig. 5. Transient acute lymphedema secondary to a traumatic infected ulcer. The patient was a 37-year-old male. Note the pitting edema This swelling subsided promptly after several days of rest and elevation, and the ulcer healed. (St. Louis City Hospital.)

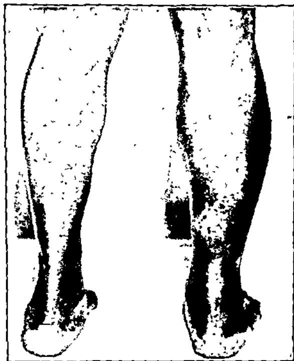

Fig. 6. Chronic lymphedema. The patient, a 59-year-old Negro, noted a gradually increasing swelling for one and a half years following a history suggestive of a venous thrombosis. Many months afterward the ulcers appeared, which are evident in the photograph although now almost healed following conservative care and elastic bandaging. The swelling pitted on pressure and decreased markedly on rest and elevation.

cal edema seen in cardiorenal disease and in hypoproteinemia, especially following the infusion of excessive salt solution (salt edema). Chronic lymphedema, to be discussed herein, is localized to one extremity or one part of the body and is due to regional lymphatic obstruction, to chronic lymphangitis, or more commonly to some unknown cause. There is a mysterious type of lymphedema which occurs commonly in young adults and represents a well-established clinical entity. When a hereditary factor is elicited, it is called Milroy's disease. In most cases, no history of trauma or hereditary tendency can be obtained and the term "lymphedema praecox" has been applied to them.

Injections of dyes and of radioopaque material for roentgenologic study into the lymphatics of the involved extremity show greatly dilated lymphatic channels and no evidence of obstruction (9). The swelling, usually confined to one leg or one arm, may subside completely on rest and elevation, the limb returning to its normal size. On ordinary use, however, the swelling recurs. Such an extremity is subject to infection of the lymphatics (reticular lymphangitis) which may lead to elephantiasis.

The group of chronic or persistent lymphedema shades off, as the disease becomes more severe, into elephantiasis. Indeed, there is considerable confusion in the use of the two terms. The term lymphedema should be confined to swellings which pit deeply on pressure and subside completely on rest and elevation. Chronic swelling, particularly when sufficiently advanced to be called elephantiasis, is probably due to chronic lymphangitis, as already indicated; diagnosis of this lesion depends, obviously, on microscopic section, particularly in patients with no history of infection and no ulcers or other obvious portals of entry for infection.

Treatment of acute lymphedema is often unnecessary, since the swelling subsides on removal of the cause. In chronic lymphedema, in the absence of a known etiology, effective therapy is difficult. Of greatest importance is the prophylaxis against recurrent infection which, as described above, will eventuate in elephantiasis. The factors which are conducive to recurrent infection are uncontrolled edema and trauma. The control of edema will also give symptomatic relief. This is best accomplished by the institution of a rigid regime consisting of the use of tightly fitting elastic bandages or stockings, applied only when the swelling has been relieved by an adequate period of rest and elevation. Usually, upon arising in the morning the swelling is gone, therefore the compression bandages are applied at this time. Scheduled periods of elevation during the day may be necessary and prolonged standing in one place is not allowed. Exercise in moderation is beneficial. The earliest symptom of an acute inflammatory episode is an indication for chemotherapy, rest, and elevation and immobilization of the extremity.

Elephantiasis. Elephantiasis is really different from lymphedema since the swelling is only partly due to edema, most of it consisting of actual hypertrophy of the skin and subcutaneous tissue because of fibrous tissue overgrowth. As the name implies, elephantiasis is a remarkable swelling or enlarge-

Fig. 7.

Fig. 8.

Fig. 7. Elephantiasis affecting both legs. The patient was a 50-year-old Negro. The swelling was insidious, without cause, beginning two years previously. It would diminish on rest and elevation, due presumably to a simple lymphedema of unknown etiology. The superficial ulceration noted in the photograph is of one year's duration and has been getting worse. The swelling now is brawny and hard, pits only slightly on pressure. After several weeks in bed the edema subsided to a moderate extent and the infection abated considerably.

Fig. 8. Elephantiasis affecting the left leg. The patient was a 14-year-old girl. The swelling was of insidious onset at the age of eight and became progressively worse, especially following mild attacks of a few days' duration, consisting of fever and redness, tenderness and pain in the leg. On admission the leg felt bulky on palpation and scarcely pitted on pressure. A Kondoleon operation was performed; a chronic lymphangitis was present in the excised tissue (see Fig. 4B). Although the patient was discharged with both limbs the same size, *the swelling recurred in the left leg and persisted (except for mild subsidence* during prolonged rest in bed). The case illustrates the difficulty in differentiating lymphedema from elephantiasis since it presents features characteristic of both.

ment which may affect an entire extremity, usually the leg (Figs. 7, 8), or in rare cases, the scrotum or vulva. Though more common in the tropics, it is seen everywhere, especially in *mild forms*.

The remarkable cases are usually seen only in the tropics. Though slight pitting edema is present, it disappears on rest and elevation, leaving a limb only slightly smaller than before, but indurated, somewhat pale and larger than its fellow. Occasionally, both legs are involved. Ulcers are present in some cases and, as already mentioned (Ch. 8), their indolence and lack of healing are no doubt due to the disturbance in lymph flow. Elephantiasis of the arm may follow radical breast amputation whenever the interruption of the lymphatics is associated with an infection; it has been designated by Halsted (10) as elephantiasis chirurgica (Fig. 9). The presence of fluid and fibrosis in the subcutaneous tissue can sometimes be differentiated by the study of soft tissue roentgenograms of the limb as pointed out by Reichert (11).

In the *pathogenesis* of elephantiasis, lymphatic obstruction plays a great role, but obstruction alone cannot explain the presence of the fibrous tissue overgrowth which is responsible for the greatest part of the enlargement. This is due, as pointed out by Matas (6) and also by Halsted, to a type of superimposed infection which is responsible for the deposition of fibrous tissue. In some patients, such infection (reticular lymphangitis) occurs in acute attacks with chills, fever, and prostration, the red swollen part finally subsiding and leaving an aftermath of diffuse fibrosis. It is after a history of many

Fig. 9. Elephantiasis chirurgica following removal of a fungating carcinoma of the breast six months previously. Note the tremendous swelling of the arm and hand. Usually, edema of the arm following radical excision of the breast is due to infection involving lymphatic vessels and veins. However, in this instance the condition is complicated by the enormous mass of recurrent carcinomatous tissue in the axilla. (Courtesy, Dr. J. W. Gale.)

such episodes that the limb finally attains a huge size. In other instances, the infection is more chronic, due, sometimes, to the presence of an indolent ulcer which acts as a permanent portal of entry, or occasionally to less evident infection. That lymphatic stasis by itself cannot cause elephantiasis is shown by the study of tropical elephantiasis in which filarial obstruction of the lymphatics has been erroneously assumed to be the sole causative factor. As pointed out by Matas, many patients infected with filaria do not have elephantiasis; conversely, in many patients with elephantiasis, no organisms can be found. Moreover, in those having elephantiasis with demonstrable filaria a history can often be obtained of recurrent acute attacks of the above-mentioned reticular lymphangitis from which a streptococcus has been isolated. Thus, it is clear that even in filarial elephantiasis it is necessary that infection as well as obstruction to the lymphatics occur before the disease is produced. Either alone will not lead to the disease.

Lymphatic infection and obstruction act together since the fibrosis which follows infection in itself obstructs a free lymphatic drainage. A vicious circle is thus doubtlessly established. Lymphedema is the primary event; secondary infection leads to fibrosis which interferes with lymph flow. This, in turn, leads to lymphedema which most likely renders the part less able to resist further infection. Such a conception of the dual role of lymphatic infection and obstruction is confirmed by the striking experiments of Drinker, Field, and Homans (12) who have produced lymphedema and elephantiasis in dogs by inducing lymphatic obstruction of the extremity which, in the successful experiments, was accompanied or induced by infection, streptococcal in nature. Typical fibrous tissue overgrowth was noted.

Treatment. Therapy based on the dual pathogenesis mentioned above is often quite efficient. Infection is first guarded against by avoiding injuries of any kind. Infection which may already be present, i.e., ulcers and indolent wounds, are treated by elevation, rest, hyperemia, and chemotherapy. Large ulcers may require excision and skin grafting. The progress of the disease may sometimes be halted in this way by closing the portals of entry for chronic infection in spite of the existence of a certain amount of lymph stasis. For those patients in whom recurrent infection occurs despite prophylactic measures, for intractable persistent or recurrent leg ulcers, and for the massive fixed enlargement, surgical treatment is indicated. The operative treatment of elephantiasis was at first directed toward efforts to provide new lymphatics to replace those which were obstructed or to by-pass the obstruction by creating anastamotic channels between the deep and superficial systems. The procedure described by Kondoleon in 1912, consisting of the excision of strips of skin, subcutaneous tissue, and deep fascia from the lateral and medial side of the extremity was based on the latter and has had the greatest clinical trial. It is now believed that the good results claimed for this operation are due to the prolonged period of bed rest and to the reduction in size achieved by the excision of tissue mass, rather than to effective improvement in lymphatic drainage. The many modifications of this procedure which have been de-

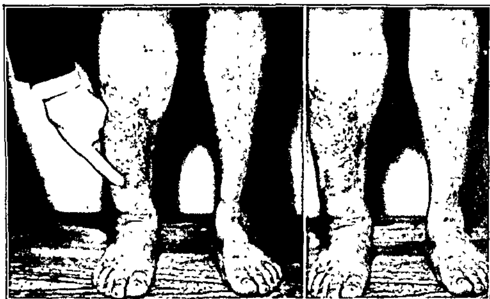

Fig. 10. Lymphangiectasis. The photographs were taken a few seconds apart. Note the compressibility of the swelling which is not due to a pitting edema; release of pressure as shown on the right results in an immediate return of the compressed point to normal. A portion of tissue which was removed showed dilated lymph channels as well as areas resembling hemangioma.

scribed have consisted of increasing the volume of excised scarred hypertrophied, edematous skin and subcutaneous tissue. Currently, good results have been obtained by the complete excision of skin, subcutaneous tissue, and deep fascia and covering denuded muscle with split thickness skin grafts obtained from the excised skin (13, 14). This procedure is done in one stage, using a pneumatic tourniquet to reduce blood loss during the excision. Operation is always preceded by a period of several weeks during which chemotherapy is administered and the limb is elevated and kept at rest to diminish infection and lymph stasis as much as possible.

Lymphangiectasis. Although often used synonymously with lymphangioma, lymphangiectasis is distinctly different because it is in reality not a true neoplasm. Lymphangiectasis consists primarily of dilatation of the lymph vessels and is commonly a sequela of lymph stasis (Fig. 10). A differentiating clinical feature lies in the fact that lymphangiectasis is compressible whereas lymphangioma is not. Small, localized areas are frequently encountered in the intestinal mesentery in association with carcinomatous metastases, but extensive lesions are perhaps most common in association with varicose veins of the legs. Transition from lymphangiectasis to a true neoplasm (lymphangioma) does occur, however, thereby accounting for considerable clinical and pathological confusion between the two lesions.

Treatment consists of excision of the involved tissue.

Neoplasms of the Lymph Vessels. Neoplasms confined to the lymph vessels are not common; the various types of lymphangiomas (e.g., cavernous lymphangiomas and cystic hygroma) are the most important in this group. They are discussed in Chapter 20.

LYMPH NODES

Knowledge of the various regions of the body draining into each of the many groups of lymph nodes helps considerably in finding the source of many apparently spontaneous lymph node enlargements which are seen by the physician. The superficial nodes are located in the subcutaneous tissue of the following areas and go by these names: cervical, occipital, axillary, epitrochlear, inguinal, femoral (subinguinal), and popliteal. The deep nodes include, among others, the iliac, mesenteric (abdominal), and thoracic (me-

diastinal) groups. In general, the two groups are separated by the deep fascia; they join, however, before they empty into the main lymph channels which enter the venous system by way of the thoracic duct.

The following inflammatory diseases affecting these nodes will be considered: acute lymphadenitis, chronic pyogenic lymphadenitis, tuberculous lymphadenitis, and syphilitic lymphadenitis. Only localized lymphadenitis will be considered because generalized lymph node enlargement is usually a manifestation of systemic disease which is nearly always of medical rather than surgical interest.

Acute Lymphadenitis. Acute infection of the lymph nodes is always regional and secondary, therefore, to inflammation in the area drained by them. Bacteria, however, may invade through a portal of entry which, for some reason, exhibits no inflammatory signs. Thus, the local lesion may be prominent and severe, or it may be hardly noticeable. In either case, the node serves as a barrier to prevent further invasion of the body. The effectiveness of the lymph nodes in removing bacteria entering them has been shown in perfusion experiments reported by Drinker, Field, and Ward (15). They found that no organisms were able to pass through the lymph node, at least during the early stages of inflammation. Specific antibodies may be produced in lymph nodes which, therefore, also play a role in resistance against the invasion of infection in an immunological manner. During the process of acute reaction the node enlarges, not only because of edema and exudation but also because of the multiplication and infiltration of phagocytes and other leukocytes.

Acute lymphadenitis is most commonly due to the invasion of bacteria of the pyogenic group such as staphylococcus and streptococcus, but in certain locations to Ducrey's bacillus, the *Bacterium tularense,* and the virus of venereal lymphogranuloma, as discussed in Chapter 7. The lymph nodes most commonly invaded are the cervical and axillary group and those in the groin, i.e., the inguinal and femoral nodes (Figs. 11, 12). The cervical nodes are perhaps the most fre-

Fig. 11.

Fig. 12.

Fig. 11. Acute cervical lymphadenitis. After two weeks of conservative care the swelling became fluctuant and was incised. On culture a streptococcus and staphylococcus were recovered; healing was uneventful but delayed. No portal of entry for the infection was found in spite of careful search of the oral and pharyngeal cavity.

Fig. 12. Acute axillary lymphadenitis. Two weeks after onset the swelling was incised. A hemolytic streptococcus and staphylococcus were isolated in this case. Ten days before the node began to swell, the patient injured the index finger with subsequent transient superficial infection.

quently infected, following acute infections of the oral cavity, including such upper respiratory infections as pharyngitis and tonsillitis, and also dental abscesses. In the latter case, however, it may be the deeper tissue of the neck rather than the superficial lymph nodes which become infected and swollen. The clinical picture as described below has been greatly modified by the advent of chemotherapy. For reasons mentioned before, the original description will be retained.

Clinical Manifestations. Acute lymphadenitis may become evident as early as 12 to 24 hours following the entrance of bacteria at the portal of entry. As stated already, however, there may be no evidence of inflammation at the primary site or in the channels which transmit the offending organism. Enlargement of the affected node, accompanied by local heat and tenderness occurs early. As the enlargement progresses, pain and disability of variable extent soon follow and become progressively more marked. For example, a severe *cervical lymphadenitis* provokes so much pain and discomfort that the patient may be unable to turn his head from side to side. In severe cases, fever will be noted early; its degree will depend, of course, on the severity of the infection. Accompanying the fever may be other symptoms, such as general malaise, weakness, anorexia, and prostration. After a day or two, the tissue about the lymph node will become swollen and edematous (periadenitis). As the infection proceeds, neighboring nodes are apt to become involved. These nodes are at first discrete but later become confluent. In a few days, redness of the skin over the involved nodes begins to appear; this usually indicates suppuration and is frequently produced by the escape of pus into the subcutaneous tissues through rupture of the capsule of the infected nodes. However, in a majority of instances, acute lymphadenitis is a transient process and subsides rapidly without suppuration as soon as the primary infection is overcome. It usually takes several days, however, before the node recedes to its normal size. In adults, this is the usual outcome; in children, however, suppuration is more frequently encountered.

If suppuration occurs, the pain persists and usually increases. Fluctuation will be demonstrable in most instances except when the node is deeply seated. In such a circumstance, suppuration will be suggested by the continued fever and local pain. Occasionally, deep suppuration is accompanied by a variable degree of overlying cellulitis as the undrained abscess breaks through the capsule of the node into the surrounding tissues; there is, however, a distinct tendency for the pus to remain localized and point outward toward the skin.

Septicemia may follow should the infection break through the line of defense within and around the lymph node and enter the general circulation. This is particularly apt to occur when the causative organism is a hemolytic streptococcus arising from an upper respiratory infection (Fig. 13). In such instances, a more serious outcome may occur, as has already been discussed under Septicemia.

The local manifestations of *inguinal lymphadenitis* may be confused with strangulated inguinal hernia. The disability and local pain produced may be the same. However, an important differential feature lies in the fact that the development of the local manifestations produced by infection is gradual, whereas those associated with a strangulated hernia appear suddenly. If there is any doubt as to the nature of the swelling, a careful search should be made of the area drained by the nodes, i.e., the perineum, the anus (e.g., infected fissures), and the genitalia. The primary lesion may be merely a small scratch, an infection about a hair follicle, or a tiny ulcer under the foreskin. Occasionally, the diagnosis is made only at operation.

Infection of *retroperitoneal or deep inguinal (iliac) lymph nodes* may simulate local peritonitis or, if on the right side, acute appendicitis. This diagnostic confusion is particularly likely in the early stage before the node has enlarged sufficiently to become palpable. Fever is higher, but vomiting less likely, in lymphadenitis. Children are much more commonly infected than adults. When a mass is palpable, it is usually felt under Poupart's ligament or in the lower abdomen just above the ligament. In the latter location, it may be impossible to differentiate from appendiceal abscess. The portal of entry for these infections is seldom demonstrable. A number of such cases have been well de-

Fig. 13. Acute cervical lymphadenitis due to a hemolytic streptococcus. The patient was a three-year-old child. During the course of over two months five of such abscesses formed and were incised for drainage, each time yielding the same organism in pure culture. The child had otitis media, pharyngitis and a streptococcus osteomyelitis. Recovery was finally complete. This type of cervical lymphadenitis (produced by the hemolytic streptococcus) which occurs so frequently in children following otitis media, etc., is particularly prone to persist for many weeks before subsiding. Chemotherapy, however, often hastens final healing.

scribed by Irwin (16). Operation for incision and drainage is usually indicated.

Acute lymphadenitis in other parts of the body may produce local effects which may or may not be characteristic. *Mesenteric lymphadenitis* is not uncommon in children and may simulate peritonitis, as discussed in Chapter 32. *Mediastinal lymphadenitis* is described in the chapter on Surgical Diseases of the Thorax.

Acute lymphadenitis may last from one to two weeks except that, if suppuration demands incision, the sinus may require longer to heal. However, there is a type of acute cervical lymphadenitis in children secondary usually to pharyngitis, otitis media, and mastoiditis, which before the days of chemotherapy used to persist for many months and require incision at intervals because of successive involvement and suppuration of various nodes. This type of infection is encountered chiefly in winter and sometimes in an epidemic form. Systemic manifestations, such as fever, malaise, weakness, anorexia, and tachycardia, are particularly apt to be present. A fever may persist every day for weeks, or may recur intermittently, apparently as new lymph nodes become involved and suppurate. The offending organism in these cases is usually the hemolytic streptococcus, or less commonly, the hemolytic staphylococcus. This type of infection is becoming rare.

Treatment. The treatment of acute lymphadenitis is the same as that of acute infection in general, as already discussed in previous chapters; chemotherapy is very helpful. Rest of the affected part is obviously necessary. For example, a patient with axillary adenitis should carry the arm in a sling in order to prevent massage of the infected nodes by motion of the arm; if the infection is severe, bed rest may be advisable. Cervical and inguinal adenitis also justify bed rest, particularly if fever is present. The primary site of infection producing the lymphadenitis should receive early attention; immobilization, application of hot wet packs, and incision of abscesses when they form are indicated. Tonsils and teeth are prone to cause cervical adenitis, particularly in repeated attacks; if such a history is obtained, the tonsils and offending tooth or teeth should be removed, *but only after all the evidence of acute infection has subsided.*

Chemotherapy, if started early, will prevent suppuration. Often, however, suppuration may develop insidiously and be difficult to detect during chemotherapy, for reasons already discussed. However, the nodes should be examined daily for the development of fluctuation; when found, incision and drainage is indicated without delay. When doubt exists as to the presence of pus, aspiration may be utilized as a method of diagnosis, but not if the nodes are deeply situated and lie adjacent to the large vessels of the neck; the danger lies more in the production of an infected thrombus by puncture of a vein, than in producing hemorrhage. Occasionally, when *fever persists for days, and local tenderness is* marked, exploration of the deep nodes will be justified; in such instances the surgeon is usually rewarded by finding pus in one of the nodes (see also section on deep cervical infections in Chapter 31). A change in the chemotherapeutic agent based on sensitivity tests of the isolated organism may be decisive.

Chronic Pyogenic Lymphadenitis. Slight enlargement of lymph nodes occurs frequently as a result of chronic or recurrent mild pyogenic infections of low grade virulence in the field drained by the nodes. Such infections are commonly seen in active boys who frequently injure their extremities, so that the resulting mild infections produce a moderate painless enlargement of the femoral and axillary nodes. The cervical region is also a common site because of the frequency of mild repeated or chronic respiratory infections. Chronic pyogenic lymphadenitis of this type has little clinical importance except for the fact that it is often mistaken for tuberculosis or malignant disease. Removal of one of the nodes for microscopic examination is usually necessary to solve the diagnostic difficulty. When possible, of course, the primary infection responsible should be investigated and eliminated.

The sinus produced by the drainage of an acute lymphadenitis persists in rare instances and the associated lymph nodes remain enlarged and palpable. In such an event, total excision of the sinus and involved nodes may be indicated; such an operation rarely results in any spread of infection and is almost always curative. In many cases, the question of whether the infection is tuberculous or not is impossible to answer on clinical evidence alone; microscopic examination of the excised tissue will nearly always result in a positive diagnosis.

Tuberculous Lymphadenitis. Though none is exempt, tuberculosis most commonly involves the cervical and mediastinal lymph nodes (Fig. 14). The portal of entry for the cervical nodes is believed to be in the oral or pharyngeal cavities, but it is seldom if ever detectable. Cervical involvement is seldom encountered as part of a systemic (pulmonary) infection. Tuberculous lymphadenitis is probably due to the bovine type of the bacillus. In the United States, at least, it has *therefore all but disappeared due to the* elimination of tuberculous milk following the rigid inspection of cows for the presence of tuberculosis and the general use of pasteurized milk in the cities.

The disease first causes infiltration of endothelial and giant cells or actual tubercle formation, which brings about a simple hypertrophy of the node. Softening or caseation may occur by the gradual breaking down and digestion of tissue by the organism or its products. Tuberculosis is also prone to lead to a deposition of calcium in the node, especially when caseation occurs. Spontaneous drainage of such softened lesions is not infrequent. The calcareous deposit in such instances acts as a foreign body and may lead to the formation of a permanent sinus until the calcified node is removed surgically.

The nodes in the early stages are moderately enlarged, firm, elastic and not tender. When several are involved they are discrete, though as they enlarge they may coalesce. They may remain in a chronic stage of enlargement indefinitely, and gradually subside or soften. Should the tuberculous nodes suppurate, the fluctuant mass is called a *cold abscess,* because it is without acute inflammatory signs. These may open spontaneously or be incised. The pus is usually thick and creamy but may be thin and watery and contain caseous particles. The resulting wound frequently fails to heal and becomes a chronic draining sinus or indolent ulcer. A positive tuberculin test is of diagnostic value only in young children.

Treatment. Systemic therapy may be indicated, especially with the tuberculostatic

Fig. 14. Tuberculous lymphadenitis. The photomicrograph is of a lymph node removed from the neck of a young woman whose only complaint was of the small mass of six months' duration. There was a history of transient pleurisy some years previously, which may have been tuberculous. Note the tuberculous tissue in the midst of normal lymphoid cells. Giant cells are obvious and there is considerable necrosis although caseation is not as pronounced as it often is (see Fig. 17, Chapter 7). No other evidence of tuberculosis was found in this patient, who remained perfectly well.

drugs. Local treatment depends upon the presence or absence of fluctuation and a *chronic draining sinus*. 1. *When no fluctuation* is present, treatment may be merely symptomatic and hygienic. Excision has the advantage of actually removing the tuberculous focus and of insuring a definite diagnosis by microscopic and bacteriologic study of the tissue. Radiotherapy often results in a subsidence and even disappearance of the swelling (Figs. 15, 16). In any case, removal of one of the more superficial nodes is advisable to establish the diagnosis before beginning treatment. 2. When the node is fluctuant, repeated aspirations may forestall its opening spontaneously, but may occasionally lead to the development of a chronic draining sinus. However, if spontaneous drainage is imminent, it is better to open the abscess with an adequate incision to obtain free drainage. Excision of all of the diseased tissue will, however, *result in the most rapid healing and* is often preferable. 3. When chronic draining sinuses do occur, healing will frequently be hastened by radiotherapy. However, a careful excision of the sinus and its attached node, which is frequently calcified, will usually save *months of care and lead to much more rapid* healing, even in the face of an open secondarily infected wound. Moreover, a positive diagnosis is thus possible (by microscopic section and bacteriologic studies).

Syphilitic Lymphadenitis. Enlargement of the lymph nodes is constantly associated with the primary and secondary stages of syphilis. Within a few days or weeks after appearance of the primary lesion, the nodes draining the area become discretely enlarged and firm, but do not suppurate unless secondary infection develops. When the secondary lesions of the disease appear, there is apt to be a generalized lymphadenopathy. This is more pronounced in the Negro race than in the white. Differentiation from tuberculous lymphadenitis is rarely difficult because syphilitic nodes are apt to be generalized at some time in the disease *and do not suppurate*; the Wassermann reaction is of value after the primary stage.

Neoplasms of the Lymph Nodes. The inflammatory lesions, as just described, consti-

Fig. 15. Chronic cervical lymphadenitis, probably tuberculous. Note the mass on the left side, which, during two months, had grown slowly in size, was not tender or painful but finally became fluctuant. A small amount of thick pus was aspirated which showed only lymphocytes and no bacteria on smear, yielded no growth on culture and did not produce tuberculosis after injection into a guinea-pig. Oral cavity, nose and throat revealed no source for the infection. The swelling disappeared following radiotherapy, and the patient has remained well.

Fig. 16. Healed tuberculous lymphadenitis of the neck. The patient was a 27-year-old woman. For five years at intervals small nodes would appear, enlarge and suppurate without pain or tenderness (cold abscess). Tubercle bacilli were demonstrated on smear of this pus. With the aid of radiotherapy healing has always occurred. The patient has evidence of a quiescent pulmonary lesion. A few nodes one to two centimeters in diameter are still present, and may be seen above the scars of the healed sinuses.

tute the most common causes of enlargement of lymph nodes. The neoplasms affecting the lymph nodes are discussed in detail in Chapter 20. Almost all of them are malignant either primary or metastatic.

Lymphatic leukemia may or may not be considered as a true neoplasm; it is characterized by a generalized enlargement of the lymph nodes; there is an associated lymphocytosis of the blood. The nodes remain discrete and do not adhere to the skin or ulcerate. Microscopically, the node is composed of a finely reticulated tissue, which is densely infiltrated with small lymphocytes. An acute form is commonly encountered in children and is rapidly fatal; the illness consists of the appearance of soft, discrete lymph nodes, anemia, and hemorrhages beneath the skin and from the mucous membranes; it may terminate in death within a few days. The chronic form occurs chiefly in adults and is characterized by remissions of anemia, weakness, enlargement of the lymph nodes, and lymphocytosis. An aleukemic form, characterized by an absence of leukocytosis but a relative increase in the lymphocytes of the blood, is also encountered. The leukemias, including the myelogenous type, are primarily medical diseases but may be of surgical interest initially, at least, when diagnosis is uncertain. Microscopic examination of an excised node will nearly always remove any doubt.

DIFFERENTIAL DIAGNOSIS OF TUMEFACTION OF THE NECK

The cervical region is perhaps the most frequent site of tumefaction in the body. Whether small or large, these swellings always present a difficult diagnostic problem. Most of them are lymph node enlargements; many are due to acute or chronic inflammation. There are many other lesions, neoplastic and congenital, which occur often enough to add to the diagnostic possibilities. The history and complete physical examination are of primary importance. A detailed chart containing a list of the most common types of tumefaction, whether of the neck or of other parts of the body, will be found on the following page.

Special Features in Examination. 1. Careful examination of the areas drained by the cervical lymph nodes should include the scalp and the oral and pharyngeal cavities. In the latter case special laryngeal mirrors are necessary to inspect all the possible sites for ulcer, tumor, chronic infection, and so forth. Search is also made for sinusitis and infections about the teeth.

2. The Wassermann or Kahn reaction is of value in the diagnosis or elimination of secondary and tertiary syphilis.

3. The tuberculin test, if positive, is of value only in children, chiefly in the very young. A negative test is of value at any age; however the test is so frequently positive in older children and adults that it is not even used on them.

4. Aspiration of fluctuant tumors will give valuable information provided the lumen of the needle is large enough to convey the contents, which sometimes are viscid and thick. Pus should be smeared, stained, and also cultured. If tuberculosis is suspected, some of the pus should be injected into a guinea pig. If nothing can be aspirated, the fluid is either too thick, i.e., contains sebaceous or fibrinous material, or the mass is a solid tumor, i.e., a nonsuppurating lymph node, lipoma, lymphangioma and the like. Aspiration should not be used deeply below the surface because of the danger of entering the large vessels of the neck. Biopsy by aspiration with a needle is an effective diagnostic mechanism in detecting cancer, but at times it may disseminate the cancer.

5. Excision of tissue for microscopic study is usually the most decisive of all diagnostic procedures. If at all possible, the biopsy should be excisional, not incisional, to avoid or minimize dissemination of cancer cells. In many cases, the operation also serves the purpose of ridding the patient of the entire lesion. In removing a lymph node, it is wise to divide the specimen in two parts, sending half of it for microscopic study and preserving the other half in a sterile container (Petri dish) in the refrigerator. Should the histologic examination show a nonspecific type of inflammation, the remaining tissue can then be subjected to various bacteriologic procedures aimed at isolating a causative organism.

Tumefaction of Lymph Node Origin. These comprise both inflammatory and neoplastic lesions and have been described in detail elsewhere. It should be emphasized that

CHART 1

COMMON TYPES OF TUMEFACTION

* Lesions likely to occur in the neck.

a distinctive feature of inflammatory lymph node enlargement is the *periadenitis* which is generally absent in neoplastic disease. However, chronic enlargement of cervical nodes in children are frequently seen with very little periadenitis, and central necrosis plus secondary infection may result in marked periadenitis in the metastases from cancer primary in the oral cavity.

(*a*) Acute lymphadenitis, because of its marked local manifestations, very rarely offers any diagnostic difficulty.

(*b*) Chronic pyogenic lymphadenitis is due to low grade or recurrent pyogenic infection whose source is searched for in the area drained by the nodes. If suppuration occurs, the pus usually shows pyogenic bacteria on smear; cultures, however, may be negative because the organisms are dead.

(*c*) Cold abscess is often due to a tuberculous lymphadenitis which has suppurated. However, it may be a manifestation of caries of the cervical spine (Pott's disease). Local examination and lateral x-ray of the spine is important.

(*d*) Tuberculous lymphadenitis has no demonstrable portal of entry, and is characterized by a painless, moderately soft swelling, consisting of nodes which at first are discrete but later become matted together. Biopsy reveals giant cells, tubercles, and the like. Tuberculous pus, when present, may not show the organisms on smear, but should produce the disease in guinea pigs. In young children, a positive tuberculin test is of considerable significance.

(*e*) Metastatic carcinoma (Fig. 17) is undoubtedly the most frequent cause of malignant disease of the lymph nodes, particularly in old people. The nodes are firm, not tender, and ultimately become fixed to adjacent tissue. In the superior portion of the neck, lymph node enlargement due to metastatic cancer commonly has its origin from epidermoid (squamous cell) cancer arising in the oral cavity, pharynx, or nasopharynx, although epidermoid cancer arising in the skin of the face or head, particularly in the region of the ear, may be the source. It is therefore of great importance to make a thorough search of these areas for a primary tumor in older patients who have a mass in the upper neck. In young women, persistent lymph node enlargement in the neck should suggest the

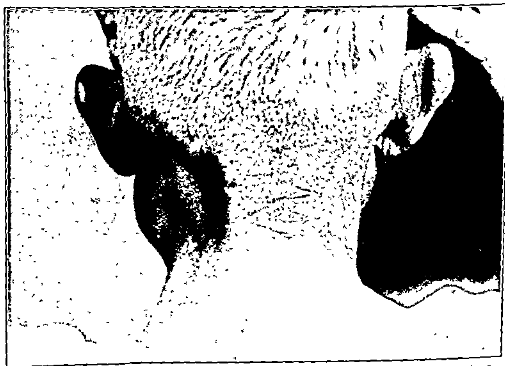

Fig. 17. Metastatic carcinoma of the cervical lymph nodes. This patient, a 59-year-old farmer, first noted a painless swelling in the left side of the neck. Later salivation developed. An extensive ulcerating carcinoma of the left tonsil was seen on inspection of the oral cavity. This patient is a suitable case for radiotherapy, preferably with the fractionated Coutard technic.

possibility of carcinoma of the thyroid, even in the absence of a palpable thyroid tumor. In the lower neck, bronchogenic carcinoma is a frequent precursor of right supraclavicular lymph node enlargement, while carcinoma of the stomach or colon metastasizes more commonly to the left supraclavicular lymph nodes. Biopsy in most cases will be necessary except in patients in whom there is a primary lesion in the oral cavity, in which case biopsy will likewise be indicated. Under such circumstances, a radical neck dissection will be indicated and is often curative.

(*f*) Hodgkin's disease (Fig. 18) and lymphosarcoma are often diagnosed with certainty only after the study of an excised node although, in a few cases, the differentiation from nonmalignant lesions will be impossible. In such a case, subsequent biopsy later in the course of the disease may be diagnostic. The enlarged nodes are usually discrete and periadenitis is absent.

(*g*) Leukemia produces a diffuse lymph node enlargement which shows typical histological features; the blood usually shows characteristic changes.

(*h*) Mild enlargement of the cervical nodes, as part of a generalized lymphadenopathy, is encountered as a systemic manifestation of syphilis. On rare occasions, the lymphadenopathy which accompanies a chancre of the lip is a source of diagnostic difficulty. Generalized lymph node enlargement is usually due to a variety of medical diseases, such as infectious mononucleosis and serum sickness.

Tumefaction Not of Lymph Node Origin. (*a*) Benign neoplasms of the skin and subcutaneous tissue, such as lipoma, fibroma, lymphangioma, and nevus, usually present no special diagnostic problem. Aneurysm and arteriovenous fistula are likewise easily detected by their local manifestations.

(*b*) Congenital cysts are rare; they may be

Fig. 18. Hodgkin's disease before and after radiotherapy. The patient was 11 years old. The diagnosis was based on biopsy at the site shown in the left photograph. The patient also had a palpably enlarged spleen, irregular fever, slight anemia and a leukocytosis of 19,000 to 23,000. The photograph on the right was taken three weeks after the one on the left, following a course of radiotherapy; the mass disappeared entirely shortly afterward as did the enlargement of the spleen. Recurrent tumors of the neck and axilla occurred three years later, which likewise responded to radiotherapy. The patient was asymptomatic for eight years when he became anemic because of persistent melena due apparently to bleeding from the stomach, which disappeared spontaneously. The patient, now aged 33, is married, has two children and is apparently free of disease 22 years after its onset. Such long survivals are seen only in a small percentage of cases.

of branchial cleft origin if on the lateral side, or of thyroglossal duct origin if in the midline. The cyst may be a part of a lymphangioma (hygroma). The fluid is clear (colorless or straw colored), unless infection is present. Fluid of a branchial cyst is turbid, and grossly could be confused with purulent fluid of cold abscess. Pathognomonic findings in the branchial cyst are the presence of cholesterol crystals.

(*c*) Sebaceous cysts are not common in the neck but present no diagnostic difficulty.

(*d*) Dermoid cysts are likewise uncommon and are often confused with branchial cleft cysts.

(*e*) Carotid body tumor is rare and slow-growing but is usually diagnosed only during or after excision.

(*f*) Tumors of thyroid origin (adenoma, hyperplasia) are characteristically in the normal position of the gland.

(*g*) There are innumerable miscellaneous lesions, many of which are common and important. Actinomycosis and mixed tumor of the parotid are often considered in the differential diagnosis of cervical tumefaction, but they really involve the lower portion of the face and jaw and thus are, strictly speaking, not of cervical origin. Swelling of the submaxillary gland is rare but is most often due to obstruction of the duct by a stone. Acute tumefactions, such as Ludwig's angina and deep cervical abscess, have such striking manifestations as to rarely cause any diagnostic difficulty.

THE NERVOUS SYSTEM

W. Eugene Stern

Peripheral and Cranial Nerves
The Brain
Affections of the Spinal Cord
The Autonomic Nervous System

From the regional standpoint the nervous system may be classified into: 1. the peripheral and cranial (somatic) nerves; 2. the brain and spinal cord; and 3. the autonomic (sympathetic) nervous system.

PERIPHERAL AND CRANIAL NERVES

Anatomically the nerve is composed of nerve fibers, the number of which decreases by branching as the terminal end is approached. Each fiber is in reality the axon of a nerve cell. The cells of the motor nerves are located in the brain and spinal cord, whereas the cells of the sensory nerves are in the specialized cranial and spinal ganglia.

Injury. When the continuity of a nerve (motor or sensory) is destroyed, all nerve function distal to this point is lost. Following an anatomic division, a peripheral *degeneration* of the nerve occurs. This process, named Wallerian degeneration after its discoverer, consists of fragmentation and absorption of the myelin and the axis cylinder, leaving the sheath of Schwann sufficiently viable and patent to receive a new fiber regenerating from the central stump. Retrograde degeneration may progress proximally for short distances, and reversible chromatolysis may occur in the cells of origin.

Regeneration of the severed nerve takes place from the central stump and, if there is no obstructive barrier, the axis cylinders find their way into the distal stump. Growth is slow, averaging perhaps less than 3 mm. per day and is influenced by the distance of the injury from the cells of origin, the rate being greater the more proximal the injury. A physiologic connection of the end of the nerve and its end organ requires an additional amount of time. The time required for regeneration and return of function even under favorable conditions varies considerably, as mentioned below. Injury may sever the axis cylinders but spare the Schwann tubules in which case the regenerating axons grow into their own tubules and excellent functional return occurs. Physiologic block of conduction may occur in closed blunt injuries without any anatomic interruption of nerve elements. Functional recovery is rapid and complete in such circumstances.

The types of injury vary, but the most common lesion responsible for complete loss of function is severance of the nerve by an incised or lacerated wound, or by avulsion. Other injuries are those produced by stretching or pressure; these may be followed by total, though perhaps temporary, loss of function. It is possible to stretch the brachial plexus or avulse the spinal nerve roots by extreme force applied to the shoulder, neck, or upper extremity. In fractures, nerves may also become pinched by fragments of bone or be compressed by callus. Injury to the radial nerve by a fracture of the humerus is the most frequent example of this type. Another type of paralysis is the so-called tourniquet paralysis; it occurs in extremities and results from the application of a tourniquet too tightly or over too long an interval. Such paralyses are usually of a temporary nature but on rare occasions recovery takes place only after re-

Fig. 1. Brachial plexus injury. Late stage of severe injury to the brachial plexus. Note the muscle atrophy, the fixed posture, and the taut, shiny skin of autonomic paralysis which accompanies the sensory and motor paralysis.

generation of the nerves. A physiologic block of nerve conduction without loss of nerve continuity may be produced by blunt injuries or pressure, and thus simulate anatomic interruption. Characteristically, motor function is more severely affected than sensory function in such injuries. A careful history of the mechanism of injury is required to assess correctly the probable underlying pathologic process and its surgical implications. A stretch injury may be anatomically complete, just as an open division of the nerve, but in the former the injury is longitudinally extended over many centimeters of the nerve trunk. In the case of closed brachial plexus injuries—as so often is seen in auto accidents—the distinction between root avulsion from the spinal cord and plexus stretch may not be readily made by careful muscle and sensory examination (Fig. 1). Specialized histamine skin tests (axon reflex) and cervical myelography may be helpful in separating the two mechanisms.

Complete severance of sensory fibers is followed by immediate anesthesia of the skin over the area supplied by the nerve, except for the margin of the area where overlapping of adjacent nerves will maintain partial function. This partial function is shown by retention of some sensation (i.e., sensibility to pin prick) in this zone, although the sensibility to light touch is lost. Deep sensibility and the sensation of position of joints and digits may be retained over the entire anesthetic area, because this function is usually ascribed to a different set of fibers which are present to a large extent at least in motor nerves. The area of sensory loss of pain and temperature is greater in the early stages after section of the nerve than it is later. The area of anesthesia decreases long before regeneration has occurred; this results from the assumption of function by the overlapping nerves and must not be confused with recovery of the injured nerve.

The anesthetic skin is apt to be dry, due to denervation of the sweat glands, and the nails become brittle and frequently deformed. Tapering of the fingers and atrophy of their pulp also occur. Important is the likelihood of unconscious infliction of trauma, such as burns, because of the anesthesia; the patient, therefore, must be cautioned about this danger.

An incompletely severed sensory nerve is followed by less definite disturbances of function. Sensation may be merely diminished (hypesthesia). There is usually considerable tingling and burning (paresthesia) over the area which may likewise be extremely sensitive to touch (hyperesthesia) or exhibit painful hypesthesia. Causalgia is a syndrome occurring occasionally after incomplete damage to nerves with a large sensory component (commonly the median and tibial nerves). It is characterized by intense, constant, burning pain, which is aggravated by emotional and psychic stimuli. Wet applications are helpful. Blocking of the sympathetics with a local anesthetic is a useful diagnostic and therapeutic tool, and it may support appropriate sympathetic denervation as effective therapy for this painful debilitating syndrome.

Complete severance of motor fibers is followed by immediate loss of the power of voluntary contraction in the muscle innervated. Electromyographic examination of the paretic muscles will in from 7 to 18 days, de-

pending on the nerve involved, demonstrate denervation fibrillation potentials and represents an important diagnostic finding. Contraction to faradic current stimulation is at first possible, but after a few days even this is lost. Contraction to galvanic current also takes place, but this too gradually diminishes. This diminution in the excitability of muscle is known as the *reaction of degeneration.* The paralysis of muscles may be recognized in various ways. First, by inspection and palpation of superficial muscles when appropriate movement is attempted, e.g., the deltoid, the biceps, or the adductor of the thumb. Second, by the performance of a movement for which the questionable muscle is solely responsible, e.g., flexion of the terminal phalanges of the fingers by the flexor digitorum profundus. Third, by palpation of the tendon of a muscle when an appropriate effort is made by the patient to use it, e.g., tightening of the tendon of the flexor carpi ulnaris as it attaches to the pisiform bone when wrist flexion is attempted. Fourth, diagnosis by exclusion, e.g., loss of flexion due to injury to the flexor digitorum sublimis by ruling out paralysis of the flexor profundus and the intrinsic hand muscles. Variation in muscle innervation by two adjacent nerves, such as the ulnar and median supply to forearm and hand musculature, may be studied by temporary local anesthetic blockade of the two nerve trunks differentially.

Recovery of Function. Numerous factors affect the range, degree, and character of recovery following division and suture of nerves. The principal nerves of the extremities are mixed—motor and sensory. The accuracy of suture of the divided nerve ends and the amount of scar tissue that forms between them will affect the result, as will the distance to be traversed by the regenerating axons in reaching their ultimate destination. In the regeneration of sensory nerves, the sensibility to pin prick is first regained, while that to light touch is the last to recover.

The time of return of motor function, likewise, depends upon the distance from the point of suture to the motor end plate in the muscle. The length of time that paralysis has persisted has much to do with the degree of improvement that follows suture. When it has existed for many months, the muscle atrophy, degeneration, and fibrosis become pronounced and often permanent. Since overstretched muscles lose their elasticity and contractility, they must be protected in positions of relaxation during the paralysis and pending recovery. Such factors affect the ultimate result as well as regeneration of the nerves themselves. It is unlikely that any mixed nerve ever shows complete recovery. Regenerating axons branch, sensory axons may grow along motor routes, and motor fibers find strange muscles, so that normal function is rarely restored. Such nerves as the radial, noted for favorable results after suture, have a relatively small number of sensory fibers in proportion to the motor, so fewer of them go astray. In addition, this nerve supplies muscles not highly specialized in function. The manner of action of a muscle has much to do with the apparent functional recovery. For example, a muscle which has regained only slight contractility may, by reason of an advantageous fulcrum, produce a wide though possibly weak movement. For example, slight contraction of the extensor carpi radialis may produce complete wrist extension. In contrast, a proportionate contraction of muscle fibers in the adductor of the thumb produces a movement with only a slight range and effectiveness.

Treatment. Immediate examination of motor and sensory functions of an injured extremity is always required. If impaired function is discovered, a detailed charting of sensory pattern (Fig. 2) and tabulation of motor strength by muscle are desirable. A standard motor grading is provided by the following:

0. No function
1. Flicker, either seen or felt
2. Contraction with gravity eliminated
3. Contraction against gravity
4. Contraction against mild resistance
5. Contraction against strong resistance

In the case of a clean, sharply incised wound under optimal conditions, primary nerve suture may be justified. Both ends of the nerve must be fully exposed and handled in the gentlest manner. Flush approximation of the nonrotated bundles is accomplished with sutures of fine arterial silk or steel after sharp razor excision of injured tissue. The sutures

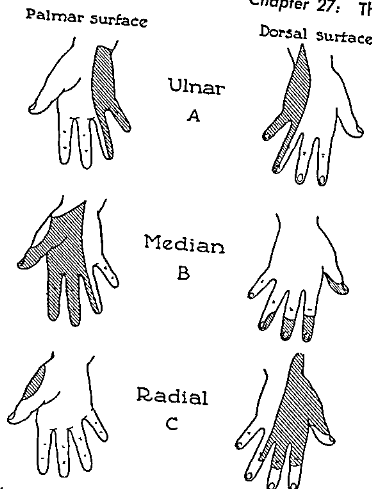

Fig. 2. Areas of hand hypoesthesia or anesthesia occurring in paralysis of nerves of the upper extremity. A, ulnar; B, median; C, radial. Due to overlap of other nerves the area of anesthesia on the dorsum of the hand following severance of the radial is usually much smaller than shown.

are placed in the epineurium only, and the line must rest with minimal tension.

In all other wounds, it is desirable to delay nerve suture until approximately three weeks following injury. At this time and for a short period thereafter, the Schwann cell proliferation is optimal for re-establishment of continuity of the tubules. There is more certain definition of the degree of injury to the nerves and consequently more accurate excision of injured nerve tissue back to succulent fibrils. The sutures hold in the thickened epineurium to better advantage and the handling of the tissue is likely to cause less additional damage. In the fresh wound, therefore, except as noted above, the nerve ends are merely noted and profitably tagged with a steel suture or possibly gently approximated by a single sling suture placed near the injured ends to retard retraction of these. Definitive neurorrhaphy is delayed until the wound is clean and healed, or until three weeks have elapsed, whichever is longer.

Secondary suture is required in wounds closed primarily without suture of the nerve and is necessary in practically all war wounds because they are not closed at the time of débridement. Numerous methods of repair of severed nerves have been suggested, and one proposed by Tarlov (1) appears to be very acceptable. The nerve ends are approximated by use of two mattress sutures of fine silk taken in the epineurium, and the suture line stabilized by fresh plasma allowed to clot around the nerve ends. Obviously, in nerve repair, great care must be exercised in prevention of rotation of one of the ends as they are approximated. Details of peripheral nerve injury may be found in the excellent monograph by Lyons and Woodhall (2).

A considerable gap between severed nerve ends may occur because of the resection nec-

essary to remove the neuroma and fibrous tissue, or from retraction of the free ends. Various methods are used to overcome the gap and permit accurate coaptation of sound tissue. Long incisions with free mobilization of the nerve, flexion of joints and favorable positioning of the extremity to shorten the distance to be bridged, and transportation of the nerve to shorter routes (viz., transposing the ulnar nerve to the front of the elbow or the radial anterior to the humerus) are the procedures which have been used. Autogenous nerve grafts have not been satisfactory in man except for the small nerves of the hand. Resection of bone to shorten the extremity and obtain approximation is infrequently justified.

The region of suture should be placed preferably in a muscle bed free from scar. The position of the extremity after operation should be such that the line of suture is not under tension. If it has been necessary to put the extremity up in flexion to accomplish this, the straightening process should be gradual and, depending upon the amount of tension, should require two to six weeks. Occasionally, the gap to be bridged may be so great as to necessitate two operations. In the first stage, a gross fastening of the nerve ends together, with the extremity in flexion, is followed by a gradual stretching and lengthening. The second stage and accurate suture may be accomplished with a repetition of the flexed position followed by gradual extension.

It should be emphasized that immobilization of joints leads to stiffness, sometimes permanent. Where splinting is required, slight flexion and extension within the permitted range is most desirable. Long, continued immobilization of joints in the presence of peripheral nerve injuries leads to irreversible joint changes.

If the axis cylinders are prevented from reaching the distal stumps because of the presence of a fibrous tissue barrier or for other reasons, the proximal stump may grow in a coiled fashion with the ultimate formation of a tumor known as a *neuroma*. If the resulting pain, tenderness, and paresthesia are sufficiently severe, the neuroma may be resected and the freshly cut ends sutured. Such tumors are also likely to form in amputation stumps and may be the cause of severe pain and local tenderness. Operative removal of the neuroma may be tried but is not always curative (see p. 620). At the flexor surface of the wrist, large sensitive neuromas are likely to follow suture and to recur if removed; cases for operation must be chosen carefully. Incomplete recovery with dysfunction may take place following injury to unsevered nerves, as well as following suture. On some occasions, a neuroma as described above is the explanation of the poor result. On other occasions the nerve becomes imbedded in callus of an adjacent fracture, or fibrous tissue is deposited to such an extent that the nerve fibers are compressed. Under such conditions, an operation (*neurolysis*) is justified. Freeing the nerve may permit resumption of part of its function. Depending upon the anatomic and physiologic condition of the nerve, actual resection with resuture may be indicated if functional loss is severe. Whereas in closed injuries with total nerve paralysis it may be justifiable to await signs of nerve regeneration, in the case of injuries with open wounds, surgical visualization of the nerve is recommended to determine its pathologic state and treat accordingly. The divided nerve requires no further comment, but the nerve in continuity may challenge the surgeon's judgment. The appearance and feel of the nerve at site of injury are important, and the response to its stimulation may guide the decision as to the correct surgical procedure—excision and suture (or resuture if a re-exploration) neurolysis, transposition to a better environment, or further observation.

The management of the patient with an injured nerve requires care to the skin and joints of the part and appropriate flexible splinting to support paralyzed or recovering muscles, at the same time permitting therapeutic and prophylactic motion; also important is the daily employment of massage and, when possible, galvanic stimulation to the paralyzed muscles to reduce the ravages of combined atrophy and fibrosis. When nerve dysfunction develops following trauma, early neurolysis is indicated to avoid nerve degeneration, muscle atrophy, and the like. (See Lesions with Incomplete Paralysis, p. 620.)

Injury to Special Nerves. Lack of space prohibits discussion of the clinical findings characteristic of all the various nerves which may be injured. There are a few (ulnar,

radial, and median), however, which are injured so frequently as to justify individual discussion. The ulnar and median nerves are readily severed or injured by lacerations of the forearm, which are so commonly sustained in both industrial and automobile accidents. Obviously, the findings will vary somewhat, depending upon the level at which the nerve is injured. Details of nerve injuries in the hand will be found in Chapter 17; however, some of the fundamental points are included below.

The *ulnar nerve* is injured most commonly by incised wounds of the forearm and wrist, penetrating wounds of the palm, and by fractures which involve the medial condyle of the humerus. The area of sensory impairment in complete division of the ulnar nerve includes the fifth finger, the neighboring half of the ring finger and the corresponding portions of the palmar and dorsal surfaces of the hand to the wrist (see Fig. 3). The only area, however, from which *all* forms of sensation are lost is the terminal phalanx of the little finger. Complete sensory loss of the terminal phalanx, therefore, is proof of complete ulnar interruption. Several types of motor disability are also produced, depending on the level of injury. Since the ulnar nerve supplies many of the intrinsic muscles of the hand (see *median*), division of this nerve results in considerable motor disability for finger movement of the hand (Fig. 3). Because of paralysis of the interossei muscles, there is a weakness of the power of flexion at the metacarpal phalangeal joints, especially of the ulnar side of the hand. Abduction and adduction of the fingers are impossible because of paralysis of the dorsal and palmar interossei, although other muscles can perform this function to a slight degree. Paralysis of the interossei also prevents extension of the tips of the fingers, particularly when the metacarpophalangeal joints are bent at a right angle. Paralysis of the adductor pollicis muscle prevents the patient from bringing his thumb against and in front of the base of the index finger. The patient is also unable to approximate the tips of the fingers. If the nerve is injured at the elbow, as frequently occurs at the groove of the internal condyle of the humerus, there will also be a weakness of the long flexors of the fourth and fifth fingers and the flexor carpi ulnaris.

As time elapses and the intrinsic muscles atrophy, a flexion deformity of the fingers (most marked on the fourth and fifth fingers)

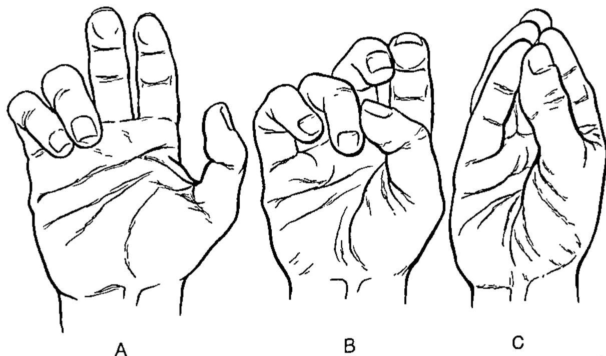

Fig. 3. Motor findings in ulnar nerve paralysis. A, clawing of inner two fingers; B, inability to oppose all finger tips as compared to the normal in C. (See also Fig. 12, Chapter 17.)

known as the "claw hand" (main en griffe), is produced. This deformity is produced chiefly because of paralysis of the interosseous muscles. Since the power of flexion of the fingers at the metacarpophalangeal joints, and extension of the second and third phalanx, is controlled by the interossei, their paralysis will allow the opposing muscles to draw the fingers into flexion with extension at the metacarpophalangeal joint. This deformity is similar to but actually quite different from that observed in Volkmann's contracture (p. 556) and other lesions. Restoration of function following suture of the ulnar nerve is unusually slow and incomplete. The first function to be regained is sensibility to pin prick. Function of the intrinsic muscles returns only after a year or two (depending somewhat upon the level of injury), but is rarely complete. After two years further restoration is unlikely.

The *median nerve* is often severed by deep lacerations above the wrist. It supplies the abductor and opponens pollicis, two outer lumbricales, and the deep head of the flexor pollicis brevis muscle of the hand. Paralysis of the opponens pollicis muscle, which is one of the most diagnostic features of injury to the median nerve, prevents rocking of the thumb, so that apposition of the tip of the thumb to the base of the little finger is impossible. Abduction of the thumb, which is performed by the abductor pollicis, is inefficient if the median nerve is severed (Fig. 4). If the nerve is injured at or above the elbow, flexion of the distal phalanx of the thumb and of the index finger is impossible because of paralysis of the flexor muscles to those digits. The sensory disturbance accompanying injury to the median nerve is the same regardless of the level of injury above the wrist; i.e., the radial side of the palm and tips of the index, middle, and ring fingers (see Fig. 3). The terminal phalanx of the index finger is the only part that is totally anesthetic in complete median lesions. Recovery of sensation is of the greatest im-

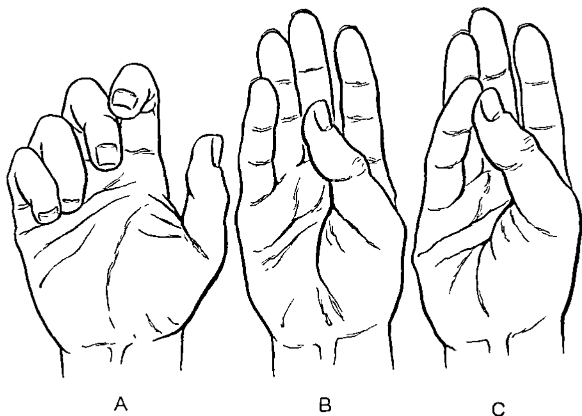

Fig. 4. Motor findings in median nerve paralysis (injury in upper forearm). A, inability to make a fist; B, inability to oppose the thumb to the little finger compared to the normal in C. (See also Fig. 9, Chapter 17.)

portance in the median nerve supply. Permanent loss of sensation in the index finger and thumb involves great disability, therefore sensory restoration in this nerve is more important than motor improvement.

The *radial (musculospiral) nerve* lies in direct contact with the humerus, winding around just below the insertion of the deltoid. It is, therefore, frequently injured, especially by fracture or by compression in the callus accompanying the healing of fractures of the middle third of this bone. Postoperative paralyses are occasionally encountered due to pressure by allowing the patient's arm to hang over the side of the table during an operation. If such pressure exists for a short time only, the paralysis is usually transient. The motor disturbance created by injury to the radial nerve is confined chiefly to the extensors of the wrist, fingers, and thumb, and produces the disability commonly known as "wrist drop." (See Ch. 17, Fig. 8.) If the nerve is injured high in the axilla, paralysis of the triceps may also occur, resulting in inability to extend the forearm. The sensory areas involved are located on the radial side of the dorsum of the hand and the radial side of the wrist.

Regeneration of the radial nerve after operative repair of the injury is fairly satisfactory and, in general, is better than that after repair of the median or ulnar nerve. Prognosis as to restoration of the power of extension of the wrist and fingers is usually favorable. It is important that wrist drop be prevented by supporting the hand in a dorsiflexed position in an elastic splint which does not immobilize the joints.

Lesions with Incomplete Paralysis. Under this heading will be considered various types of nerve lesions many of which may be classified as *neuritis;* some are presumably caused by toxins or chemicals and others by *trauma.* The important feature, however, is that the disturbance is only partial, and if the causative factor can be found and eliminated, complete recovery usually can be expected. Such lesions may present either sensory or motor manifestations or both. The most frequent of this type of neuritis is produced by *pressure* or *mechanical irritation* of a nerve, and manifests itself by pain, paresthesia, tingling, numbness, hyperesthesia, paresis, and the like, in the region of the nerve and its distribution. Stretching of the peroneal and ulnar nerves during manipulation for the correction of deformities are examples. Other examples are: injury to the peroneal nerve just below the head of the fibula by a plaster cast, injury to the ulnar nerve accompanying fixation of a fractured elbow put up in flexion, and paralysis of the median nerve from kinking at the annular ligament when a swollen wrist and hand is put up in flexion. The pathologic changes in and about the nerve are variable and depend upon the type of injury. They may vary from demyelinization to hemorrhage and crushing of a small amount of tissue, followed by deposition of scar tissue in and adjacent to the nerve. Early operation is advisable in injuries of this type because of the muscle atrophy, stiffness of joints, and nerve degeneration which might result from prolonged nonoperative therapy. Operation should be performed within a month following injury if no improvement is noted by that time, or if partial involvement progresses. Operation consists of removal of constricting bands of scar tissue about the nerve, neurolysis (i.e., lysis of the thickened sheath), and transfer of the nerve to a new position out of its bed of scar tissue if possible. On some occasions, removal of the cause may be followed by rapid amelioration of symptoms. On other occasions, contusion of the nerve may be so severe as to produce paralysis (sensory or motor) until regeneration takes place. Since the nerve itself is usually not severed, regeneration takes place after removal of the cause unless sufficient scar has been deposited actually to interfere with the growth of the axon down the sheath. If motor paralysis remains after removal of the cause, protective measures, such as splinting of the part to prevent contracture due to an overpull by the antagonistic muscles, must be instituted. All such splints must be removed several times daily, and joints manipulated by active motion to prevent stiffening.

Transplantation of the ulnar nerve to the antebrachium is often remedial to the condition of tardy ulnar paresis occurring following injuries about the olecranon groove. Occupational hazards may cause recurring mild injury leading to fibrosis about this same nerve in its vulnerable position, and produce

incomplete lesions which may be benefited by transposition. Compression of the median nerve *in the flexor carpal canal is another* example of the role of joint injury or arthritis or recurrent minor traumata in producing a painful or weak extremity. Section of the flexor retinaculum with release of the nerve is often helpful.

Another group of incomplete nerve damage syndromes is due to a *toxin* or *chemical poison*, e.g., lead, alcohol, and arsenic poisoning affecting also other parts of the body. The symptoms reduced by this type of neuritis, which is frequently designated as polyneuritis, consist of paresthesia and various motor nerve paralyses, especially wrist drop. Important surgically is the use of supports and appliances to prevent contractures.

Cervical ribs have a surgical interest because they may produce neurological as well as circulatory changes. This congenital anomaly is almost always confined to the seventh cervical vertebra; the ribs vary considerably as to their stage of development. Very *few are sufficiently developed* as to be attached to the manubrium. More commonly the rib is short; it may or may not terminate in a fibrous band which is attached to the first rib near the scalene tubercle. Most cervical ribs are found accidentally in x-ray films and do not produce symptoms. When symptoms are produced, the most common manifestation is numbness and tingling of the hand in the distribution of the ulnar nerve. The fibers of this nerve are contained in the lower cord of the plexus and are, therefore, most susceptible to pressure by the cervical rib (Fig. 5). However, other fibers may be involved. Actual weakness of muscles of the hand or flexors of the wrist may be present. Less often there may be evidence of compression or spasm of the subclavian artery as exhibited by coldness and cyanosis of the fingers and decrease in volume of the radial pulse, par-

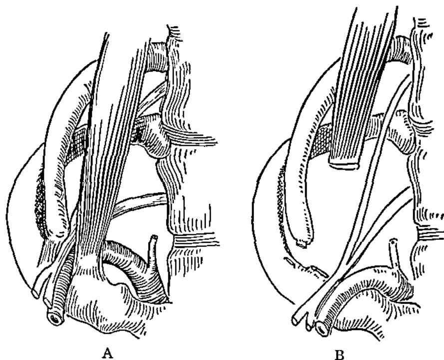

Fig. 5. The mechanism by which cervical ribs may produce unilateral disorders of nerves and blood vessels (scalenus anticus syndrome). Cervical ribs may compress the nerve trunks constituting the brachial plexus and produce a type of traumatic neuritis. They may likewise diminish the volume of the radial pulse, with decreased blood pressure on the side or sides affected. A, the end of the cervical rib or its fibrous attachment (when present) to the first rib may compress the subclavian artery and nerve trunks against the scalenus anticus muscle; B, section of the scalenus anticus near its attachment to the rib allows the artery and nerve trunks to slide medially and downward, thereby eliminating the pressure on them.

ticularly when the arm is held in a dependent position with the shoulder relaxed. On rare occasions, superficial areas of gangrene will develop on the fingers.

The *treatment* of symptoms produced by cervical ribs is satisfactory and consists of release of the pressure upon the artery and nerve trunks. Although this may be accomplished best by removal of the larger ribs, it will not be necessary when the rib is very short or terminates in a fibrous cord. In most instances, the artery and nerve trunks are compressed between the scalenus anticus muscle and the cervical rib or its fibrous attachment. Section of this muscle at its insertion without removal of the cervical rib will allow the artery and nerve trunk to slide forward with subsidence of symptoms.

The symptoms of *brachial plexus neuritis* first described by Murphy (3) and Naffziger (4), are similar to those produced by cervical rib, but occurs in absence of a cervical rib. The term *scalenus anticus (Naffziger) syndrome* (Ochsner and associates, 5) seems to be an appropriate designation, because section of the scalenus anticus muscle is usually curative. Other mechanisms may produce symptoms and findings similar to those of the rib and muscle complex just described. The cords of the brachial plexus may be compressed by normally occurring structures such as the first rib, a pectoralis minor muscle, or the subclavius muscle. It may be involved by a superior sulcus tumor or an aneurysm of the subclavian artery. The most common error in diagnosing the cause of upper extremity pain is lack of recognition of the importance of cervical root compression by intervertebral disk disease.

Causalgia is characterized by severe burning pain, occurring at intervals up to several weeks following injury but usually appearing within 24 hours of injury (6). The syndrome occurs in mixed sensory motor nerves in which the sensory component is prominent, and in most every instance the lesion of the nerve is incomplete. Weir Mitchell, who originally described the condition, noted it was observed most commonly following war wounds. The pain occurs in attacks and is commonly revived by a touch or slight jar to the affected extremity; paresthesia is fairly constant. At times the discomfort is severe, demanding specific therapy. Bone atrophy in the affected extremity is common; at times it may become severe and may be responsible for symptoms, particularly pain. Any sensory stimulation (sound, light, and so forth) aggravates the pain. Emotional and psychic stimuli aggravate the pain. The patient with hysteria shows no vasomotor changes except those due to immobility. Sympathectomy is usually effective. Early diagnosis and immediate treatment save much suffering and eliminate permanent disability.

Involvement of segmental peripheral nerves of the trunk in operative incisions upon the thorax and abdomen may produce disagreeable and, at times, incapacitating neuritis. It is most frequently encountered in thoracotomy and herniorrhaphy incisions. Revision of the painful scar and nerve section rarely stops the pain, particularly after the pain pattern has become well established. Local nerve block may be tried, but alcohol used too near the spinal canal may spread proximally into the subarachnoid space and should be used with great caution. Infrequently the condition may call for posterior root section of several segments or tractotomy. The best treatment is prevention.

Hiccup (*Singultus*) is a common complaint, produced by a sudden spasm of the diaphragm associated with the closure of the glottis, and has been classified, though perhaps incorrectly, as a type of neuritis. The abnormal impulse is transmitted by the phrenic nerve. In its most frequent form it is apparently of reflex origin from disorders of the stomach or intestine. It is commonly encountered as a complication of abdominal operations; in other instances it is instigated perhaps by irritation or inflammation of the diaphragm as produced by peritonitis, mild or severe. Occasionally the condition is caused by intracranial tumors but in such instances, is not severe. Various methods of treatment are available but not specific. Sedation, gastric lavage, inhalation of carbon dioxide, rebreathing into a paper bag, and many other remedies may be helpful. Friedgood and Ripstein (7) report good results in 80 to 90 per cent of patients treated with chlorpromazine. They used a dose of 50 mg. intravenously but reduced the dose to 25 mg. in elderly patients. When the above conserva-

tive measures fail and the condition is proving to be an exhaustive complication, the phrenic nerve may be blockaded or isolated by operative procedures and the impulses broken by various means. In most cases, however, in the absence of serious disease such as peritonitis or uremia, the hiccup even after days or weeks of unsuccessful therapy will disappear as quickly as it came.

Herpes Zoster (Shingles). This condition is caused by a neurotropic virus located in the cranial or spinal ganglia and posterior roots. The ganglia associated with the fifth cranial nerve and the intercostal nerves are most commonly affected. Severe pain, which is usually of a constant debilitating character, radiates along the course of these nerves. The skin over the area supplied by the nerves becomes red and edematous and vesicles soon appear. Such vesicles may become secondarily infected. In the severe cases, the pain is intense. The disease occurs, however, in all variations of severity and frequently is so mild or of such short duration as not to demand special treatment. Since pain precedes the herpes, which in some cases may be absent, the disease may be mistaken for other lesions, particularly acute intraabdominal disease.

TREATMENT. In the acute phase of vesicular eruption, irradiation of the spinal segment involved, paravertebral sympathetic blockage (8, 9, 10), and various systemic medications have unpredictable results. The pain frequently is self-limited but in a minority of patients severe posthepatic neuralgia persists and is disabling. In the treatment of this chronic form of posthepatic neuralgia, local nerve blocks or resections may have temporary benefit. Dorsal root section is useful in a further group, and, in severe intractable spinal cases, spinothalamic cordotomy may be recommended with relief in about 50 per cent of cases. Prefrontal lobotomy is required rarely. The operative procedure of peripheral elevation of pedicled flaps in the area of the diseased skin and denervation of such flaps with or without grafting holds promise.

The Cranial Nerves. The *first* or *olfactory* nerve carries impulses responsible for the sense of smell, and by this means likewise contributes to a great extent to the sense of taste. Its chief surgical significance lies in the fact that loss of the sense of smell aids in the localization of brain tumors and the site of brain damage in head injuries, particularly those accompanying fracture of the anterior cranial fossa.

The *second* or *optic* nerve, transmitting stimuli which give rise to the sense of sight and the light reflex, is one of the most important of the cranial nerves. Lesions affecting one or both optic nerves or visual pathways produce defects in the visual fields which are commonly due to a surgically important lesion. Papilledema, which is a swelling of the nerve trunk ending in the retina, is secondary usually to an increased intracranial pressure of subacute or chronic nature. This condition may be brought about by a number of causes, including brain tumor, brain abscess, intracranial injury, encapsulated blood or fluid, or blockage of cerebrospinal fluid flow. If the intracranial pressure is allowed to persist, the papilledema passes into the stage of "secondary atrophy" with impairment of vision or permanent blindness.

The *third* (*oculomotor*), *fourth* (*trochlear*), and *sixth* (*abducens*) nerves innervate the external muscles of the eye. Inflammatory or neoplastic lesions of the brain or fractures of the base of the skull may create a disturbance in the normal movements of the eyeball by injury to these nerves. A carotid aneurysm is a frequent cause of oculomotor paralysis and is to be particularly suspected if the onset of the paralysis is sudden. Careful examination of the movements of the eye is obviously important in detecting intracranial lesions of various types. Malignant tumors arising in the nasopharynx frequently invade the base of the skull and cause paralysis of isolated nerves or nerves in combination, the most common being the sixth cranial nerve and the fifth cranial nerve.

The *fifth* (*trigeminal*) nerve is rarely injured, but is frequently the seat of a neuralgia which is known as *tic douloureux*. Involvement of the trigeminal nerve from whatever cause if combined with a facial paralysis requires prompt tarsorrhaphy to protect the cornea from ulceration.

Trigeminal neuralgia (tic douloureux) produces severe, excruciating paroxysms of pain distributed along one or more of the divisions of the nerve (usually the second and third).

The onset is abrupt, with severe pain radiating to the upper or lower jaw. If the second division is involved, the pain will be confined chiefly to the cheek and upper lip. Although the disease usually affects one division at first, there is a tendency in time for all three to become affected. There are no objective sensory changes in the skin over the area of the face affected, but there is a peculiar reflex sensitivity insofar as a slight touch may at times set off a paroxysm which characteristically is located in the upper jaw but may extend to the mandible and nose (trigger zones). In character it is sharp, lightninglike, stabbing, or electric in quality. One shock may succeed another over a few seconds, the offset of the pain is as abrupt as the onset. In the intervals there may be no pain whatever, though at times there is a more or less persistent discomfort. Remissions of weeks or months characterize the disease. The average age of the sufferers is between fifty and sixty. In the very young there may be an association with other nervous diseases, such as disseminated sclerosis or a tumor in the cerebellopontine angle or gasserian ganglion. The pain is usually severe enough to require sedation, although such narcotics as morphine should be avoided because of the danger of drug addiction. Permanent cure is produced by section of the sensory root of the fifth nerve, either in whole or in part. The motor division can be spared. The anesthesia is permanent. If the pain does not involve the first division, that portion of the root should not be sacrificed, as permanent anesthesia of the cornea involves obvious dangers.

It may be wise first to inject the involved branch with alcohol. This is usually effective in relieving the pain for several months. It may be repeated, or avulsion of the root be performed by operation. Alcohol injection may be a useful therapeutic test for what may be accomplished permanently by operation. It also acquaints the patient with the numbness he will have after nerve root section. Trichloroethylene inhalations are effective in alleviating the attacks in a minority of cases.

The etiology of trigeminal neuralgia is unknown. There are no objective neurological findings. It is unaffected by the removal of teeth or surgical attack on the sinuses. It tends to become worse. Decompression of the sensory root and internal neurolysis of its fibers in its dural canal over the apex of the petrous bone (Taarnhøj, 49) may produce relief without sensory loss. Division of the sensory root gives permanent cure and in skilled hands carries a mortality of less than 1 per cent.

It is important to distinguish between major trigeminal neuralgia (tic douloureux) and the atypical neuralgias of the face which arise in other pain-sensitive structures about the neck, face, and cranium and for which fifth nerve section is decidedly not the correct treatment. Migrainous hemicrania of vascular origin, pain from disease or malocclusion of the temperomandibular joint (Costen's syndrome), pain from dental and cervical disease, and pain of muscle spasm and tension are examples in point.

The *seventh (facial)* nerve, which is primarily a motor nerve supplying the muscles of the face, is occasionally injured by operative procedures, fractures of the base of the skull, infection about the middle ear, and mastoid operations. Paralysis of the facial nerve results in a disfiguring deformity due to the unilateral loss of facial expression and shifting of the mouth toward the unaffected side (Fig. 6). Since the nerve divides into its branches in the outer surface of the parotid gland, operations in this area may result in injury to the nerve. Spontaneous, though often transient, facial paralysis also occurs without evidence of any other disease or as the result of various infections, viruses, and toxins (Bell's palsy). These seventh nerve paralyses are of the peripheral type, characterized by inability to close the eyes or wrinkle the forehead. In contrast to this are the lesions which are of supranuclear origin, in which only the lower facial muscles are affected. Thus the patient retains the ability to close the eye and wrinkle the forehead.

In permanent facial paralysis of the peripheral type, the facial deformity may be corrected to a great extent by a plastic operation, which includes the transplantation of facial strips, anchored subcutaneously in order to hold up the paralyzed face, particularly the side of the mouth. In peripheral facial palsy where there is some possibility of recovery, the facial muscles should be supported and

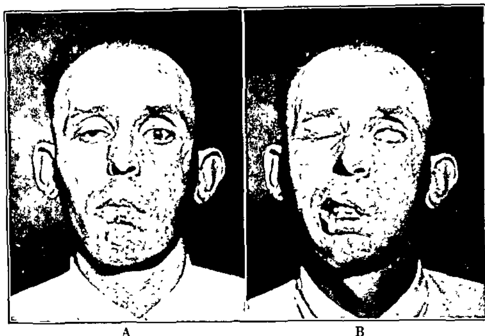

Fig. 6. Paralysis of the seventh nerve produced by a gunshot wound of the face. A, with the facial muscles at rest the only evidence of paralysis (in this instance) is a slight deviation of the mouth toward the unaffected (right) side, and a lack of wrinkles on the paralyzed (left) side; B, when the patient is instructed to close his eyes and "show his teeth," a marked distortion results because of the paralysis of muscles on the left side.

kept relaxed to prevent overstretching. Manual massage inside and outside the cheek will aid in accomplishing this. Adhesive straps attached to a band about the head may be used.

For permanent, complete injuries of the facial nerve proximal to the stylomastoid foramen, a hypoglossal-facial anastomosis performed in the neck is the treatment of choice. Discrete facial motions do not return but facial tone and gross movements do, and provide a more acceptable cosmetic result. Spasmodic facial spasm is usually of psychogenic origin, but in certain cases of nuclear facial spasm of presumed organic origin, partial peripheral fiber section is advantageous. Electromyographic study of the facial muscles is helpful in distinguishing the two.

The *eighth* (*acoustic*) nerve is occasionally injured in fractures of the skull, but more commonly the equilibratory sensation is impaired by cerebellar lesions (tumor). The nerve itself may be the seat of neoplastic growths, *e.g.*, acoustic neurinoma or von Recklinghausen's disease. Ménière's disease, which is characterized by severe vertigo, nausea, vomiting, and unilateral tinnitus in an ear which is partially deaf, is treated successfully by the intracranial section of the eighth (auditory) nerve or of its vestibular portion. Streptomycin may lead to eighth nerve involvement when given to susceptible patients as chemotherapy. A form of "toxic" labyrinthitis associated with respiratory infections often leads to temporary dizziness from intense stimulation of this nerve.

The *ninth* (*glossopharyngeal*) nerve is of surgical significance because of the occurrence of *glossopharyngeal neuralgia*, which is similar to trigeminal neuralgia except that it is more rare and is confined to the anatomic distribution of this nerve. The act of swallowing is usually most painful and the tonsillar fossa is the "trigger point" which initiates the pain. Local anesthetization of the tonsillar fossa may be helpful in stopping the pain and aiding in diagnosis. Pain in the ear often accompanies the paroxysm. *Treatment* consists of the intracranial section of the ninth nerve. Occasionally, intracranial lesions (tumors, and so forth) compress the fibers constituting this nerve and produce an impairment in taste and deglutition. By receiving the carotid sinus

nerve of Hering, the ninth nerve is the important afferent limb of the carotid sinus reflex and is of importance in transmitting impulses which may produce asystole and syncope from excessive vagal influence—the carotid sinus syndrome—mediated by the tenth nerve (see below).

The *tenth* (*vagus*) nerve is of special significance since section or destruction of both nerves in the cervical region is fatal to man. It contains fibers which carry autonomic impulses of the parasympathetic type to and from the abdominal and thoracic organs. Occasionally, tumors compress the vagus in such a manner as to create an irregularity in the cardiac rhythm. Because of its position in the posterior portion of the carotid sheath, it has no doubt been mistaken for the phrenic nerve or sympathetic trunk and occasionally removed. Its peripheral branches below the diaphragm have been divided in the treatment of peptic ulcer (see p. 735). Injury to the recurrent laryngeal branch of this nerve in cervical surgical procedures and involvement of the nerve in cervical malignant tumors are well recognized.

The *eleventh* (*spinal accessory*) nerve supplies the sternomastoid and trapezius muscles and may readily be injured or severed during operations upon the lower part of the neck, such as dissection for carcinoma, or removal of lymph nodes in the posterior triangle of the neck. The degree of disability and discomfort following such paralysis is variable; at times it is extreme.

The *twelfth* (*hypoglossal*) nerve which supplies the muscles of the tongue should be avoided in block dissection beneath the jaw for carcinoma. Severence of one hypoglossal nerve results in unilateral atrophy of the tongue with deviation to the side of the injury. Disturbances in deglutition and articulation are not marked, so that this nerve is often severed and crossed with the facial nerve in instances of permanent facial palsy.

THE BRAIN

Craniocerebral Injuries. The term *head injury* is often used to include three groups of trauma, which occur so frequently together that they are described here in the section on brain: 1. injury to the scalp; 2. fracture of the skull; and 3. intracranial injury. This classification will be used in the following discussion, except that most of the space will be devoted to varieties of intracranial injuries which, it should be emphasized, represent the most important of the three groups, being responsible for the serious and often fatal results. In the following discussion, a distinction must be kept in mind between the closed head injury on the one hand and the open, compound, or penetrating wound on the other. The mechanism of injury varies with each and clearly the surgical pathology is different.

1. *Injury to the Scalp*. In any patient with such an injury it is obviously important to know whether or not a skull fracture and intracranial injury are present. A history of the mechanism of trauma and of the presence or absence of impaired consciousness immediately following injury is of importance. Examination of the head may reveal contusions, hematomas, or ecchymotic patches anywhere about the scalp. The presence of a laceration of the scalp is of extreme importance because of the possibility of detecting an underlying fracture which may demand repair, as will be discussed later. Local tenderness may be elicited even if the patient is only partially conscious. Clipping of the patient's hair may be required to discover signs of scalp injury which may constitute important evidence of the role of injury in explaining a clinical picture of impaired consciousness.

Edema of the scalp extends along linear fractures. Presence of pitting and tenderness may permit the diagnosis of linear fissures. A scalp hematoma with a soft crater may sometimes simulate a depression in the skull though continued pressure on its margins may alter it and indicate its character; frequently, differential diagnosis between it and a depressed fracture may be possible only by x-ray. Aside from the opportunity to estimate damage to the underlying bone and brain, a simple scalp injury presents no other feature of importance. It needs emphasis, however, that extensive scalp lacerations may be associated with important blood loss and shock. The treatment of this uncomplicated lesion has been described under Wounds; such injuries will heal readily if clean, because of ample blood supply. Careful separation of the wound edges, inspection and cleansing are commonly neglected. In World War II this

resulted in so many serious infections of scalp and bone that in England scalp lacerations were listed as reportable to the area consultant. Wide shaving of the surrounding scalp, thorough cleansing and removal of avascular contused and ragged scalp edges, inspection and palpation for underlying fissure fracture lines or other evidence of bone injury, are first principles to be followed. Suture without tension with nonabsorbable silk or steel wire utilizing a buried galeal layer or figure-of-eight single layer suture which includes the galea is recommended. Antitetanic serum or tetanus toxoid (if the patient has been previously immunized) should be given, as discussed elsewhere.

2. *Skull Fracture.* Fracture of the skull rarely occurs alone; injury to the underlying brain is often associated, and injury to the overlying scalp is frequently present. Fracture can occur without brain injury, such as the eggshell fracture of a vise-type mechanism; it often dissipates the force and spares the brain of further injury. Its presence indicates the mechanism and degree of severity of the force applied but not necessarily the amount of brain injury. The serious and often fatal effects of skull fracture are *due to injury of the brain or a blood vessel, and not to the fracture itself*, except in basal fractures when meningitis may develop, regardless of the presence or absence of brain injury. When the compressing force acts from pole to pole the fracture is apt to be linear. If the head is struck a direct blow with a small object, a stellate fracture, with lines radiating outward from a central point, is apt to be produced. Such a blow, if severe enough, will result in a depressed fracture. An important example of the indirect localized depressed type is a fracture of the base of the skull sustained when the patient falls to the ground from a height, and lands on his feet or buttocks so that the impact of the heavy head strikes against the vertebral column and literally caves in the base of the skull. Such injuries are serious and usually fatal, because of the damage to the adjacent vital medullary centers. Because of the thinness of the bone in certain parts of the base of the skull, fractures in this region are particularly common. Bullet wounds produce a variable amount of shattering, depending on the speed of the missile and other factors. Because of the arrangement of the two concentric tables of the skull, a blow to the outer table may produce an innocent linear or stellate fracture line in the thin outer table but be associated with a serious fragmentation of the inner table with possible underlying soft-tissue laceration.

Fractures of the skull may be classified in many different ways. From the standpoint of the mechanism of production they may be bursting, indented, or expansile; according to the character of the fracture itself, they may be linear, stellate, comminuted, depressed, or penetrating.

Diagnosis of fracture of the skull may be made occasionally by simple clinical observations. The fracture may sometimes be palpated when depression and comminution are present; it may be seen and felt occasionally through a laceration; local tenderness is usually present over the fracture. Bleeding from the nose or ear is indicative of skull fracture if direct injury of the soft tissue can be excluded as the source of the hemorrhage. Escape of cerebrospinal fluid through a scalp wound, or from the nose or ear is pathognomonic of cranial fracture.

The diagnosis of skull fracture may require x-ray films taken in several views and often stereoscopically. From the therapeutic standpoint, x-ray is necessary insofar as it may reveal a depressed fracture which might otherwise be undemonstrable and which may require correction, or to visualize air which may enter via fractures into the sinuses. Views taken with the ray tangential to depressions are necessary to show their depth. In the case of open, compound, or penetrating wounds operative management is of course mandatory, and good quality films are required for intelligent handling. In the restless or comatose patient, it may be necessary to induce anesthesia and to guarantee an adequate airway to obtain films before taking the patient to the operating room. In the case of the closed head injury, however, x-rays will add little to the initial management of the patient except as mentioned with respect to depressed fractures; their taking is best deferred until full examination has guaranteed that the patient's condition is sufficiently stable to withstand the handling attendant upon the roentgenologic study. X-rays are recom-

mended in all cases of craniocerebral trauma.

Treatment of skull fractures is that of the associated intracranial and scalp injuries. It is directed toward minimizing the damage done by penetrating objects, to prevent infection, and for the removal of gross clots.

In the absence of demonstrable intracranial injury, ambulation is encouraged two or three days after injury (11) to minimize post-traumatic headaches. Brain damage is often present although not evident clinically. When the fracture is depressed or compound, operation is indicated. Since treatment of fractures of the skull is directed toward the brain injury, it is discussed under the various types of intracranial injury.

Depressed fractures are important because of the association with brain injury. This may be only local or it may be associated with so much widespread damage that any of the manifestations described on page 630 may be produced. Naffziger and Glaser (12) have shown that the changes in the brain are caused by the force producing the injury rather than continuing depression of the bone. However, depressions in excess of the width of the tables of the skull should be elevated. With depressed compound fractures, the problem is the prevention of infection and the removal of devitalized material to minimize gliosis and scar contraction, which may lead later to convulsions.

The skin may or may not be broken over the site of injury. An x-ray should always be taken, since a hematoma in the scalp may simulate a depressed fracture. An early neurologic examination is essential, particularly noting the eye signs and evidences of a hemiplegia. Detailed neurological examination is usually difficult because of the inability of the patient to cooperate. The reflexes should be recorded together with continued observation of voluntary movements of the extremities. Decreasing movements of one side of the body often precede actual paralysis or altered reflexes. Nurses should be instructed to make this observation. Findings carefully recorded permit comparison with later examinations and changes serve to distinguish between signs of primary damage and those which appear later due to hemorrhage.

Simple (presumably nonpenetrating) depressed fractures (Fig. 7) with an intact scalp should be elevated soon, but as an elective procedure except when progressive signs, as from hemorrhage, make operation imperative or when focal neurologic deficit corresponding to the site of injury indicates a "coup" injury with a possible subcortical clot.

Fig. 7. Depressed skull fracture. Closed, comminuted, depressed skull fracture of the frontotemporal area with laceration of meninges and cortex. Most depressed fractures, even though they be closed injuries, should be elevated if they are displaced the width of the skull or more. In the closed injury, such treatment may be delayed a day or two, unless focal neurologic deficit exists, in which case treatment should be emergent as it must be in the case of compound depressed fractures.

The most appropriate time for operative closure of open penetrating wounds is based on the general condition of the patient, the previous treatment of contamination and the presence or likelihood of infection. Débridement of devitalized tissue, including the brain, and dural repair scalp closure in general should be performed as early as possible.

Open (compound) fractures associated with in-driven bone fragments and penetrating wounds due to missiles are treated along similar lines and as early as suitable personnel and facilities are available.

It is the aim to prevent infection and minimize the damage done. Devitalized scalp margins are excised. Depressed areas may be removed en bloc or the opening enlarged and bone fragments removed piecemeal. Retention of contaminated bone fragments commonly leads to late abscess. Metal fragments, if accessible, are also removed, but widely separated fragments may be left justifiably if removal requires extensive excision of nontraumatized tissue. Devitalized brain is irrigated and sucked out so as to lessen the nidus for infection and minimize the amount of later scar. The entire tract of a penetrating wound must be cleansed back to normal bleeding tissue, but the principle of "block excision" of a contaminated wound, when applied to the brain, may cause too much sacrifice of functionally vital tissue. Watertight dural closure is a first principle. Scalp closure without tension may require extensive undermining beneath the galea and is a first requisite. Systemically administered antibiotics may decrease the risk of infection.

3. *Intracranial Injury With or Without Fracture.* Many fatal brain injuries occur without fracture of the skull. Rapid acceleration or deceleration of the head alone produces varying degrees of contusion and laceration of the brain. With generalized brain injuries the under surfaces of the frontal lobes and the tips of the temporal lobes, especially on the opposite side from the point of impact, are most prone to show damage. Focal neurological signs may not be present. If they appear later a clot is the probable cause. Bloody spinal fluid signifies brain laceration.

The simplest manifestation of intracranial injury is transient unconsciousness sustained immediately after the accident, followed later perhaps by dizziness, headache, or visual disturbances which clear up within a few hours without producing any permanent effect. This type of manifestation is often called *concussion,* a physiopathologic state due to microscopic or perhaps only functional trauma to the brain cells and reversible chemical and electrical alterations. Of considerable interest is the fact that repeated episodes of this type may lead to permanent brain damage which is observed in boxers who are said to be "punch drunk." Organic injury, consisting chiefly of minute hemorrhages particularly in the pons, is responsible for this condition. In the severe cases, the mental disturbances may develop into almost complete imbecility.

More obvious manifestations of intracranial injury consist of a great variety of specific signs and symptoms sometimes masked by the effects of coexistent acute alcoholism. Moreover, they may vary greatly from hour to hour in the same patient which emphasizes the importance of frequent observation. Many of them have already been discussed to a certain extent in Chapter 16 and include surgical shock, abnormalities in respiration, manifestations of increased intracranial pressure, and various types of sensorial changes from coma to hyperactivity; other evidences comprise those more local in character, such as cranial nerve paralyses and leakage of cerebrospinal fluid from wounds, ear, or nose. So important are these various types that they are discussed in some detail. Treatment is also described under each variety of injury. In the civilian automobile injury of today it is well to remember that when a patient is hurt he is often hurt all over and the responsible surgeon must be alert to injury to all parts of the body.

There are *several varieties of intracranial injury* consisting of contusion and laceration of brain tissue, of hemorrhage, edema, and compression, and of actual destruction or loss of brain tissue. The hemorrhage may be massive and local, or diffuse and petechial in type; it may be within the brain, subdural, or extradural. The contusion or laceration of brain tissue may be diffuse or localized; cerebrospinal fluid may escape subdurally (extra arachnoid), where it is absorbed slowly thus increasing intracranial pressure, or it may leak externally when a compound fracture exists. Most of these various lesions may be differentiated clinically. Often a combination of two or more will be present, thus complicating differential diagnosis. Nevertheless, the therapy may be so different in each type that the surgeon should seriously attempt to determine the type and severity of the injury and particularly its development by frequent observation. In the following classification, *four types of injury are discussed:* 1. diffuse injury with edema; 2. extradural hemorrhage; 3. subdural hemorrhage; and 4. intracerebral

Fig. 8. Fatal cerebral contusion. Severe craniocerebral injury with cerebral contusion associated with temperoparietal fracture. Note the widespread subarachnoid blood and massive swelling of the hemisphere with displacement and distortion of the ventricles and other midline structures.

hemorrhage. The treatment indicated will be described in each type.

1. *Diffuse Injury.* This group represents the most serious type of injury and is frequently fatal. Contusions and lacerations may be extensive throughout the brain. A variable amount of tiny and massive hemorrhages within the brain or along the meningeal surfaces is associated with the injury. The contusions and lacerations are responsible for the development of edema which, with hemorrhage, may readily produce serious manifestations purely from increased pressure (Fig. 8).

A variable degree and duration of *unconsciousness* will be present, dependent upon the severity of the injury. In many instances, vertigo and headache will be fairly constant complaints. Nausea and vomiting may be present. In the more severe cases the skin is usually pale and the extremities are cold and moist. If death is not immediate, the temperature will rise. Localizing signs may or may not appear. Convulsive seizures may occur in the acute phase of such injuries. The contusions which occur about the midbrain may be contributed to by shifts of the brain stem against the rigid tentorial edges at time of injury, and they may result in a decorticate or decerebrate state with an ominous prognosis.

Manifestations of *increased intracranial pressure* (produced by edema and hemorrhage) may be noted within a few hours; if active hemorrhage is the cause of the compression (see p. 634) these manifestations may be noted sooner. As a rule, the blood pressure rises and the pulse rate decreases (down to 40 to 60 per minute). A sudden decrease in blood pressure, particularly if it drops below normal, is usually serious and may be a sign of impending death. The same may be said of an increase in pulse rate, par-

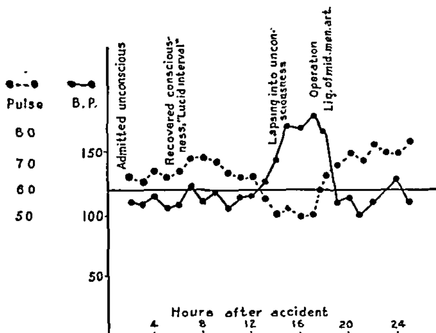

Chart 1. Extradural hemorrhage from the middle meningeal artery. Note that as the patient recovered consciousness (lucid interval) the pulse and blood pressure remained unchanged. The rise in blood pressure and drop in pulse rate at about the fourteenth hour was caused by the pressure effect of the bleeding from the torn artery. While this type of chart is almost pathognomonic of increasing cerebral compression, it should be emphasized that this complex is not always present with such lesions.

ticularly if it rises to above 120 or 130 per minute. The optic disks occasionally swell. The respirations become abnormal and are commonly slow and deep, but may be stertorous or of the Cheyne-Stokes variety.

Signs of compression of the brain may be produced also by the simple accident of rupture of the arachnoid, thus allowing fluid to escape into the subdural space. However, the manifestations of this injury are more apt to simulate those of middle meningeal hemorrhage, except that the rise in blood pressure may not be so great.

In injuries which are fatal, the blood pressure falls and the pulse rate rises as death approaches (Chart 1). Other manifestations of shock, including pallor and cold extremities, become more pronounced. The breathing becomes more abnormal, particularly slower and more irregular. A terminal rise in temperature is commonly noted in patients who have survived longer than a few hours. It is worth emphasis that of all the clinical observations which are helpful in judging such cases the one of prime importance and the one most often neglected in favor of less useful data (such as reflexes) is the *level of consciousness* of the patient. So important is this index of progress that its determination, regardless of the course of vital signs, pupillary reactions, and so forth, often by and in itself dictates surgical measures and exploration for hemorrhage or other fluid collection.

It may be noted that, except in children or in adults with massive scalp hemorrhage, the findings of shock are transient in the patient with head injury and, if persistent, usually point to another site of injury, such as the chest, abdomen, or extremities. It is not safe to ascribe true surgical or hypovolemic shock to the head injury alone.

Fractures of the base of the skull are usually, but not invariably, associated with diffuse damage to the brain. Such fractures are usually serious (because of the proximity of the vital centers) even though the damage is local. Involvement of the facial nerve and nerves supplying the eye indicates basal damage. Injury to the olfactory nerve with subsequent anosmia is common. If the fracture passes through the petrous portion of the temporal bone, bleeding from the ear may be noted. In fact, bleeding from the ear, not arising from the external ear or canal, is in-

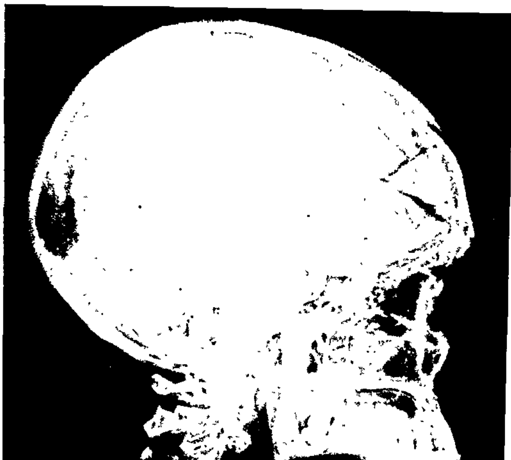

Fig. 9. Depressed skull fracture with complications. This patient suffered a cerebral contusion of the frontal lobes, proptosis of the eye and blindness from orbital involvement, and persistent cerebrospinal fluid rhinorrhea accompanying these serious, depressed, comminuted fractures. Operation repaired the lacerated meninges and sealed the cerebrospinal fluid leak from the frontal sinuses and cribriform plate.

dicative of a basal fracture, usually of the middle fossa.

Bleeding from the nose and mouth suggests a basal fracture if there has been no direct injury to these parts. The escape of spinal fluid from the ear or nose is proof of the presence of a fracture through the base. Orbital ecchymosis and subconjunctival hemorrhage, when distinguished by their configuration from a "black eye" of local trauma, points to an anterior fossa fracture (Fig. 9).

Operative *treatment* is directed toward the removal of extradural, subdural, and intracerebral clots and the control of bleeding. The brain compression syndrome may include:

(*a*) Progressive impairment of consciousness. (It is unnecessary to wait until the patient is profoundly comatose; for example, the appearance of urinary incontinence in an otherwise wakeful patient may be sufficient evidence of deterioration.)

(*b*) Appearance or progression of focal neurologic deficit, such as extremity weakness.

(*c*) Focal ocular signs (the unilaterally dilated pupil) or abducens paresis.

(*d*) Vital sign alteration, as discussed above.

The presence of such a syndrome, complete or in part, is an indication for operative intervention. It is caused by surgically important lesions, such as clots and loculated fluid collection, but it is also caused by the cerebral edema or swelling attendant upon the lacerations or contusions which may be present. It may also be produced by fat embolization or metabolic disturbances such as fluid and electrolyte imbalance. It is often impossible to distinguish between these major categories clinically, and operation must be done. The use of electroencephalography is an adjunct only, and cannot be relied upon to diagnose

a surgical lesion. Cerebral angiography in the patient with head injury has an important place among the diagnostic tools and may disclose or distinguish the presence and nature of intracranial hemorrhage. The introduction of intravenous urea solutions in 15 to 30 per cent concentration by Javid (13) and the administration of U.S.P. urea by mouth or intragastric tube have provided the most useful of many tried procedures to combat diffuse brain swelling. Urea may be helpful in the patients treated by operation as well as in those with the nonoperative lesion of brain edema. The intense diuretic effect of urea requires careful attention to fluid balances in such patients. The presence of active bleeding, or the suspicion thereof, is a contraindication to the use of such urea solutions.

Restlessness is controlled by such drugs as sodium phenobarbital administered parenterally and chloral hydrate or paraldehyde, by mouth or rectum. It should be emphasized that the restlessness of disturbed patients may be due to a full bladder and a desire to void. All respiratory depressants (e.g., morphine) should be avoided. Fluid intake should be kept at body needs. Hot weather, sweating, and food intake vary the requirements. A urinary output of from 0.6 to 1.0 ml. per kilogram body weight per hour should be maintained. Patients in deep stupor should be turned on the side or kept in a Sims' position to permit the tongue and jaw to come forward and secretions to drain out. Maintenance of a clear airway is of utmost importance and tracheotomy is occasionally required. Ordinarily postural drainage or suction through a bronchoscope is adequate. For cyanosis, or when respiration is difficult, oxygen should be given.

In a study of 1,000 consecutive patients with head injury admitted to their hospital, Ulin and associates (14) noted that respiratory embarrassment was the most serious complicating factor; the liberal use of tracheotomy or endotracheal suction will minimize the serious effects of these respiratory complications and often be life saving. The use of lumbar puncture should be individualized. The presence of signs of meningeal irritation, the new appearance or persistence of fever, and the presence of severe headache may be indications for lumbar puncture.

Recent evidence indicates that prolonged confinement to bed does not lessen the incidence of post-traumatic symptoms (15). The degree of activity desired by a conscious and rational patient is usually a safe guide. Activity can be increased gradually when evidences of bleeding have ceased and intracranial pressure is normal.

2. *Extradural Hemorrhage.* In most instances, extradural hemorrhage arises from the middle meningeal artery which is torn by a fracture. On rare occasions a fracture is not present. The occasional occurrence of such a hemorrhage in the posterior fossa needs recognition. A history of at least a short period of unconsciousness followed by a lucid interval of variable duration (2 to 18 hours) is the classical clinical picture observed, but is seen in the minority of cases. Persisting unconsciousness with the development of localizing signs and evidences of increasing intracranial pressure is a more frequent sequence. The patient then becomes stuporous and sinks into coma. The blood pressure usually rises sharply, and this, when it occurs, is perhaps the most valuable diagnostic sign of middle meningeal hemorrhage, with the exception of the periods of unconsciousness just described. The slowing of the pulse rate is a more constant finding. The respirations may become stertorous. Swelling of the optic disks may develop. Localizing symptoms may be observed, indicating that the clot has progressed upward over the motor area; weakness of one side of the face or an extremity (usually the arm) opposite the side on which the hemorrhage is located, constitutes the chief local sign. A unilaterally dilated, fixed pupil, which is an ominous sign, usually on the side of the hematoma, is seen in half the cases by the time operation is performed. It will be noted that most of the manifestations accompanying middle meningeal hemorrhage are in reality those of a gradually increasing cerebral compression. Death may follow in a few hours; for this reason it is important that the condition be recognized promptly and immediate operation performed for the evacuation of the blood clot and control of any active bleeding. The mortality rate following extradural hemorrhage is remarkably high (30 per cent or more).

Schneider and Tytus (16) have made a

study of the causes of this high mortality rate; they conclude that failure to suspect the condition and to operate promptly, failure to realize that the decereberate rigidity pattern may result from an extradural hemorrhage, failure to appreciate that otorrhea or rhinorrhea may mask the symptoms, and lack of familiarity with the condition by all physicians treating head injuries represent factors explaining the poor results.

3. *Subdural Hemorrhage.* Hemorrhage of this type usually arises from rupture of veins on the surface of the brain. The amount of bleeding is extremely variable. Thus the symptoms may arise shortly after the injury, or their appearance may be delayed for weeks or even months.

The mortality of acute subdural hematoma (occurring in hours up to one week) is from 30 to 50 per cent, being higher the more acute the process. Such a mortality is not caused by the lesion in question alone but signifies the mortality of the multiple and complex injuries of such cases.

Much of what has been said relative to extradural hemorrhage may apply to acute subdural hematomas in adults. Fractures are less common, and the mechanism of injury may have been less vigorous with less evidence of trauma about the scalp. In children, the clinical symptoms and signs differ somewhat. The occurrence of vomiting and irritability, the more frequent association of convulsion, the mild change in head size or changes in fontanelle tension, and the development of more frequent retinal hemorrhages are notable differences.

It is in the chronic subdural hematomas that a history of earlier injury is necessary for diagnosis, yet may be overlooked. Blood which persists in the subdural space may become encapsulated and, possibly by osmosis of cerebrospinal fluid, the mass enlarges. The exact mechanism of the formations of such sacs is not fully understood. Evidences of chronically increased pressure then appear. Localizing signs may or may not be present. It should be emphasized that, regardless of signs, subdural hematomas are often bilateral. Evidences of blood in the spinal fluid are frequently lacking and are not essential to the diagnosis. The most common symptoms are those seen in increased intracranial pressure —such as headache, vomiting, irritability, change in personality, sometimes mental deterioration including inattentiveness, forgetfulness, and even stupor or unconsciousness. Weakness of an extremity and exaggerated reflexes on the side of the body opposite the hemorrhage may be demonstrable. Choked disks are usually present. The diagnosis is usually difficult, particularly in the chronic cases, because the trauma producing the injury may be so slight as to have been forgotten. Moreover, symptoms and signs may be few in number and atypical. The electroencephalogram and cerebral angiogram will be useful diagnostic adjuncts (Fig. 10).

Fig. 10. Post-traumatic subdural hematoma. Cerebral angiogram several weeks following a minor head injury. Note the smooth displacement of the cortical vessels from the inner table of the skull and the displacement of the midline vessels to the opposite side. At operation, a large, encapsulated collection of old, liquefied, subdural hematoma was evacuated.

Treatment consists of removal of the blood and fluid through trephine openings. It may be necessary to turn down a flap. In the adult, the sac surrounding the clot need not be removed except with recurrent accumulations, but in the infant the problem is altered. The use of subdural aspiration and trephination may be adequate to control early fluid collection. Persistence of the encapsulated fluid then requires craniotomy with excision of the membranes and expansion of the brain to obliterate the subdural space.

4. *Intracerebral Hemorrhage.* Solitary intracerebral hemorrhages of large size are not uncommon shortly after injury. The evidences of general pressure plus focal findings are present. Exposure of the involved area at operation and, if no surface bleeding is present, puncture and aspiration reveal the accumulation of black liquid blood. A small cortical opening may be required to permit the extrusion of a clot.

The diagnosis of possible intracranial hemorrhage or local compression may be as far as the surgeon can go preoperatively. In the face of indication for operations, viz.: (*a*) open wound, (*b*) depressed fracture, and (*c*) the brain compression syndrome, the surgeon must plan his operative approach to permit proper evacuation of fluid or clot regardless of its final location as discovered at the operating table. The various specialized neuroradiological technics may reduce the uncertainty, but the surgeon must be capable of adapting to the presence of lesions in varying locations and at varying levels.

Late Complications of Head Injury. Elective repair of a cranial defect by premolded radiolucent plates or by methyl methacrylate plates molded aseptically at the operating table is an advance over the metallic plates. Persistent cerebrospinal fluid rhinorrhoea or otorrhoea may demand intracranial repair of the lacerated dura mater at the site of communication. Late post-traumatic epilepsy occurs in 3 to 5 per cent of closed head injuries and 30 to 40 per cent of open penetrating injuries which lacerate the dura mater and brain. Seizures early in the course of an acute injury need not presage the development of late epilepsy but the latter requires careful anticonvulsant regulation.

Post-traumatic Syndrome. Not infrequently, serious symptoms persist for many months after severe intracranial injury. Headache of an inconstant type, exacerbated by fatigue, is perhaps the most disabling complaint. Persistent dizziness, irritability, loss of memory, and lack of initiative are common complaints. There is little correlation between neurologic deficit and this syndrome. Treatment should consist of reassurance, graduated exercises, and other means of rehabilitation (Voris, 17).

Intracranial Neoplasms. These include neoplasms of brain tissue, of the meninges, of cranial nerves, and of the pituitary gland. Other developmental faults such as Rathke pouch tumors, dermoids, epidermoids, and chordomas are not rare.

Roughly half the intracranial tumors have their origin in the supporting tissues of the brain, the glial cells. The gliomas vary widely in gross appearance and cell type and have corresponding differences in rate of growth. All are infiltrating in character and with rare exceptions will recur after removal. In gliomas, as well as in other intracranial tumors, the age of the patient, the site of the tumor, its rate of progress, and its x-ray characteristics, aid in preoperative judgment of the pathological type. Certain of the gliomas, e.g., some astrocytomas and oligodendrogliomas, are slow growing and relatively benign. Others, such as the glioblastoma multiforme, recur rapidly. Some types, such as the medulloblastoma, which is most frequently seen as a fourth ventricle tumor in small children, respond to radiotherapy and may be controlled for a few years.

The tumors of meningeal origin account for perhaps 15 per cent of the intracranial tumors, often invade bone, but are encapsulated tumors which displace the brain and are benign. Their favorite locations are over the vault and at other areas in the base where the arachnoidal villi are numerous (Fig. 11).

Of the cranial nerves, the eighth gives rise to the most common tumor of the cerebellopontile angle, the acoustic neurinoma; the optic nerve and chiasm are the sites of gliomas.

Of the various pituitary adenomas, the chromophobe adenomas of the anterior lobe are most common. These have no secretory function and show their presence by neigh-

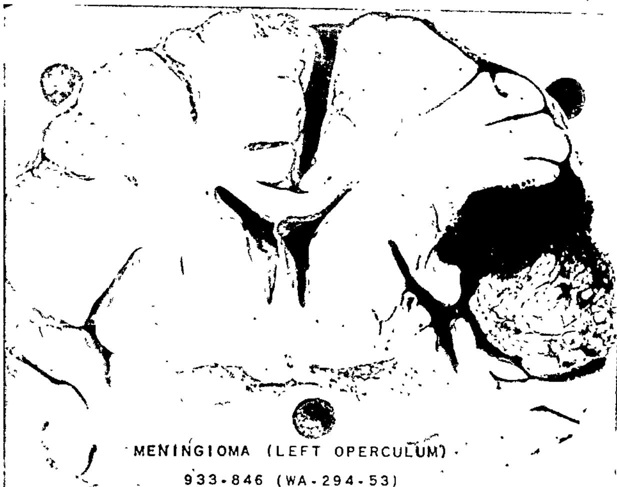

Fig. 11. Hemispheral meningioma. This patient suffered focal epileptic seizures and a progressive speech loss and motor paresis. He died without surgical therapy. Such a favorable meningioma may be totally resected with ultimate recovery of the patient.

borhood signs, such as visual field defects, enlargement of the sella turcica, and disorders of glandular secretion by compression of the remaining cells of the gland. The adenoma which gives rise to acromegaly is composed of eosinophilic cells which do have a secretory function. Most of the basophilic adenomas which are related to Cushing's disease are not large enough to deserve consideration of surgical removal. Malignant adenomas are infrequent, and occur in 5 to 8 per cent of tumors.

The diagnosis of tumor must be considered when the symptoms and signs can be explained by a *single* lesion. If there is evidence of its enlargement by increasing local neurological signs, a tumor should be diagnosed. Finally, if there is evidence of its space-consuming (chorophagic) character, the diagnosis is certain. These final signs are due to intracranial pressure from the size of the tumor or because, even if small, it may be so placed as to obstruct the flow of cerebrospinal fluid. These signs are headache, vomiting, choked disks, enlargement of the head in the young, alterations in the x-ray appearance of the bone from pressure (beaten silver appearance), a cracked pot note on percussion, paralysis of the sixth nerve from distortion, and variable degrees of stupor in the far advanced stages, in which the intracranial pressure may be greatly elevated.

Metastatic tumors are by no means infrequent. The commonest primary lesions are carcinoma of the lung in the male and of the breast in the female.

TREATMENT. The treatment of brain tumors is by operative removal and, for certain types, radiotherapy. The type of tumor and its accessibility are determining factors in the result. Practical descriptions of brain tumors, with classification and treatment, may be

found in the publications by Spurling (18) and Davis (19).

Intracranial Suppurative and Inflammatory Masses. The infectious granulomata, such as tuberculoma or parasitic lesions, are rare and usually masquerade as a brain neoplasm and are treated by surgical excision.

Bacterial infections of bone, meninges, and brain, although not as common as before the development of antibiotics, are dangerous and potentially lethal. *Osteomyelitis* of the skull requires excision of diseased bone and intensive chemotherapy. *Subdural purulent collections* may occur after acute frontal sinusitis or other contiguous infectious foci, and if not promptly recognized by the occurrence of the brain compression syndrome as well as acute systemic reactions to infection, a fatal outcome ensues. Brain abscess retains a high mortality but is more successfully treated now than formerly. Mastoid infection and sinusitis, especially of the frontals, are the common origins; spread to the brain is by an infective thrombophlebitis and less often by contiguity. Other sources are penetrating wounds, osteomyelitis of the skull, or through the blood stream, usually from foci in lung or pleura. The diagnosis is based on the criteria given above for the recognition of a tumor, plus an infectious focus as a primary lesion. Mastoid infections are most apt to cause abscesses in the temporal lobe, less often in the cerebellum. Frontal sinus infections spread to the frontal lobe and occasionally to the temporal. Brain abscesses are treated by aspiration and enucleation; intensive chemotherapy should also be utilized for several days following operation. Eradication of the initiating focus, if present, is a first principle but usually is best delayed until the more lethal brain abscess is successfully controlled.

Surgical Lesions of the Vascular Tree. Saccular and berry or developmental aneurysms commonly lie on the circle of Willis and may manifest themselves (*a*) by spontaneous subarachnoid hemorrhage, (*b*) by cranial nerve paresis (commonly oculomotor nerve when located on the internal carotid artery), and (*c*) by focal neurologic deficit from intracerebral rupture or neighborhood pressure by the mass itself. The lethal nature of recurrent spontaneous subarachnoid hemorrhage when due to intracranial saccular aneurysm requires that patients suffering from unexplained hemorrhage be studied by cerebral angiography. The location and configuration of the aneurysm, if present, will dictate the correct therapy which may be the successful surgical exclusion of the aneurysm from the vascular system to preclude further expansion and hemorrhage. Rupture of such aneurysms explains the large majority of spontaneous subarachnoid bleeding.

Arteriovenous malformations manifest themselves (*a*) by subarachnoid bleeding; (*b*) by focal neurologic deficit, usually hemiparesis; and (*c*) by focal epilepsy. Intracranial bruit may occur in 30 per cent of such cases and is more often associated with such a developmental anomaly than with aneurysm. Angiographic visualization of the intracranial circulation will define accurately these lesions which, when favorably located, may be totally excised. Fistulas between the carotid artery and the cavernous sinus may follow cranial trauma but when spontaneous usually are due to rupture of an aneurysm within the confines of the sinus; the dramatic picture of pulsating exophthalmos ensues together with bruit and cranial nerve paresis. Cervical carotid occlusion and intracranial carotid occlusion are the usual measures required for successful therapy.

Internal carotid artery atherosclerosis may produce signs and symptoms of cerebral arterial insufficiency. In properly selected patients, cervical carotid thromboendarterectomy may re-establish adequate cerebral circulation.

General Manifestations of Intracranial Lesions. Sooner or later in their development and growth, tumors and abscesses (especially the former) will produce an increase in intracranial pressure, whose relation to trauma has already been discussed. Ordinarily, however, trauma produces increased pressure so much more rapidly that the clinical manifestations are quite different. Until tumors do produce signs of increased intracranial pressure, there may be no means of discovering their presence unless, as occasionally happens, focal signs develop. The general manifestations may be listed as shown below. These are nonspecific and of little value in localization of

the intracranial mass responsible. They may be late in occurrence yet all too often they are among the earliest manifestations. The physician must be alert to the possible diagnosis of a mass lesion before these signs and symptoms appear.

1. *Headache.* This is, no doubt, the most common of the symptoms of intracranial disease and may be the first to appear. As the tumor increases in size the headache increases in intensity, though it is intermittent. It may be confined to any part or be found in all parts of the head. From lesions in the posterior fossa causing hydrocephalus, the headaches are frequently suboccipital. With cerebral tumors, the pain is over the vault or frontotemporal area. In early phases of disease before the development of raised intracranial pressure, unilateral headache may have lateralizing value.

2. *Vomiting.* After the increase in the intracranial pressure becomes significant, vomiting becomes a prominent symptom. The vomiting may be projectile, but more characteristic is the fact that it may occur with little or no nausea. It is much more common with subtentorial than with supratentorial growths.

3. *Papilledema.* If increased intracranial pressure has been present for some time, only on rare occasions does a brain tumor fail to produce a choked disk. The "choking" of the disk (papilla) is presumably due to obstruction of the veins of the disk, created by the increased intracranial pressure. Hemorrhage and exudate in the retina are also present and are more important in determining the age of the process than is the amount (number of diopters) of swelling of the optic disk. Secondary atrophy results from persistent pressure.

4. *Convulsions (General).* Although the exact mechanism of generalized convulsions (tonic, clonic, without aura) is not clear, they are frequently observed and are presumably of irritative origin. They are especially common when the tumor involves the cerebral cortex.

5. *Mental Dullness.* As the intracranial pressure increases, there is a tendency for the patient to become mentally dull. Cerebration is slow, and at times the patient may become so stuporous as to be aroused with difficulty. It is not uncommon, however, for a normal sensorium to be retained even in the presence of marked increase in intracranial pressure. Lesions in the temporal lobe are more apt to be associated with mental dullness than lesions in other areas.

6. *Slow Pulse.* Slowing of the pulse rate (presumably of medullary origin) appears late. It is much more common in brain abscesses than in tumor. The rate may be as slow as 45 beats per minute.

7. *Unconsciousness.* A pronounced increase in intracranial pressure with its attendant shifts of intracranial mass may lead to unconsciousness and may progress to deep coma. If it appears suddenly, the possibility of hemorrhage (into the tumor) should be considered; however, this is of infrequent occurrence. More commonly, ventricular obstruction is the cause of the unconscious state.

8. *Miscellaneous Manifestations.* Vertigo and dizziness are frequently produced by an increased intracranial pressure, but on many occasions are focal signs, i.e., produced by lesions involving the eighth nerve, which supplies the semicircular canals. Hiccup, yawning, and sighing respirations are evidences of medullary compression and therefore are usually serious symptoms. Respiratory difficulty of various types may be observed (including cessation). Changes in the blood pressure rarely occur except as an accompaniment of sudden hemorrhage within a tumor, but are more frequently encountered in acute intracranial injury with hemorrhage, as has already been discussed. The presence of increased intracranial pressure over a long period of time produces a thinning of the skull, especially in children, as shown by a "beaten-silver" appearance in the roentgenograms or, more commonly, demineralization of the sella turcica, especially the floor and dorsum.

Important to recognize are the intracranial shifts and herniations which occur with supratentorial masses such as take place at the tentorial incisura. These shifts may cause false localizing signs such as third nerve palsies, hemianopias, hemiparesis, and may also be responsible for severe midbrain compression, hemorrhage, and death.

Focal Manifestations. In order to determine the location of the lesion it is important to determine the presence or absence of the various focal manifestations which are listed

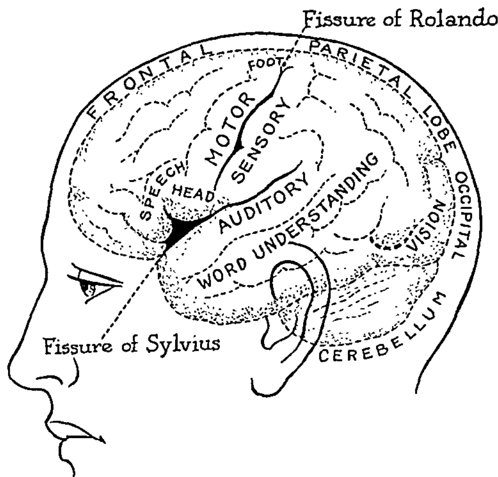

Fig. 12. Diagram of the brain to show its anatomic divisions and a gross localization of some of the important cortical, subcortical centers.

below under the various areas of the brain. Any or all of the general symptoms and signs already described may also be present (Fig. 12).

1. *Frontal Lobe.* One of the most characteristic symptoms of frontal lobe lesions is a change in the patient's personality. The type of change is not always the same, but the development of childish characteristics, a disregard of social propriety, irritability, lack of adaptability, and symptoms and signs of an organic dementia including defective recent memory are commonly observed. Emotional changes, such as the tendency to laugh or cry without ample provocation, are likewise commonly encountered. Unilateral facial weakness and other muscular motor disturbances, particularly of the extremities (on the side opposite the lesion), are usually indicative of a frontal lesion. Pathologic reflexes may be demonstrable; forced grasping is encountered. Speech disturbances, progressing even to complete aphasia, may be present if the lesion is located on the dominant side. Convulsions of the Jacksonian type are particularly common in patients with tumor of the frontal lobe. Anosmia may point to a subfrontal tumor.

2. *Parietal Lobe.* Tumors in the parietal lobe may produce convulsions, but they are usually of the type preceded by sensory aura. Motor deficit can, of course, occur. Sensory disturbances may be present but usually consist of errors in two point discrimination, in which a true hypesthesia does not exist. Astereognosis (inability to identify objects placed in the hand) is occasionally demonstrable. Pathologic reflexes as well as motor and sensory disturbances may be present. Occasionally, aphasia of varied types will be present, but usually only when the tumor is located low down near the fissure of Sylvius.

Deep parietal lesions will produce homonymous visual field defects.

3. *Temporal Lobe.* Lesions in the temporal lobe commonly produce a characteristic defect in the visual field, consisting of varying degrees of homonymous hemianopsia. For example, a patient with a left-side temporal lobe tumor would have blindness on the left side of each retina; this is called a right homonymous hemianopsia because the patient is unable to see objects on his right. Lesions confined to the temporal lobe show a superior homonymous quadrant opsia. Those farther posterior and medially may cause a complete hemianopsia. Hallucinations of smell or taste may occur with deeply placed lesions as may formed and colored visual hallucinations. Temporal lobe seizures may occur and are characterized by repetitive, purposeless, automatic behavior. Facial and upper extremity weakness is often found with temporal lobe lesions.

4. *Occipital Lobe.* Lesions in the occipital lobe commonly produce homonymous hemianopsia which usually does not extend to the center of vision. Visual hallucinations (usually unformed flashing lights) may occur and represent a focal epileptic attack.

5. *Cerebellum.* Ataxia, asynergia, and atonia are characteristic features of cerebellar lesions. When the patient walks there is usually a tendency to fall toward the side of the lesion. Adiadokokinesis (inability to rapidly pronate and supinate the hand) is likewise usually present. Nystagmus is commonly observed. Occasionally the attitude of the head may be characteristic, i.e., flexed toward the side of the lesion with slight rotation so that the chin is pointed to the opposite side. The general symptoms and signs of increased intracranial pressure are usually present to a marked degree when cerebellar lesions are present, because of the obstructive hydrocephalus which is produced.

Knowledge of the sequence and chronology, as well as the tempo of the appearance and progression of signs and symptoms, is indispensable to the diagnosis of mass intracranial lesions. The same may be said of much disease. Progressive mental deterioration, cranial nerve paresis (especially in combination with neighborhood nerves, such as the fifth, seventh, and eighth), progressive motor or speech deficit, involvement of the visual apparatus, and epilepsy of focal or late onset (after 30 years of age)—these are common clues suggestive of an intracranial mass lesion and require full investigation.

Diagnostic Tests. These may be extremely helpful in making a diagnosis and accurate localization of various lesions affecting the brain or spinal cord. Of the various procedures, *spinal puncture* is perhaps most often used. This is performed by having the patient lie in a lateral decubitus position and inserting a needle into the spinal canal, usually through the fourth or fifth lumbar interspace. A pressure reading is always desired; the normal pressure is 80 to 150 mm. of water in adults. Fluid examination for cells and protein, as well as serological tests, is recommended. Spinal puncture is contraindicated in the presence of choked disks.

An effective method of detecting a block in the spinal subarachnoid space is the *Queckenstedt test,* which consists of observations of the pressure while the cervical veins are compressed. If no obstruction is present, the pressure should rise an additional 200 mm. of water promptly with a prompt return. A combined cistern and lumbar puncture will be more effective in discovering a partial block. Such manometric studies are applicable in the study of spinal disease and should not be employed either routinely with all lumbar punctures and certainly not in association with intracranial disease.

Injection of radiopaque substance is frequently used to determine encroachments upon the spinal canal by neoplasms, herniations from intervertebral disks, and the like. Such substances can and should be aspirated from the spinal canal following fluoroscopy and films. Air is enjoying an increasing place in such studies.

Encephalograms are performed by injecting a gas (e.g., air, oxygen, or ethylene) through a lumbar puncture needle with the patient in a sitting position. In this way the subarachnoid space and ventricles are filled with air, and distortions may be noted by the x-ray. The method has risks and should not be employed when increased intracranial pressure with choked disks is present.

Ventriculograms, made by injecting air or oxygen (preferably the latter) into the ventri-

cles, through trephine openings, gives an accurate outline of the ventricles. It is a very valuable aid in the localization of intracranial tumors. However, the procedure is not without danger. In the presence of excessive intracranial pressure, ventriculography is performed rather than insufflation of air through spinal puncture.

Angiography is an equally important diagnostic test and permits visualization of the vascular system via the carotid and vertebral arteries. It is indispensable in the diagnosis of lesions of the vascular tree and is used alone and in combination with the air tests to study all other types of intracranial surgical lesions.

Radioactive isotope technics as introduced by Moore (20), are occasionally helpful in the localization of brain tumors. The radioactive material is detected in the tumor by counting devices.

Apart from the eradication of specific lesions from the brain substance, such as tumor, there are other conditions for which operations on the brain are undertaken:

Epilepsy. This is usually a symptom of a disease process and therapy is directed toward the primary lesion, such as tumor or abscess, and the treatment of the epilepsy is of secondary consideration. In the absence of a progressive disease which in itself may be dangerous to the patient, the treatment of a locally discharging epileptogenic focus may be possible. Such foci may be caused by trauma (often paranatal), developmental deficits in brain structure, acquired focal vascular disease with scarring, cicatrix after tumor or abscess excision. Careful selection of patients with clinical, radiological, and electrical (E.E.G.) evidence of a single focal lesion permits marked improvement from cortical and subcortical resections in cases inadequately controlled by medical management.

Abnormal Movements. Disease processes such as parkinsonism and choreo-athetosis involve complicated neural circuits, details of which are under constant study. As knowledge of the abnormal neurophysiologic integration increases, the surgeon can apply precise technics, such as stereoencephalotomy, to create deeply placed lesions which, by paralyzing one circuit, may balance another and ameliorate the clinical state. The details of one such precise method is described in the monograph of Spiegel and Wycis (21). Others, notably Cooper (22), have utilized less exact methodology to produce successful results in parkinsonism in 60 per cent of cases.

Hypophyseal Destruction. Destruction of the pituitary gland has offered some palliation for metastatic carcinoma, notably of the breast whereby elimination of target organ secretion and some primary secretion by the hypophysis alters the growth potential of the tumor. Pain relief is the most striking benefit achieved. Other conditions have been treated by ablation of the gland, notably juvenile diabetes mellitus for which the operation is at best in its experimental period. The gland is destroyed by direct surgical excision or by irradiation from implanted isotopes placed into the pituitary.

AFFECTIONS OF THE SPINAL CORD

Congenital lesions, such as spina bifida, have already been mentioned (see p. 423). Detailed discussion of these diseases may be found in a publication by Elsberg (23) and Ingraham and Matson (50).

Injuries to the Spinal Cord and Cauda Equina. The spinal cord terminates at the lower margin of the first lumbar vertebra. Below this level the cauda equina occupies the dural canal. Damage to nervous structures occurs in about 10 per cent of all injuries to the spinal canal. In first aid to potential spinal injuries the patient should be handled so as not to alter the alignment of the spine and increase the damage. The neurological findings vary with the site of injury, from the foramen magnum to the coccyx, and with the severity of damage. Bone and/or ligament damage is associated. In the accidents peculiar to civil life we deal usually with closed wounds. In war we deal also with open wounds, but many are fatal because of associated injury to chest and abdomen. Fracture dislocations of the cervical region incurred by diving or in football are common. Compression fractures by crumpling of the spine in acute flexion occur from falls on buttocks and cave-ins in mining accidents.

About 40 per cent of the neurological injuries occur at the thoracolumbar region, particularly at the twelfth thoracic and first lum-

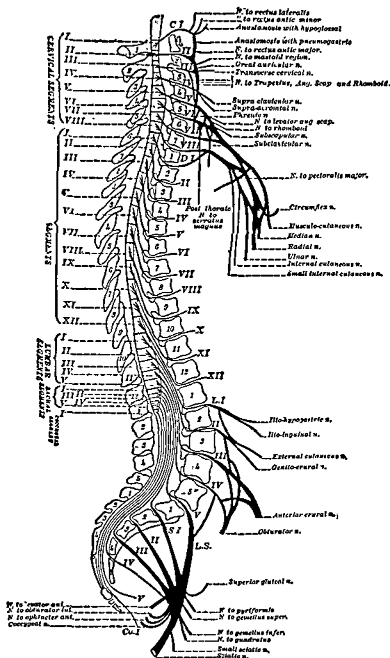

Fig. 13. Relation of the segments of the spinal cord and their nerve roots to the bodies of the vertebrae. (After Frazier and Allen.) Note the progressive upward migration of the cord segments in relationship to the corresponding vertebra. This difference is less pronounced in the infant.

bar vertebrae. Cervical injuries, usually between the fifth and sixth cervical, are next in frequency. In the case of cervical injuries it is not infrequent for severe damage to occur to the cord, and yet x-rays show no evidence of abnormality. *Under such circumstances it* is either an acute extrusion of a cervical intervertebral disc which strikes the cord a blow and produces the paraplegia or a hyperextension mechanism of injury whereby the cord contusion occurs. Any level of the spine may be affected. Dislocation between the atlas and axis and fracture of the odontoid, compression fractures of the thoracic vertebrae, and fracture dislocations of the lumbar vertebrae with caudal injuries are not uncommon. *Much has been learned about paraplegia from* such injuries sustained in World War II.

Morbid Anatomy. The cord may be contused, lacerated, or severed. Hemorrhage, rarely great, and edema follow. Petechial hemorrhages are common. Hemato-

myelia is not frequent. Cavitation following hemorrhage and degeneration appears later and involves several cord segments above and below the injury site (Fig. 13). In direct injuries and penetrations, all grades of trauma may be seen. From missiles, all grades of cord damage may occur, including a physiologic blockade of impulses with a good prognosis (so-called concussion), when the missile has not been in contact with the dura but has struck some part of the vertebra.

Neurological Findings. When the spinal cord is acutely divided there are, below the level of the lesion, complete anesthesia, complete flaccid motor paralysis, loss of all deep reflexes and usually of all superficial reflexes, loss of all bladder control with retention of urine and loss of rectal control. The same picture, but of short duration, may occur if the cord is so damaged as to transmit no impulses past the site of injury. This is called a physiologically complete lesion, although anatomic division may not be present. This phase of "spinal shock" may then recede, leaving the permanent sequela of injury which, if the damage had been severe, may be as complete as in the case of actual cord division. The return of segmental reflex activity signifies the end of spinal shock and the resulting findings may be considered due to structural changes in the cord.

Days to weeks after an anatomically complete lesion, deep reflexes may return and automaticity of bladder and rectum, involuntary movements, and mass reflexes of flexion may occur. In the lesions which are incomplete varying degrees of power, sensation, and some reflexes appear and improvement is slow, continuing over months or years until maximum benefit is obtained.

The upper level of sensory loss and motor paralysis indicates the site of cord injury. Certain major landmarks can be easily remembered. With injuries between the fifth and sixth cervical vertebrae abduction at the shoulder, elbow flexion, and movement of the radial wrist extensor are retained. A sensory level at the ensiform is at the sixth thoracic; the umbilicus is at the tenth thoracic. Injury to the tip of the cord, viz., the conus medullaris, may produce urinary incontinence instead of retention.

That a sensory loss is complete below the lesion can be readily determined if the patient has no sensation on severe flexion of a toe, since deep painful sensation is the last to disappear. The sensory level of the lesion should be promptly noted so that alterations in it may be recognized (Fig. 14). In the examination and detailed x-ray studies, the patient should be spared movements which may exaggerate his cord damage. Lumbar puncture to determine a block (Queckenstedt test) should be performed.

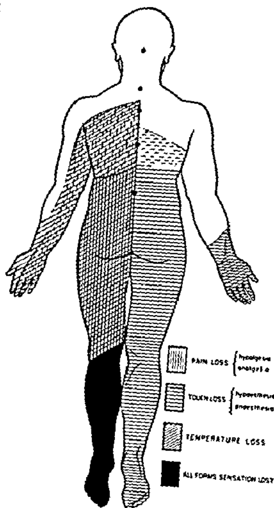

Fig. 14. Sensory charting in spinal cord lesions. Charting of sensory loss using the patterns noted above on plain body diagrams will then permit comparison with various dermatome charts and represent more truthful expression of the deficit.

General Consideration in Prognosis and Treatment. The cord and nerve injury is of more importance than trauma to skeletal structures and requires first thought. Certain axioms are well established. The cord in man

has not evidenced capabilities of regeneration. Certain elements of the cauda equina may regenerate as does a peripheral nerve. *In the first few hours or two or three days, it* may be impossible to differentiate between a cord lesion that is complete anatomically and one that is physiologically complete. If, however, signs of a complete lesion persist longer than this, the lesion may be considered permanent and irrecoverable. Recovery seldom takes place after an injury in which the sensory loss is absolutely complete below the *level of the lesion.*

If, after injury, the paralysis (motor and sensory) is immediate and complete, it may be regarded as permanent. Under these conditions, such operations as laminectomies are misguided efforts. Less severe injuries (incomplete) to the cord may require operation if there is evidence of depressed bone or a positive Queckenstedt, indicating a block. In*complete injuries which become progressively* worse require operation. Intolerable pain may require operation early or late. Operation may be required to unlock overriding facets in fracture dislocations to permit alignment. Skeletal traction for neck dislocations is commonly required. The later man*agement of the skeletal injuries requires* maintenance of the bone and joint alignment by external or internal fixation. Penetrating wounds of the spine require added treatment directed toward débridement and prevention of infection and cerebrospinal fluid fistulas. Evidences of "complete" lesions, yet with *later improvement, may continue longer in* the case of cord concussion than with injury from cord compression or fracture dislocations of the spine.

Nonsurgical Management. These patients are prone to decubitus and urinary tract infections. An air or innerspring mattress, a cradle to remove the weight of bedclothes, smooth, dry sheets, turning every two hours and care of the skin are imperative, beginning at once. Superior care is obtained by the use of pancake turning beds, such as the Foster bed or Stryker frame *which should be provided in all* medical installations treating such cases. Urinary antiseptics should be begun immediately and continued in appropriate doses. In civilian care, tidal drainage methods (Munro) require detailed attention but have proved satisfactory. An indwelling catheter or drainage by a suprapubic catheter introduced midway between pubis and umbilicus is satisfactory *when the above is not practicable.* Emptying the bladder by well-distributed manual compression *may be safe in selected patients* (Browder and Grimes) but not in elderly patients with urinary obstructions and thin vesical musculature. Intermitttent catheterization is justifiable only if carried out as a sterile surgical operation by the surgeon himself. In permanent paralysis an automatic *bladder is desired, and its establishment is* aided by tidal drainage. Ambulation tends to prevent urinary calculi, which develop often in paraplegic patients. Details of spinal cord injuries and their urological aspects may be found in the publications by Prather and Mayfield (24) and Prather (25).

Tumors of the Spinal Cord. Tumors may be primary or secondary. Of the primary *growths about half are benign,* encapsulated, intradural but extramedullary, removable meningiomas or neurilemmomas. If recognized and properly removed, recovery is striking and often complete. The mortality of such operations is very low (under 2 or 3 per cent). Other primary growths may be intra*medullary (gliomas,* ependymomas, angiomas, and the like) or extradural (cysts, lipomas, hemangiomas). Tumors in the caudal region (epidermoids, meningiomas, gliomas, and ependymomas of the filum terminale) may attain giant size. Hour-glass *tumors,* so-called because they consist of extravertebral *portions connected* by a neck through intravertebral foramina or interlaminal spaces, are common. They are most often of neurogenic origin. Oblique x-rays are essential parts of detailed radiographic studies if they are to be recognized. Tumors may *arise in bone* and cartilage, e.g., giant cell tumors, aneurysmal bone cysts, osteoclastomas, osteomata, chondromata, and the malignant chordomas.

Diagnosis of cord tumors, as of brain tumors, involves appreciation of *the fact that* the neurological findings must be explainable *upon the basis of a single, progressing* lesion with, in the later stages, evidence of its space-consuming nature as shown by a positive Queckenstedt test, often with xanthochromic fluid, or obstruction noted after the injection *of radiopaque or radiolucent* substances into

the spinal canal. Pain of a radicular nature, followed by such progressive signs of cord involvement as altered reflexes with sensory changes, is a common finding. The aim of treatment is radical removal by operation. Spinal cord compression may present with a slow tempo of progressive symptoms and signs. If allowed to progress to later phases it becomes a surgical emergency which requires prompt diagnosis and operation to prevent irreparable functional loss. Total clinical paralysis from benign lesions is not incompatible with satisfactory return of function after operation, whereas total paralysis from metastatic malignant disease is rarely if ever benefited. It is of utmost importance, therefore, to discover and treat cord compression before the late stages of paresis.

Secondary tumors, such as metastases from carcinoma of prostate, breast, and pelvis organs, are common. Invasion of the canal occurs in the course of Hodgkin's disease and neoplasm of the hematopoetic system (lymphomas). Granulomas occur, especially in tuberculosis with or without abscess as do parasitic infections and implantations from cerebral tumors (medulloblastomas and other gliomas). Pyogenic abscess is usually extradural and associated with osteomyelitis.

The primary indication for operative decompression in these lesions is developing cord or cauda equina dysfunction from compression. Operation may also be required for pain relief or more rarely for external drainage. The spinal cord may be compressed by an acute collapse of a vertebral body secondary to metastatic disease in which case the cord compression, rather than being due to tumor per se, is due to the bony abnormality. Decompressive operation is frequently indicated in such a case.

Protrusion of an Intervertebral Disk (Nucleus Pulposus). This lesion is responsible in many instances for pain in the lumbar region, and particularly for pain extending down along the course of the sciatic nerve (sciatica). Protrusion of the disk into the spinal canal or intervertebral foramen, with consequent pressure on the nerve roots, is the mechanism responsible for most symptoms. The disks between the fourth and fifth lumbar vertebrae, and fifth lumbar vertebra and sacrum are most commonly involved. Whereas trauma may be an initiating cause or a precipitating factor, a clear history of injury is often lacking. Degenerative changes in the intervertebral disk permit tears in the annulus fibrosus, extension of the nucleus pulposus, and abnormal weight-bearing sprains on the adjacent vertebrae and apophyseal joints. Naffziger and associates (26) emphasize that lifting imposes an enormously increased amount of pressure upon the intervertebral disks because of the leverage action, thereby encouraging damage and protrusion. Other points in the mechanism of the production of the lesion and the pathologic processes are discussed in detail by Hyndman (51) and Falconer et al. (52).

Pain is located over the distribution of the site of the sciatic nerve, being mild at first and becoming more intense as time passes. It may be located in the lumbosacral region, and even in the hip joint. Pain is apt to occur in attacks, it is frequently induced by coughing or sneezing, a feature characteristic of root compression syndromes, whatever their origin. Back pain and extremity pain are the leading symptoms. Limitation of back mobility and aggravation of symptoms by maneuvers which accentuate the protrusion or stretch the involved nerve root are common findings. Neurologic deficit depends upon the nerve root involved and may be slight with a mild weakness and depression of reflex in the segmentally innervated zone. Sensory deficit may be mild. It should be remembered, however, that whereas a unilateral single root syndrome is most common, all degrees of protrusion may occur even to bilateral cauda equina compression, spinal block, and severe neurologic deficit.

It may be difficult to differentiate the condition from a neoplasm of the spinal cord. Lumbar puncture, together with the Queckenstedt test. will be of assistance. The cell count and other spinal fluid findings are relatively normal in nucleus pulposus herniations. The spinal fluid in the presence of a protruding disk frequently has a mild increase in the amount of protein in it. It must be stated, however, that this disease is not the only cause of sciatic pain. Myelography, with the use of radiovisualization contrast technics, is helpful in diagnosis. Electromyographic studies of the involved extremi-

ties give information of muscle electrical potential changes and are useful. Dislocation of the disk is a common cause of upper extremity and neck pain. When severe degenerative disk disease occurs in the cervical area, spinal cord symptoms may develop in the cervical spine (27). A review of these problems is well presented in the monographs of Spurling (28, 29).

Absolute bed rest is often associated with subsidence of symptoms of lumbar disk protrusion and is recommended in the initial attack. Refractoriness to bed rest for two to three weeks, recurrent attacks closely spaced, and moderately severe neurologic deficit are clear indications for operative treatment. In cervical disease, the use of gentle head halter traction is advised initially and operation is reserved for those with the same indications as noted for lumbar protrusions. In their series of 278 patients Spurling and Grantham (29) noted that 85 per cent of operated patients are able to return to work.

Operative Procedures for the Relief of Pain. Severe intractable pain below the costal margins, as produced by malignant tumors and the like, may be eliminated by operative procedures. For this purpose, Spiller and Martin initiated *chordotomy*, i.e., cutting the spinothalamic tracts. The operation is usually performed in the upper thoracic region but may be done in the high cervical area (Fig. 15). Another procedure for the relief of pain, namely, section of the cerebral or spinal nerve roots central to their ganglia of origin, known as *posterior rhizotomy*, is satisfactory in properly selected cases. Prefrontal lobotomy (i.e., section of the frontal lobe) removes the ability to evaluate pain but, if performed on both sides, produces serious changes in personality (30). Precise denervation of most portions of the body with resulting pain re-

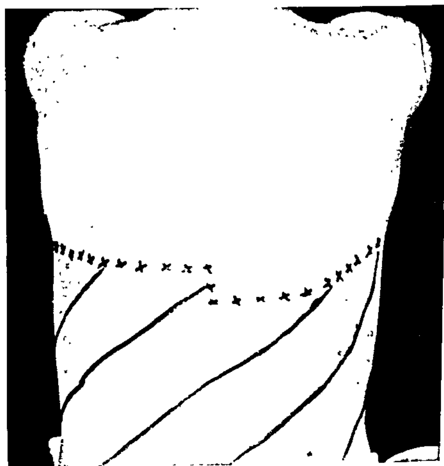

Fig. 15. Thoracic spinothalamic cordotomy. This patient suffered intractable pelvic pain from widespread carcinoma of the rectum. Bilateral anterolateral cordotomy produced complete relief from pain and a level of analgesia as outlined on the trunk. The incision between the scapulae left only a slight scar. (From Stern. California Med., 83:68, 1955.)

lief can be obtained by operations at hand. Bilateral facial pain and upper extremity pain remain exceptions to this, although high cervical cordotomy for upper extremity pain may be gratifying as reported by Horrax and Price (53). Patients should be offered the benefit of appropriate relieving procedures before the ravages of disease become too advanced. The oft-occurring destruction of personality following lobotomy is to be avoided unless addiction is present and pain relief cannot be hoped for from the more precise procedures. Details of mechanisms and control of pain may be found in the monograph by White and Sweet (31).

THE AUTONOMIC NERVOUS SYSTEM

The nerve cells and fibers comprising the autonomic nervous system are concerned in general with the control and regulation of the so-called involuntary or automatic functions of the body—such as the heart activity, in-

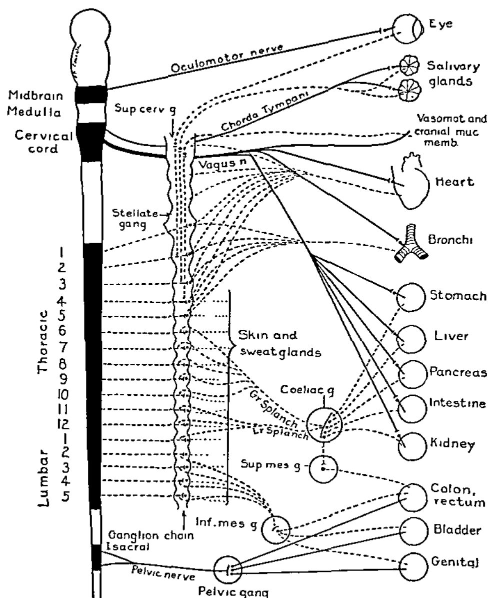

Fig. 16. Schematic drawing illustrating the components of the autonomic nervous system. The solid black lines indicate the craniosacral or parasympathetic nerves, whereas the broken lines indicate the thoracolumbar or sympathetic nerves. (Modified from Kuntz, Autonomic Nervous System, Lea & Febiger.)

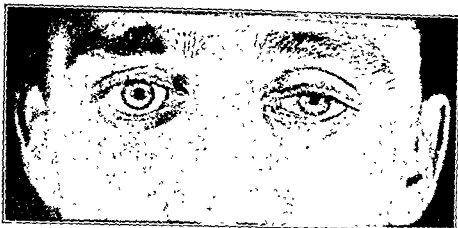

Fig. 17. Horner's syndrome (left eye) produced by gunshot wound injuring the left cervical sympathetic chain. The two important signs of Horner's syndrome, namely, constricted pupil and drooping of the upper eyelid, were present in this patient. Narrowing of the lid slit in Horner's syndrome leads to the false impression that an enophthalmos is present.

testinal movements, respiration, glandular secretion, vasomotor caliber, and sweating (Figs. 16, 17). It should be emphasized, however, that many of these involuntary functions (particularly digestive and endocrine) are also influenced by hormones of various types. Of great importance is the fact that in its control of important and vital visceral functions, the autonomic system is greatly influenced through the emotional states and through the stresses and strains to which the individual is exposed in his work and play. This important influence is not only able to produce *abnormal function* with its resultant symptoms but is probably able to initiate definite organic visceral and peripheral disease which are of great surgical interest and importance. Of great clinical importance, too, is the fact that the autonomic nerves carry impulses of visceral pain, which is discussed later in this chapter, and can frequently be abolished by severing the appropriate fibers. Though the autonomic system is a complex ramification of nerve cells and fibers, there are certain general anatomic features which are simple. One may identify three elements in the autonomic system aside from their central sources in the brain and cord; 1. fibers (preganglionic) which connect these centers with 2. ganglion cells outside the central nervous system and 3. fibers (postganglionic) which connect these ganglion cells with the end organs. The automatic system is usually divided into two groups: (*a*) the sympathetic or abdomino-thoracic-cervical chain (thoracolumbar outflow), and (*b*) the parasympathetic or craniosacral group. These two divisions have a different segmental origin and have antagonistic functions, as will be mentioned below. (It should be noted that the word sympathetic is often loosely used as an all-inclusive term synonymous with autonomic. It is used in this chapter to designate only one part of the system as opposed to its complementary part, the parasympathetic.)

Because of the antagonistic character of the functions of the two systems (sympathetic and parasympathetic) it is obvious that a clear conception of the disease processes associated with these systems is dependent upon an accurate anatomic discrimination between the two. The fibers of the two systems may be identified separately at the points of origin, but distal to the prevertebral ganglia (celiac, pulmonic, and so forth) this is impossible.

The *sympathetic chain* is so-called because its ganglion cells are arranged in a chain on each side of the vertebral bodies in the form of tiny ganglia which are called paravertebral ganglia. In general, the fibers entering the ganglia are called preganglionic or white rami communicantes, and those leaving are called postganglionic or gray rami. In the neck there are three pairs of ganglia: the superior, the middle, and the inferior cervical, and in the thorax, twelve, one for each segment. Occasionally the inferior cervical and the first thoracic ganglia are united into one, which is

known as the stellate ganglion. In the lumbar region, the number of ganglia on each side is variable, but usually four.

The sympathetic fibers supply the various viscera via special nerves and plexuses. The innervation of the heart (sensory as well as motor) is derived from the cardiac plexus which receives the superior, middle, and inferior cardiac nerves (from the superior, middle and inferior cervical ganglia respectively) and also thoracic cardiac nerves from the first to the fifth thoracic ganglia. In addition to these fibers the cardiac plexus receives branches from both vagi (parasympathetic). The celiac (solar) plexus, which surrounds the celiac artery and overlies the aorta at this point, is the most extensive of the prevertebral plexuses. It is supplied primarily by the greater splanchnic nerve which is formed by the union of fibers from the fifth to the ninth or tenth thoracic ganglia. However, the celiac ganglion also receives parasympathetic fibers (from the vagus). There is a series of small plexuses, including the aortic, ureteral, hypogastric, and iliac, which are for the most part extensions of the celiac plexus lying in approximation with the aorta. The abdominal organs are innervated by this series of plexuses, but also receive parasympathetic fibers from the vagi, some of which enter the plexuses and some of which do not.

The sympathetic fibers going to the periphery (skin, muscle, blood vessels, sweat glands) are distributed largely through somatic nerves, i.e., the peripheral (spinal or cranial) nerves which carry voluntary motor and ordinary sensory impulses as well. The sweat glands (supplied only by the sympathetics) comprise one of the few organs which definitely do not appear to have also a parasympathetic innervation.

The *parasympathetic system*, which consists primarily of the craniosacral portion of the autonomic system, innervates, by means of the vagus and pelvic nerves, practically all the thoracic and abdominal organs which likewise have a sympathetic innervation. As mentioned in the preceding paragraph, the thoracic and upper abdominal organs receive their parasympathetic innervation by the vagus nerve which supplies fibers either directly or by traversing the prevertebral ganglia. Shortly after piercing the diaphragm, the vagus nerves divide into three main divisions: left, middle, and right. The left and middle branches of the left vagus innervate the fundus and pyloric region of the stomach, respectively, and the right branch passes to the liver. The left and middle branches of the right vagus go to the stomach, but the right enters the celiac ganglion (Kuntz, 32). Within the wall of the digestive tube are two systems of plexuses (the submucous or Meissner's and the myenteric or Auerbach's) which are associated with peristalsis and glandular secretion. The nerves supplying these plexuses are preganglionic, arising from the vagus and sacral nerves. The pulmonary plexus which distributes fibers to the lungs (particularly the bronchi) is really continuous with the cardial plexus, but consists primarily of vagus fibers. The pelvic nerve arising from the sacral nerves is distributed to the distal part of the colon, the bladder, and perhaps to parts of the genital system.

Functions of the Autonomic System. These are manifold and for the most part motor (efferent), but also include sensory (afferent) impulses which are important in initiating reflex activity and the sensation of visceral pain which, as mentioned previously, is frequently referred to skin areas. The sensory impulses that, of course, reach consciousness pass over afferent fibers which, strictly speaking, do not belong to the autonomic system but belong to the cerebrospinal system and are merely in the same nerve trunks (such as the splachnic nerves) with the efferent fibers. These sensory fibers have their cell stations in the posterior root ganglia as do all other somatic sensory fibers. Motor function is of two kinds, excitatory and inhibitory. A functional or physiologic balance between these two activities is maintained by the opposing innervation of the sympathetic and parasympathetic systems, with one or two exceptions (e.g., the sweat glands), which is controlled in part by the higher centers (anterior hypothalamus parasympathetic and posterior hypothalamus sympathetic).

Motor Functions. The motor functions of the *sympathetic system* as contrasted to the parasympathetic system comprise acceleration of the heart rate, arterial constriction, inhibition of intestinal peristalsis and secre-

TABLE 1. The Balanced Motor Function of the Autonomic System

Organ		Sympathetic	Parasympathetic
Heart (rate)		Acceleration	Slowing
Intestines	peristalsis, secretion	Inhibits	Stimulates
Anal sphincter		Contracts	Relaxes
Urinary bladder	wall	Relaxes	Contracts
	sphincter	Contracts	Relaxes
Eye	pupil	Dilates	Constricts
	lid slit	Widens	Narrows
Arteries		Constricts	Dilates (?)
Sweat glands		Stimulates	——
Bronchi		Dilates	Constricts

tion, contraction of the bladder and anal sphincters, and so forth (Table 1). There is considerable evidence that sympathetic stimulation through excitation of the adrenals causes contraction of the spleen with consequent outpouring of blood. It is likewise responsible for the outpouring of epinephrine which occurs during excitement. Epinephrine has, in general, an action similar to that of the sympathetic nerves, i.e., it is responsible for liberation of glucose from the liver, for increases in the heart rate, and inhibition of digestive secretion. The sympathetic system is important in the maintenance of vital processes of the cells of skeletal as well as smooth muscle, and has a definite effect on muscle metabolism (Kuntz, 32). Years ago, Cannon emphasized the fact that the bodily functions which are stimulated by the sympathetics are those necessary for the efficient mobilization of forces and energy, which are required in times of stress (mental as well as muscular, but especially the latter). Important also in this way are the emotional states, such as fear and rage.

The motor functions of the *parasympathetic system* include such activities as slowing of the heart rate, excitation of the digestive glands, intestinal peristalsis, contraction of the bladder and rectum, along with relaxation of their sphincters, and the like (Table 1).

Sensory Function. Although of less physiologic significance than the motor, the sensory function of the fibers, which are anatomically associated with the autonomic nervous system, is nevertheless important. For example, the integrity of many reflex arcs is dependent upon sensory stimulation. Moreover, visceral pain is obviously dependent upon afferent fibers for transmission and may be eradicated by severance of these fibers which travel in anatomic trunks. Visceral pain may be intense but because of the relative sparsity of nerve ending population in the viscus compared with somatic structures, and so forth, is poorly localized; because of this fact it is often referred to parts of the body other than its site of origin (Fig. 18). In addition to visceral pain, the sensory fibers may carry impulses which reach consciousness and are perceived as discomfort, or fullness, and the like: in many hypersensitive individuals impulses due to normal peristalsis are perceived. The various types of visceral sensation are important in the diagnosis of abdominal disorders, particularly those of nonorganic or functional nature.

Additional data on the anatomy and physiology of the autonomic system may be found in the books by Larsell (33), Kuntz (32), and Ranson and Clark (34).

Disorders of the Autonomic Nervous System. There are a number of diseases whose pathogenesis is associated, at least to a great extent, with dysfunction of, or perhaps a lack of balance between, the sympathetic and parasympathetic nervous systems, even though the exact relationship in most instances is poorly understood. They are discussed in detail in the monograph by White, Smithwick, and Simeone (35).

Megacolon (Hirschsprung's Disease). This disease, consisting primarily of marked dilatation of the colon, is a congenital lesion starting soon after birth or in early infancy. It must be differentiated from acquired megacolon which usually does not occur until the

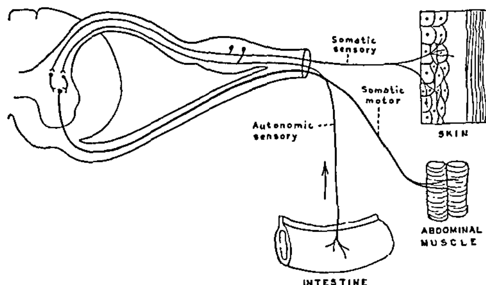

Fig. 18. The nerve pathways producing referred pain and involuntary muscle spasm. The impulse originates in the intestine or other viscus and travels along the autonomic sensory fibers (indicated by the arrow) to the central nervous system. Here it reaches ganglion cells which normally are excited by impulses reaching them over somatic pathways entering the central nervous system at the same level. The pain is experienced as coming from the region supplied by these somatic fibers. The activation of these central sensory cells provokes reflex muscular contraction by way of the somatic motor nerves; this reaction is called involuntary muscle spasm.

age of two or more years. Although absence of ganglion cells of the myenteric plexus was suggested years ago (Cameron, 1928) the major credit for solution to the various problems of this disease should go to Swenson (36) because of the curative operation which he has devised.

The patient may have few symptoms in spite of the fact that the dilatation may be enormous and affect the entire colon. Constipation is, of course, universally present except that diarrhea caused by expulsion of fluid contents of the ileum around the solid impacted fecal masses in the colon may occasionally develop. Very little pain is experienced in spite of the fact that peristalsis may be very vigorous indeed. The degree of abdominal distention varies with the degree of dilatation of the colon. Symptoms including headache, nausea, and vomiting occur occasionally but are rare. In neglected cases, severe malnutrition may develop. Rectal examination is negative; the fecal mass itself cannot be felt (except through the walls of adjacent loops of colon). This finding helps to differentiate the lesion from acquired megacolon in which condition the fecal mass is palpable just inside the anal sphincter. Passage of the fecal material into the rectum is prevented by a functional obstruction located in the upper rectum; this obstruction is caused by faulty peristalsis resulting from absence of the ganglion cells. The dilated colon ends in a narrow segment, usually of upper rectum, which can be identified as the point of the obstruction radiologically by barium enema (Fig. 19), providing films are taken in the proper plane.

Treatment, as advised by Swenson, consists of resection of the aganglionic area (from the rectum to well above the narrowed segment even to the splenic flexure) and anastomosis of the proximal colon to the rectal stump just above the sphincter; this is best accomplished by a pull-through type of procedure which places the anastomosis just above the sphincter, but preserving it. Results are excellent in 80 to 90 per cent of cases, provided the diagnosis is accurate. The danger of giving tap water enemas in provoking "water intoxication" has been mentioned on p. 160.

Vascular Disease of the Extremities. These diseases have already been discussed in

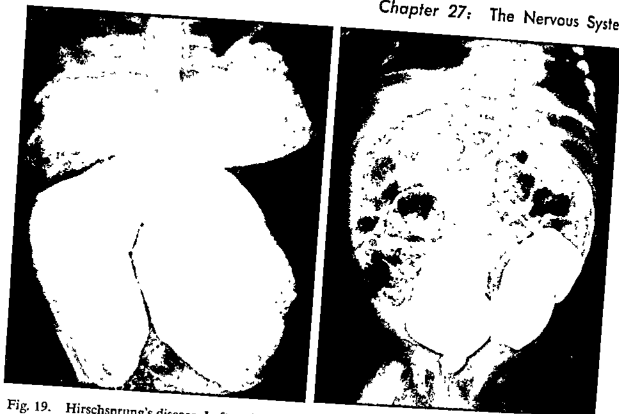

Fig. 19. Hirschsprung's disease. Left, redundant dilated colon is revealed by barium enema. Right, after partial evacuation of the barium. The constricted segment of upper rectum is outlined by the barium.

Chapter 25. In Raynaud's disease, particularly, it is assumed that vasoconstriction of the smaller vessels, produced presumably by overstimulation of the sympathetic system, is an important factor in the pathogenesis of the disease. It is thought by some that the fault is a local one in the vessels themselves in that patients suffering from Raynaud's disease have been found to be unusually sensitive to adrenalin. It should be emphasized, however, that in many instances organic obstruction of the vessels also exists as a late manifestation. On the other hand, in patients with definite organic changes in the vessels, such as Buerger's disease, vascular spasm often plays an important role. Insofar as vasoconstriction is present in some patients with obliterative vascular disease, a disorder of the autonomic system is assumed also to be present. The various diagnostic methods have been discussed in Chapter 25.

Carotid Sinus (Body) Syndrome. The carotid sinus, which exerts a reflex regulatory effect on the blood pressure and heart rate, has connections with the vagus nerve, the cervical sympathetic chain, and the medulla through a branch of the ninth cranial nerve. It may become hypersensitive and give rise to symptoms. Manifestations consisting of weakness, dizziness, fall in blood pressure, and unconsciousness with or without convulsions, occur in attacks. Pressure over the bifurcation of the carotid may reproduce an attack. The cardio-inhibitory reflex which is mediated through the vagus nerve can be abolished by atropine. However, correction of the cerebral type requires excision of the periarterial tissue at the carotid bifurcation.

Tumors of the Carotid Body. These lesions are comparatively rare, but are important because many are malignant or potentially so, yet are associated with a good prognosis when completely removed. It is often very difficult to differentiate benign from malignant lesions microscopically. Most of them produce no symptoms other than gradual growth of the tumor. Despite their location at the carotid bifurcation, these tumors rarely produce symptoms of the carotid sinus syndrome; fainting is rare. Clinically, it may be difficult to differentiate these tumors from a branchial cleft cyst. However, they are located deeper in the neck than branchial cysts and frequently project into the pharynx,

sometimes producing obstructive symptoms. Accordingly, they are best palpated bimanually, with one finger in the mouth. Complete removal of the tumor will require ligation of the internal carotid in about half the cases. Since ligation of the internal carotid can be associated with hemiplegia and death (particularly in the older group), excision of the tumor may at times be undesirable, particularly since no more than 10 per cent of these tumors are malignant. Unfortunately, however, experience shows that even benign tumors ultimately lead to death of the patient in a large percentage of cases. To reduce the risk of carotid ligation it used to be customary to compress the vessel for a period every day for several days to help establish collateral circulation before operation. This procedure was seldom effective. However, since blood vessel grafting can now be carried out so successfully, operation is no longer hazardous and is carried out with little reservation. A homologous (preserved) arterial graft or synthetic prosthetic tube thus permits safe removal of the tumor, even if resection of the carotid is required. Details may be found in an article by Lahey and Warren (37).

MISCELLANEOUS DISORDERS. It is possible that many of the disorders of intestinal peristalsis, including especially spastic colon, as discussed in Chapter 31, are due to an imbalance of the sympathetic and parasympathetic innervation, resulting, perhaps, in a defective peristaltic mechanism.

Scleroderma, a rare disease, is assumed by many to be due to a derangement of the sympathetic nerve supply to the skin. Manifestations consist of the deposition of a dense fibrous layer beneath the skin, associated with a sclerosis of the smaller arteries. The skin may become pigmented, the extremities cyanotic, and the face masklike. Edema is usually present but is not of the pitting type. The outcome is frequently fatal, but sympathetic neurectomy has been devised for certain types of the disease.

OPERATIVE PROCEDURES UPON THE AUTONOMIC SYSTEM. Perhaps the earliest significant operation upon the autonomic nervous system was performed by Jaboulay (38), who resected the cervical sympathetic chain and ganglia for exophthalmic goiter. This procedure has, of course, been supplanted by subtotal thyroidectomy and medical treatment (radioactive iodine). A few years later, lumbar sympathectomy was recommended (Royle) for spastic paralysis of the lower extremity, but results are not good. Sympathectomy was also recommended (Leriche) for *scleroderma,* asthma, and a type of polyarthritis with vascular deficiency to the extremities. Sufficient reports are not available to determine the efficacy of the operation in these diseases. Lumbar sympathectomy combined with excision of the presacral plexus is quite effective in the treatment of various types of *pelvic pain,* especially those of uterine, tubal, and ovarian origin. Section of the appropriate sympathetic nerves has been successfully performed for *localized hyperhidrosis.* Sympathectomy is fairly efficient in relieving the shortening, atrophy, and cold skin of a limb paralyzed by *poliomyelitis.* Presacral neurectomy is sometimes performed (Learmonth) for *spasm of the neck* of the bladder in "cord bladders." Pudendal nerve block or section may be a superior procedure.

Periarterial sympathectomy was popularized by Leriche in the treatment of spastic vascular disease of the extremities but cannot be considered logical since the nerves supplying the vessels enter at numerous points and do not traverse the entire length of the artery. On the other hand, sympathectomy (i.e., removal of ganglion or preganglionic fibers) is a well-established procedure. The better results which are being obtained are produced by a more accurate choice of patient for operation and improvements in operative principles. The indications for sympathectomy in vascular diseases may be summarized to include Raynaud's disease when there is no marked structural damage to vessels, Buerger's disease (except in the acute stage) when good collateral reserve is present, vasospastic painful limbs resulting from poliomyelitis, causalgia (including Sudeck's atrophy) arterial emboli, arteriovenous aneurysms, hyperhidrosis, and certain cases of early gangrene due to arteriosclerosis. It is usually preferable first to demonstrate a favorable effect with local anesthetic injection of the sympathetics, as noted by skin temperature or oscillometric readings, before sympathectomy for this condition. In the upper extremity,

section of the whole rami from the second and third thoracic nerves (Telford) and removal of the proximal segments (Smithwick) of the second and third thoracic nerves, i.e., preganglionic section instead of sympathectomy has been effective, as long as the sympathetic trunk below the third thoracic ganglion is sectioned. Improved results, however, are obtained when the ganglionated chain itself is excised; *although entailing the production* of Horner's syndrome, it does not in man sensitize the end organs to circulating epinephrine as was thought earlier. An important concept of the pupillary fibers' anatomy as related to thoracic sympathectomy is presented by Palumbo (54). In the lower extremity, it is now agreed that removal of the sympathetic trunk with the lumbar ganglia as performed with very little modification for the past several years is an effective procedure in the various vascular lesions mentioned above. The good results are due for the most part to the vascular dilatation obtained, including particularly that of the collateral vessels.

Blockage of the cervical sympathetics by *injecting the stellate ganglion* may be beneficial for selected cases of cerebral thrombosis and cerebral embolism (Gilbert and de Takats, 39; Naffziger and Adams, 40). Paravertebral injection of thoracic nerves is useful in the treatment of the *pain caused by aneurysms and aortitis*. Gage (41) has reported relief of pain and more rapid recovery in acute pancreatitis after paravertebral block of the sympathetic chain. Splanchnic nerve section may be quite effective in the relief of pain caused by chronic pancreatitis. The hypogastric plexus may be removed for intractable pain arising in the bladder or internal sex organs, the lumbar sympathetic chain for painful vascular lesions in the lower extremities, and the cervical or thoracic system for angina, causalgia, or certain types of vascular pain. When disease of viscera and vascular systems involves also the somatically innervated structures, as is usually the case with malignant neoplasms and so forth, sympathetic blockade or section will fail to produce complete pain relief. *Success with cases* of locally confined disease by such blockade is reviewed by Trimble and Morrison (42).

Although not all surgeons performing sympathectomy for *essential hypertension* report good results, the majority do. De Takats and associates (43) report 85 per cent good results in 55 patients in Group I (age below 40 years) who had minimal organic damage with diastolic pressure occasionally above 100 mm. Hg. In 123 patients in Group II (age from 20 to 55 years) with moderate vascular sclerosis in all organs and a diastolic pressure *which could* not be *lowered below* 110 mm. Hg by any method, good results were obtained in 75 per cent of cases. In 24 patients in Group III with retinal hemorrhages, papilledema, fixed diastolic pressure of more than 120 mm. Hg and poor renal function, there were no good results. Zintel and associates (44) report similar results. In their series the five-year survival rates were as follows: Group I, 100 per cent; Group II, 85 per cent; Group III, 86 per cent; Group IV, 63 per cent; and Group V, 45 per cent. They conclude that survival rates are good enough even in Groups IV and V to justify sympathectomy for patients in those groups. Over half the patients having sympathectomy for hypertension have definite improvement in symptoms; *headache is the symptom most* improved after operation, having disappeared in over 90 per cent of Learmonth's series (15). The hypertension may decrease, but in few patients does it reach normal (Evelyn and associates, 45). Postural hypotension is *perhaps the most significant disadvantage of* the operation, being particularly troublesome for the first few months; it may be prevented to some degree by belts or pads worn around the abdomen.

In the surgical treatment of *essential hypertension*, numerous technics have been adopted, but the method recommended by Smithwick (46) appears to be superior to others. De Takats (43) reports his best results in "the post-eclamptic or post-toxemic type of hypertension in women who obviously had organic vascular disease." He likewise obtained good results in "the early juvenile type of hypertension with minimal or not detectable organic changes and with complete response to sedation." Results were good in the latent nephritic type of hypertension. However, results were poor in the malignant phase or the late benign phase of hypertension *with rigid arteries*. In selected

cases of unilateral renal disease complicated by hypertension, nephrectomy may be effective in lowering the blood pressure. The introduction of *blood-pressure reducing drugs* has greatly reduced the number of patients with hypertension seeking operative treatment. A survey of the clinical groupings and the results of operation compared with nonsurgical treatment in 2,227 cases followed five or more years is presented by Smithwick and associates (47). The selection of patients for operation is best made from those with intermediate grades of severity of disease in the cardiac, renal, and cerebral vascular systems and function. The 10-year follow-up of White (48) demonstrates that the methods of 10 years ago applied to comparable patients was less satisfactory than sympathectomy of the Smithwick variety. This is the case in the so-called "Goldblatt" kidney described by Goldblatt years ago.

It must be apparent from the great diversity of operative procedures noted above, that much remains unknown of the anatomy and physiology of the autonomic system. Predictable results following severance of specific fibers must depend on specific knowledge of the impulses they carry. This type of investigation will undoubtedly contribute greatly to the surgery of the sympathetics in the years to come and will extend the field of many other types of disease.

LIVER, GALLBLADDER, AND BILE DUCTS

Liver
Gallbladder
The Bile Ducts

LIVER

The liver is the largest organ in the body and, perhaps, performs more functions than any other organ. It is necessary for life; its removal results in death of the animal within 24 hours.

Anatomy. There are two major lobes, the right being much larger than the left. On the inferior posterior surface is an area designated as the quadrate lobe; on the posterior surface is a small lobe identified as the caudate lobe (Fig. 1). The hepatic artery branches into the right and left before entry into the inferior surface of the liver. The portal vein divides in 90 per cent of cases

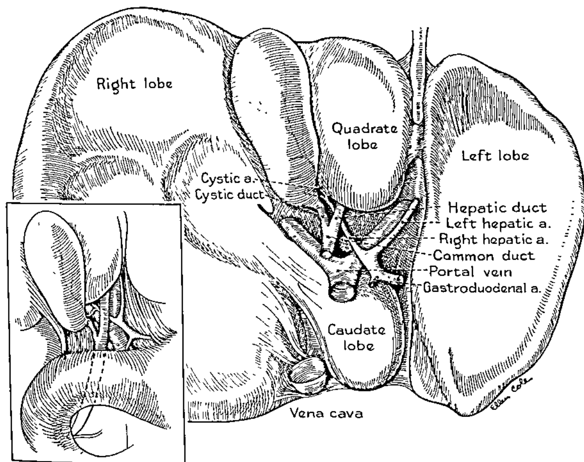

Fig. 1. Anatomy of the ventral surface of the liver.

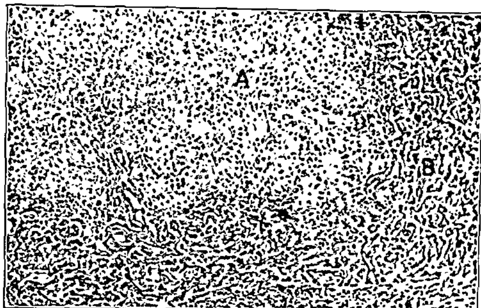

Fig. 2. Photomicrograph (biopsy from operation) to illustrate the remarkable regenerative power possessed by the liver. The patient had been jaundiced for several weeks because of an accute hepatitis of unknown etiology. Represented at A are recently regenerated cells; the portion of the section marked B represents a compressed mass of bile ducts and remains of necrotic hepatic cells. In the process of hepatic necrosis, the bile ducts are the last to be destroyed; the deeper staining tubular structures probably represent newly regenerated bile capillaries. It is probable that considerable fibrous tissue will be deposited in this area, B, and in time, the liver will present a picture like that of cirrhosis.

before it enters the inferior surface of the liver; in the remainder of cases it enters the liver before dividing. The reverse is true for the common duct, inasmuch as the right and left intrahepatic ducts join in 90 per cent of cases before leaving the liver surface.

Physiology. Over 40 functions are known to be performed by the liver (1); no doubt there are many, many more unknown. The liver probably has a wider margin of safety from the standpoint of the amount of tissue necessary for the performance of its functions than other organs, but this wide margin of safety is obviously necessary in times of stress, such as illness and excessive exertion. It is one of the few organs which has the power to regenerate rapidly after injury (Fig. 2). For example, Mann and associates (2) and others have proved that after removal of 70 per cent of an animal's liver, regeneration takes place so rapidly that the normal size is regained within a few weeks following removal.

1. *Carbohydrate Metabolism.* Our knowledge of this important function of the liver was initiated by Claude Bernard in 1857. The liver is able to form glycogen (a carbohydrate) from various other substances, such as hexose sugars, lactic acid, and pyruvic acid (glycogenesis), and is able to produce glucose from glycogen (glycogenolysis). The liver is an important storehouse for glycogen —a ready source of energy. The liver is also able to form glycogen from substances other than carbohydrates, such as amino acids and glycerol fractions of fats (glyconeogenesis).

2. *Secretion of Bile.* The average daily output of bile varies between 600 and 800 ml. per day. It contains bile acids and salts, bile pigments, nucleoproteins, lipids, various electrolytes, urea, ammonia, vitamines, enzymes, and innumerable detoxified or conjugated substances.

3. *Protein Metabolism.* Amino acids resulting from digestion in the intestinal tract are carried to the liver where they are stored and converted to proteins or deaminated. The parenchymal cells of the liver are the primary sites of formation of plasma proteins, such as albumin and fibrinogen; plasma globulins are formed by the Kupffer cells. The amino acids not required for protein synthesis are broken up by splitting off the amino groups—NH_2 (deamination); certain amino acids, such as leucine, isoleucine, and tyrosine, are oxidized as fats. The split-off amino groups are con-

verted to urea, most of which is excreted in the urine as waste. The presence of xanthine oxidase (an enzyme necessary for production of uric acid from nucleic acid or nucleoprotein) in the liver suggests that uric acid may be formed primarily in the liver.

4. *Metabolism of Vitamins.* Carotene in the ingested food is converted into vitamin A by the liver, which also stores it. The liver is probably responsible for the phosphorylation of thiamine to thiamine pyrophosphate, an important coenzyme. Bile is necessary for the proper absorption of vitamin D, which is stored to a slight extent in the liver. Vitamin K is utilized by the liver in the synthesis of prothrombin, which is necessary in the process of blood coagulation.

5. *Fat Metabolism.* The liver forms cholesterol and is concerned with the esterification of free cholesterol. In certain liver diseases the power to produce cholesterol ester is lost. Fats are transported in the body partly as phospholipids, which are formed in the liver and intestinal mucus (3). If certain substances are not available, the liver is unable to form phospholipids and neutral fats are deposited in the hepatic cells. Lecithin, the most abundant phospholipid, is formed in the liver. Fatty acids are oxidized by the liver to ketone bodies. About one third of the carbohydrate brought to the liver by the portal system is converted into fat (lipogenesis).

6. *Blood Formation and Coagulation.* In fetal life, the liver is active in the formation of erythrocytes, but in the postnatal period, this function is lost. The liver is the primary site for the storage of iron, copper, and other products necessary for the production of hemoglobin and erythrocytes. As noted above, the liver synthesizes prothrombin (from vitamin K) and stores it. Likewise, it forms heparin, which is important in preventing intravascular clotting. The importance of the liver in hematopoiesis is clearly demonstrated by the effect of liver extract on pernicious anemia.

7. *Detoxification.* Harmful products may be detoxified by oxidation or reduction by the liver or by combination with other products to form a less harmful product (conjugation). The sulfur liberated from proteins in the food is converted to inorganic sulfate. Bacterial action on certain products of digestion may produce toxic substances—such as phenol (from phenylalanine and tyrosine), indole, and skatole (from tryptophane). The liver conjugates these substances with inorganic sulfate to form ethereal sulfates which are excreted in the urine.

8. *Reticuloendothelial Function.* The Kupffer cells (part of the reticuloendothelial system) of the liver are able to engulf and destroy numerous organisms which may be brought to it from the intestinal tract by way of the portal venous system. The Kupffer cells are active in the destruction of erythrocytes and formation of bile pigment. These cells may also aid in the reparative processes in the liver by means of fibroblastic activity. By means of the gamma globulin produced by the Kupffer cells, the liver aids greatly in defense of the body against infection.

9. *Miscellaneous Functions.* The liver is important in the alteration of blood volume since it can store large quantities of blood. It can exert a role on body fluids because it inactivates (by conjugation) estrogenic steroids and the antidiuretic principle of the pituitary gland. The liver exerts an important role in the regulation of osmotic pressure because it is responsible for formation of albumin and a large portion of the globulin in the blood. Urobilinogen is converted to bilirubin by the liver. Porphyrins are excreted by the liver.

Injury. Although the liver is partially protected by the lower portion of the thoracic cage, it is frequently lacerated, with resultant hemorrhage and escape of bile into the peritoneal cavity. Since the liver is a bulky organ, and somewhat friable, it is commonly damaged by blunt trauma. In a small series of 18 cases of hepatic injury studied by Musselman and associates (4), over half were sustained by blunt (nonpenetrating) trauma. In half of them fractured ribs were present.

Manifestations. Pain is fairly common, although it often is produced by rib and soft tissue injury. Occasionally it is referred to the right shoulder. Over half of the patients will be in shock when they arrive in the emergency room; the cause of this shock is hemorrhage and/or bile peritonitis, the latter being caused by the bile escaping from the severed bile ducts. Hemorrhage alone may cause the shock, but a collection of bile in the peritoneal cavity is alone enough to cause it; bile is

irritating, causing a chemical peritonitis and an exudate of plasma into the peritoneal cavity with resultant decrease in blood volume and often a drop in blood pressure. Although three fourths of the patients studied by Musselman (4) had tenderness and muscle spasms in the right upper quadrant, it must be remembered that occasionally very few local signs are present; the presence of local signs may be explained by damage to a minimal number of bile ducts and minimal soft tissue injury. Nausea and vomiting are uncommon. At times, abdominal distention and areas of dullness with or without a mass (massive blood clot) may be encountered. If the diagnosis is in doubt, aspiration of the peritoneal cavity with a syringe and needle may yield blood and reveal the diagnosis.

TREATMENT. If a laceration of the liver is suspected and the evidence of bleeding does not disappear after two or three units of blood and the lapse of a few hours, celiotomy will be indicated. If the hemorrhage (with or without the escape of bile) has been severe enough to produce shock, immediate operation is indicated (after procurement of several donors) because bleeding from the liver that has been severe enough to produce shock will rarely stop spontaneously. Moreover, even if it did stop, there is usually ample indication for operation because a tear deep enough to produce severe hemorrhage is invariably associated with severence of bile ducts of sufficient size to give rise to bile peritonitis, which so often leads to bacterial peritonitis unless the bile is removed. In the operation, the laceration should be repaired by suture. Actively bleeding vessels can usually be tied or controlled by mattress sutures in the liver; if they cannot, application of gelfoam and use of sutures extending through the liver on each side of the laceration will usually be adequate for control of bleeding. The abdomen should be explored thoroughly for evidence of other injuries requiring operative therapy. Drainage of the abdominal cavity is indicated in all severe lacerations of the liver to prevent accumulation of bile in the peritoneal cavity from postoperative leakage at the site of injury and repair.

Hepatitis. The term hepatitis is an inclusive one and comprises various types of inflammations of the liver, which may be classified roughly into those produced by chemicals and those produced by various types of infection. In many instances, however, the etiology of hepatitis, particularly the noninfectious type, is unknown.

Whether inflicted by chemicals or bacteria, the injury may be difficult to detect microscopically. Frequently, nothing more than a cloudy swelling is noted, but there is no doubt that considerable damage to the function of the cell may be sustained without revealing microscopic change. On the other hand, the damage may be so severe as to cause necrosis of the cells without producing very serious clinical manifestations. This, no doubt, happens frequently, but the remarkable power of cellular regeneration in the liver replaces the damaged cells very rapidly.

TYPES OF HEPATITIS. As already mentioned, two general groups of hepatitis are recognized: (*a*) chemical (toxic) and (*b*) bacterial (infectious). In a few cases, however, both mechanisms may play a role. It is possible also that other types of etiologic agents may be responsible in obscure cases.

(*a*) *Chemical or toxic hepatitis* is likewise known as acute hepatic necrosis, originally designated as acute yellow atrophy by Rokitansky (1842). Numerous chemicals, including arsenic, chloroform, atophan (cinchophen), sulfonamides, carbon tetrachloride, and carbon bisulphide, have been identified as etiologic agents (Fig. 3). However, on many occasions, no causative factor can be discovered and the toxic agent is probably of intrinsic origin. Various toxins formed in the intestinal tract during the process of digestion and absorption may reach the liver by way of the portal vein and exert direct damage on the parenchymal cells so that actual necrosis occurs. Early manifestations are restlessness, headache, lethargy, anorexia, and jaundice. The thymol and cephalin tests are strongly positive early in the disease. The severity of the disease is variable, but on most occasions it is fulminating with a high death rate. In the fatal cases, the lethargy is followed by stupor, coma, and death.

Cholangiolitic hepatitis is a term popularized by Watson to designate certain types of hepatitis (or cirrhosis) in which cellular damage is minimal; the damage is sustained primarily in the cholangioles. The etiology is

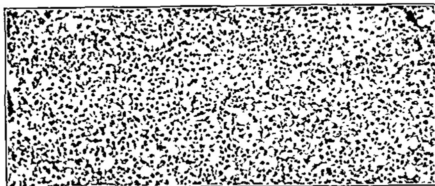

Fig. 3. Acute hepatitis with necrosis, probably of chemical origin. Note the diffuse destruction of hepatic cells with mild infiltration of lymphocytes and fat. The liver was small and yellow, and of the type described as "acute yellow atrophy." The patient, a 40-year-old woman, complained of slight abdominal pain and jaundice of three weeks' duration, and had been taking a drug almost daily for many months, for arthritis. Among other ingredients the drug contained cinchophen, a chemical noted for its toxic action on the liver.

not clear. At times, the causative factor appears to be an intrinsic toxin. On other occasions, chemicals or poisons (e.g., arsenic and thorazine) can be identified as the causative agent.

The status of hepatic function is an important feature of cholangiolitic hepatitis. The thymol and cephalin tests are usually normal and the alkaline phosphatase elevated. Jaundice is common; during the acute stage, stools are acholic. The liver is enlarged. Unfortunately, biopsy is not diagnostic. In the chronic form, the disease resembles Hanot's cirrhosis; during recent years, many clinicians have abandoned this latter term, identifying this disease as chronic cholangiolitic cirrhosis, largely because the manifestations of cases originally described by Hanot were not sufficiently consistent. This disease is a medical disease but has surgical significance because it is so difficult to differentiate from obstructive jaundice, which it resembles very closely. Fortunately, operations erroneously performed are usually tolerated fairly well since liver function is not significantly disturbed.

(*b*) *Hepatitis due to infection* may be divided into that produced by 1. viral infection; 2. pylephlebitis (via portal vein); 3. cholangitis (via bile ducts); and 4. pericholangitis (via lymphatics).

1. *Viral infection* of the liver may be of two types. Both are medical diseases but are summarized briefly here because of their importance in differential diagnosis of jaundice. The type identified as *infectious hepatitis* has an incubation period of two to six weeks; the source of infection may be food, water, milk, or infected feces. The onset is usually abrupt with fever and jaundice. It is more common in young people. The mortality is low, less than 1 per cent. *Homologous serum hepatitis* has an incubation period of 6 to 25 weeks; the source of infection is plasma, serum, whole blood, and contaminated syringes and needles. The onset is usually insidious, with little or no fever. It may occur at any age. Weakness, malaise, anorexia, and nausea are common early symptoms. Jaundice develops within a few days following onset. Stools are usually acholic in viral hepatitis for a week or two and then gradually become cholic; on rare occasions (in severe cases), the stools may be acholic for many weeks. The disease varies in intensity but its mortality rate is much higher than for infectious hepatitis. The thymol and cephalin tests are usually positive early in both types of viral hepatitis. The disease, though medical, has surgical significance because an operation is occasionally performed erroneously; if this is done in the acute stage when liver functions are seriously impaired, a fatality may result. In 5 to 15 per cent of patients with viral hepatitis the liver function tests will be normal (Capps, 5, 6). Under such circumstances, this type of hepatitis resembles acute cholangiolitic hepatitis, which has already been discussed. Neither of the two types of viral hepatitis responds to antibiotics.

2. *Pylephlebitis* or inflammation of the portal vein may develop in the vein itself or in its tributaries (Fig. 4). Complete throm-

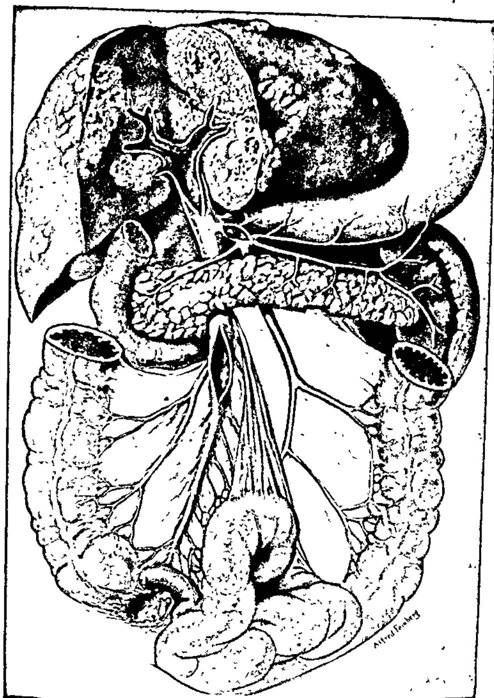

Fig. 4. Suppurative pylephlebitis arising from appendix abscess. Numerous abscesses in the liver. (From MacCallum. Textbook of Pathology, W. B. Saunders.)

bosis of the large trunk may or may not be produced. Extension into the portal tributaries within the liver takes place readily and produces serious symptoms of surgical significance. Such a condition appears usually as a complication of suppurative appendicitis, but may accompany any septic process within the peritoneal cavity. The symptoms of pylephlebitis involving a large portion of the portal system are difficult to differentiate from such complications as intraabdominal suppuration of various kinds. As stated previously, if thrombosis occurs during convalescence of a patient operated on for suppurative appendicitis, the temperature which might have been receding to normal will gradually ascend along with various symptoms, such as prostration, tachycardia, malaise, anorexia, and occasional vomiting. Jaundice may or may not be present. Chills are common. Dis-

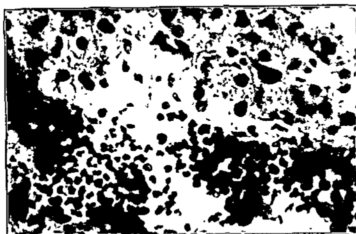

Fig. 5. Acute cholangitis from biopsy taken at laparotomy. Note the infiltration of polymorphonuclear cells; this is in the periportal area, and in reality, constitutes a miliary abscess. The patient's illness was of four weeks' duration and was manifested by high fever, jaundice and large liver with elevated diaphragm. A liver abscess was suspected and the patient operated on, but no abscess was found. For some unexplainable reason sharp improvement took place beginning a day or two following operation; the temperature dropped to normal and all symptoms subsided within a few more days.

tention with a small amount of fluid in the peritoneal cavity usually develops. The patient is obviously very ill and usually symptoms progress until death intervenes. There is a tendency for production of multiple small abscesses throughout the liver. These abscesses, along with obstruction of the portal vein and the suppurative process about the original focus, are, of course, ample cause for the fatal termination. Occasionally when the obstruction of the portal vein is complete, there may be numerous intestinal hemorrhages secondary to the portal obstruction. The production of such symptoms is readily understandable inasmuch as experimental ligation of the portal vein is often fatal due, in part, to trapping of huge quantities of blood (Elman and Cole, 7). Antibiotics are useful in preventing pylephlebitis and in controlling its effects, except that they are relatively ineffective in the treatment of the resultant liver abscesses.

3. *Cholangitis* is primarily an inflammation of the bile ducts and may be acute or chronic. The acute *suppurative* type of infection is a serious lesion, most commonly encountered in obstruction of the common duct, such as that produced by stone or by stricture. It may also be secondary to carcinoma of the head of the pancreas and ampulla of Vater, but is comparatively less common in such lesions. The infection may extend upward into the tributaries of the biliary ducts and involve the entire liver (Fig. 5). Microscopically, it may be difficult to differentiate this type of infection from pylephlebitis; multiple abscesses may likewise be formed. Edema occluding the walls of the ducts is frequently sufficient to produce biliary obstruction, thereby leading to jaundice (Fig. 6). Chills and fever, malaise, nausea, and vomiting are common manifestations. Leukocytosis is usually pronounced. Stools are acholic except when the obstruction becomes intermittent, as occurs not infrequently in patients with stones in the common duct or carcinoma of the ampulla of Vater. Treatment consists primarily of relief of the obstruction, i.e., by choledochostomy (Chart 1). If the obstruction is caused by stone, it should be removed; if caused by a malignant tumor, resection (i.e., a cancer operation) at the time of drainage for the acute suppurative process is rarely safe.

4. *Pericholangitis* is an infection or inflammation which, in most instances, is of lymphatic origin. This lesion is in reality a type of hepatitis (Graham) which, as already mentioned, arises primarily from cholecystitis but also from other infectious processes within the abdominal cavity. The liver, in such instances, is slightly swollen and the edges rounded (Fig. 7). The polynuclear and lymphocytic infiltration extends throughout the

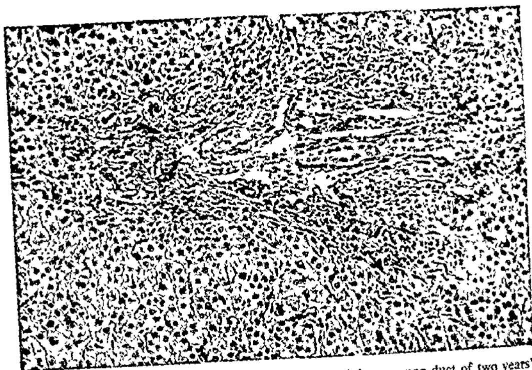

Fig. 6. Early biliary cirrhosis. The patient had a stricture of the common duct of two years' duration with alternating attacks of jaundice and freedom from obstruction. In such cases infection is constant, and, along with the biliary stasis, is an important factor in production of severe liver damage. Note the marked lymphocytic infiltration and early scar formation around the duct.

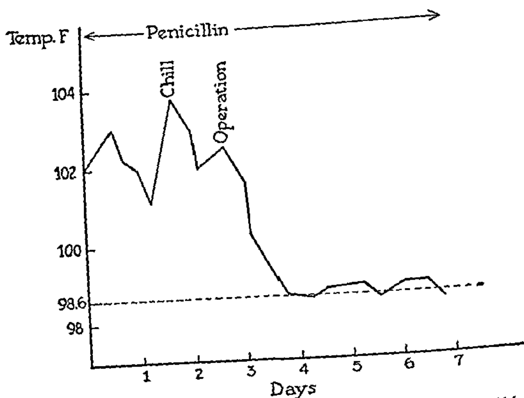

Chart 1. Suppurative cholangitis relieved by choledochostomy. Patient was a 45-year-old female who developed jaundice and severe pain in the right upper quadrant 10 days previously. She had had several lesser attacks without jaundice during the past five years. Chills and fever developed four days before entrance. Three days after admission one large stone was removed from her common duct, and a T-tube was left in for drainage. The fever subsided almost immediately. Penicillin had been of no value.

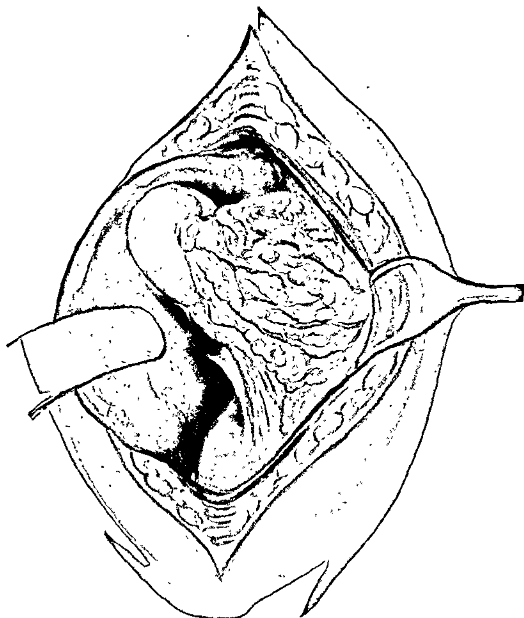

Fig. 7. Hepatitis associated with subacute cholecystitis. The rounded edge is indicative of a moderate edema. It is a common complication of cholecystitis, particularly the acute and subacute types.

portal spaces (Fig. 8). A variable amount of necrosis of adjacent hepatic cells may be present. Such processes may be secondary to acute infections not only in the gallbladder but also in the appendix, pancreas, and other organs and are associated occasionally with jaundice, fever, and so forth. Chronic pericholangitis produces very few manifestations; jaundice is usually absent. However, when the process becomes acute, all the manifestations (including jaundice) of an acute infection may be produced. Although tenderness may be quite marked over the liver, pain is usually not severe. Treatment should be directed toward the primary source of infection; antibiotics are, of course, indicated.

Clinical Manifestations of Hepatic Insufficiency. All types of hepatitis may produce hepatic insufficiency which, if severe, may in itself be lethal; impaired hepatic function occasionally develops following operations upon the biliary tract in which severe

Fig. 8. Pericholangitis produced by chronic cholecystitis; from a biopsy of the liver obtained at time of cholecystectomy. The patient had several attacks of pain in the right upper quadrant during the past several months, but no jaundice. Note the lymphocytic infiltration with beginning scar formation in the periportal area, surrounding three or four small bile ducts.

hepatitis is already present. Weakness and lassitude are usually the first symptoms complained of and become noticeable on the second or third postoperative day. The pulse rate and temperature usually remain near normal until shortly before death, but the pulse itself is soft and poorly sustained. A fall of blood pressure may accompany a collapse which simulates that due to a severe hemorrhage. Anorexia and nausea are prominent, but vomiting is unusual. Difficulty in "getting his breath" may be complained of by the patient, but there is no change in the rate or depth of respirations. Drowsiness often develops, but in the severe cases pronounced restlessness and hyperactivity may occur. Although the patient may complain of severe abdominal distress, examination of the abdomen rarely reveals anything abnormal. Jaundice is usually present. Edema of the ankles is not uncommon, and after several days the urinary output decreases alarmingly. Urobilin is found in the urine in large quantities. Severe renal damage with disturbed function may accompany acute hepatic insufficiency. The patient continues to grow weaker and more drowsy until 18 or 24 hours before death, when he is apt to become irrational. Death, which occurs near the eighth or tenth day, is preceded by coma. The term "hepatic asthenia" would appear to be appropriate when referring to patients suffering from this disease because of the debility and weakness associated with the malady. Fatalities are not uncommon in the acute insufficiency encountered in viral hepatitis and "toxic" hepatitis.

From the above discussion it will be noted that hepatic insufficiency may be of great importance surgically, particularly because it is so frequently unrecognized. Liver function tests, including particularly the thymol and cephalin tests, will be very helpful in identifying hepatic damage of this type. The alkaline phosphatase test will usually be positive (i.e., above 4 Bodansky units). This may be confusing, because a positive alkaline phosphatase test is usually indicative of ductal obstruction; however, in this case the obstruction is caused by cellular damage and edema (see also p. 660).

Treatment of Hepatic Insufficiency. Although therapy has been discussed briefly under the various types of hepatitis, a summary of therapy appears indicated because hepatic reserve is so important to the surgeon. If an obstruction to the common duct is present, it should be relieved. Fluids up to 2,500 ml. per day should be given; if the patient is unable to take fluids by mouth, this will have to be given by vein (e.g., 5 or 10 per cent glucose). An adequate carbohydrate and protein intake must be maintained (8, 9), if oral feeding is possible. The observations of Maddock and associates (10) illustrate the beneficial effect of glucose on maintenance of liver glycogen. They noted an average level

of 5.03 per cent liver glycogen in patients given supplementary glucose feedings for 12 hours previous to operation, contrasted to an average of 3.96 per cent found in normal control patients. Inasmuch as hypoalbuminemia is frequent in liver disease, repeated and large plasma and whole blood transfusions may be necessary. Obviously, an effort should be made to determine the cause of the hepatic insufficiency. Any drugs which could possibly have been a factor in the hepatic injury should be discontinued. Specific questions concerning the intake of drugs, such as thorazine, arsenic, and the like, must be asked. Abscesses should be drained, particularly if they are intraabdominal. Bed rest is necessary. Sufficient narcotics must be given to ensure adequate sleep. *If the hepatitis is of infective* origin, chemotherapy (utilizing tetracycline, streptomycin, chloromycetin, penicillin, terramycin, and so forth) should be tried.

Abscess of the Liver. Abscesses of the liver may be of two types: pyogenic, which is usually multiple, and amebic, which is usually solitary.

Pyogenic Abscess. Abscesses of this type most frequently accompany suppurative processes in the abdomen (appendicitis, and so forth) and are usually secondary to pylephlebitis or to cholangitis of the acute suppurative type. The organisms most frequently responsible for infections of this type are *E. coli*, streptococcus, and staphylococcus. The abscesses are apt to be multiple unless they happen to coalesce and form one or two large cavities. Symptoms, including weakness, malaise, anorexia, chills, and mild pain in the right upper quadrant or right shoulder, are similar to the severe manifestations of pylephlebitis and cholangitis, as already described. Ochsner and associates (11) noted nausea and vomiting, loss of weight, and jaundice in one third of the series reported by them. Intermittent fever and slight elevation of the diaphragm with lack of movement during respiration are usually the most objec*tive diagnostic signs (Fig. 9). Differentiation* from subphrenic abscess may be difficult or impossible when a large single abscess is present. Leukocytosis is pronounced and usually *higher than that noted in amebic abscesses.* The *treatment* of these abscesses may be operative (Chart 2); but they are not so amenable to drainage, chiefly because of the fact that they are usually multiple. The mortality is therefore high; however, when there are but one or two large abscesses, treatment is more hopeful. Drainage should be established

Fig. 9. Pyogenic abscess of the liver; roentgenogram showing marked elevation of the right diaphragm, which was also immobile. Operation was performed for drainage by resection of the ninth rib in the posterior axillary line; about 300 ml. of foul-smelling pus was evacuated. Recovery was uneventful (see Chart 2).

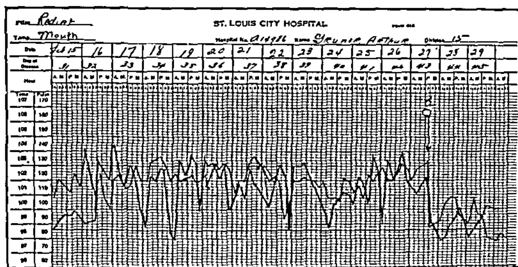

Chart 2. Temperature chart of pyogenic abscess of liver shown in Fig. 9. The patient, aged 37, was first operated on one month previously for drainage of a large intra-abdominal abscess, presumably of appendiceal origin. The abdominal and general conditions gradually improved and the temperature returned to normal. Four weeks after admission, the fever recurred (as noted above on the second day of the chart) and assumed a swinging septic form. 12 days later, as indicated on the chart, operation was performed. Following drainage of the hepatic abscess the temperature returned to normal. Recovery was uneventful.

if possible, but in such a way that the pleural and peritoneal cavities are not contaminated; the retroperitoneal approach (Ochsner) should be utilized whenever possible. Penicillin and streptomycin or some other antibiotics (depending upon sensitivity tests, if a culture is available) should be given.

Amebic Abscess. Years ago, amebic abscess of the liver was thought to be a tropical disease but it is well known now that it is encountered in the temperate as well as tropical climate. As the name implies, the causative organism is the *Endameba histolytica*. The lesion is much more common in males than females. The relationship of the development of the abscess to the initial intestinal infection is extremely variable. Furthermore, a history of diarrhea may be absent. In a series of 741 collected cases (including their own), Ochsner and DeBakey (12) noted a history of diarrhea in only 58 per cent of cases and diarrhea at time of entry in only 21 per cent of the cases. The symptoms of amebic abscess are fever, weakness, malaise, and mild pain in the epigastrium, right upper quadrant, and right shoulder. Fever is apt to be of the remitting type, accompanied by sweating and exhaustion; loss of weight is common. Examination may reveal nothing more specific than a mild degree of tenderness over the liver (Fig. 10). However, as the abscess increases in size the area of hepatic dullness likewise increases. The diaphragm may be elevated, and upon fluoroscopic examination is usually found to be immobile. Perforation of the diaphragm may occur, with the production of an empyema. More rarely, the pus breaks through the lung into a bronchus, producing a bronchial fistula. The pus found in an abscess of the liver is characteristically of a brick red color. The amebas are found in the pus in only about 30 per cent of cases (DeBakey and Ochsner, 13), but more often from the wall of the cavity.

The treatment is largely medical. Rogers (14) was perhaps the first to demonstrate the truth of this statement; he noted a decrease in mortality from 56 per cent after open drainage to 14 per cent after conservative treatment, including closed drainage (aspiration) and medicinal therapy. Rogers attributed the high mortality following open drainage to secondary infection of an abscess cavity which was initially sterile. Occasionally, spontaneous secondary infection develops; if microorganisms are found in the pus, open drainage is usually indicated. The drug most commonly used is chloroquine, in doses of 0.6 gm. by mouth daily for two or three

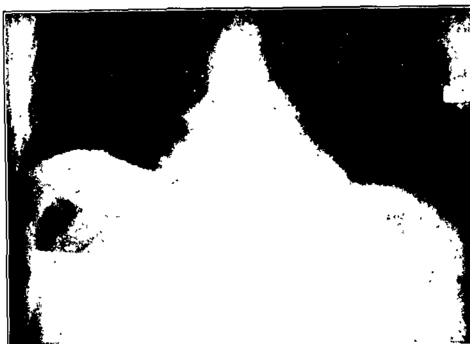

Fig. 10. Amebic abscess of the liver. The patient, a 45-year-old male, complained of loss of weight and strength; examination revealed an intermittent fever and a palpably enlarged liver. The roentgenogram was taken in the upright position after part of the aspirated pus had been replaced by air; note the fluid level. Emetine was injected into the cavity; it was also given by mouth. Recovery was uneventful without operation. (St. Louis City Hospital.)

days followed by 0.3 gm. daily for two or three weeks. Emetine and diodoquin are also used, but the former cannot be used longer than 10 days with safety. Irrigation of the abscess cavity is not desirable, although it may have to be aspirated more than once (Ochsner, 15). In the New Orleans series, Ochsner reports that the mortality rate has now dropped to 3.2 per cent. Seldom do patients with amebic hepatitis (without abscess) die, and seldom indeed do patients with multiple abscesses survive. Empyema caused by perforation through the diaphragm may be treated by aspiration, but if culture reveals pyogenic organisms, surgical drainage will be indicated.

Jaundice. To understand the mechanism of production, and the signficance of jaundice, it is necessary that the chief factors in the metabolism of bile pigments be understood. Bilirubin is present in the blood normally in quantities equal to 0.1 to 0.4 mg. per 100 ml. of serum (quantitative Van den Bergh). When the content rises to 2.0 or 2.5 mg. per 100 ml. of serum, macroscopic jaundice results. Levels above 0.2 mg. are abnormal for the one-minute test for bilirubin. Latent jaundice may be defined as hyperbilirubinemia without visible jaundice. Bilirubin is made by the reticuloendothelial system, e.g., the bone marrow, lymph nodes, spleen, and the Kupffer cells of the liver, but is normally excreted only by the liver. Bilirubin is formed from hemoglobin, probably through the intermediary product hematin. After bilirubin is excreted with the bile into the intestine, the action of the bacteria converts it into urobilin which is absorbed and reconverted, in part at least, into bilirubin, chiefly in the liver. Urobilin is found normally in human bile and in traces in the urine. The stools, however, contain large amounts. Urobilin may be found in the urine in certain diseases. It is assumed that in such instances a slight degree of hepatic insufficiency exists to the extent that the urobilin cannot be converted into bilirubin, and is therefore excreted by the kidney. In other instances, urobilinuria occurs when the liver, though normal, is unable to remove the urobilin from the blood stream when produced in excess by such conditions as hemolysis. On the other hand,

when no bile reaches the intestine, as in complete obstructive jaundice, urobilin disappears from the urine.

Jaundice first appears in the scleras and conjunctivas and gradually becomes noticeable over the skin and mucous membranes throughout the rest of the body. When severe jaundice has been present for a long time the skin turns to a dark greenish bronze color because of the transformation of bilirubin to biliverdin.

For obvious reasons, it may frequently be of considerable advantage, from the surgical as well as medical standpoint, to determine the intensity of jaundice and to follow its course with reference to a decrease or increase. As stated previously, jaundice is dependent upon the amount of bilirubin in the blood. There are several methods of estimating the bilirubin content of the blood; the quantitative Van den Bergh test (or a modification) is the one most commonly used. It is much more accurate than the icterus index test, which is no longer popular because of its inaccuracy.

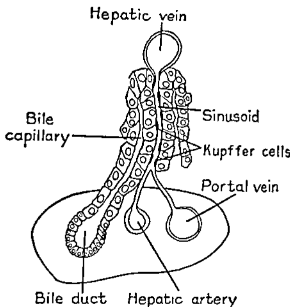

Fig. 11. Diagram to illustrate the mechanism of obstructive jaundice. If the bile duct becomes obstructed, the bile obviously is blocked from its normal exit and "spills" over into the sinusoid, which empties into the hepatic vein; the bile thereby gains access to the general circulation. The manner in which the capillaries of the portal vein and hepatic artery unite to form the sinusoid is not clearly understood and is illustrated in a diagrammatic fashion. (Modified from McNee. Quart. J. Med.)

TYPES OF JAUNDICE. Aside from hemolytic jaundice, which is really a disease of the spleen and hematopoietic system and not of the biliary apparatus, jaundice is due to the failure of bile to reach the intestine. Because bile is constantly formed, this failure obviously results in the accumulation of bile in all the tissues of the body and in the blood, as already mentioned. There are a variety of diseases which result in a failure of bile to reach the duodenum; these can be conveniently divided into two general groups, *hepatogenous* and *extrahepatic* (Fig. 11), each of which is described later in more detail. In hepatogenous jaundice the liver parenchyma itself is diseased so that it cannot excrete bile; such lesions include acute hepatic necrosis, the two types of viral hepatitis, and cirrhosis. In extra hepatic jaundice the disease is in the biliary ducts which become obstructed by one lesion or another, usually either stone or tumor; this type is therefore called obstructive jaundice. Hepatogenous jaundice is, in general, a medical disease; surgery has little to offer aside from the value of laparotomy in making the diagnosis and excluding obstructive jaundice. Obstructive jaundice, on the other hand, is a surgical disease because operation often permits relief of the obstruction or even cure of the lesion producing it. The importance of both types of jaundice to the surgeon is that the clinical differentiation is sometimes difficult or impossible to make, thus justifying an operation for such a purpose.

Regardless of the cause of the jaundice, it is important to recognize the existence of any damage to the liver parenchyma for reasons to be discussed later. For this purpose, the patient's symptoms may be of value but *tests of hepatic function* are often more informative. Of the many tests which have been devised, the thymol turbidity test, the cephalin test, the alkaline phosphatase test, the urobilinogen test, reversal of the plasma albumin and globulin ratio, and the bromsulphalein test are the most important. The latter test is a sensitive liver function test, but is not very accurate in the presence of jaundice. On the basis of the results of these tests, it is usually possible to differentiate extrahepatic types of jaundice from hepatogenous jaundice, as will be discussed later. Regardless of

the absence or presence of infection, the retention of bile salts alone, if continued long enough, will eventually produce hepatic damage and actual necrosis of many of the cells. The liver then will become enlarged and a mild edema as well as a lymphocytic infiltration will take place. Ultimately, scar tissue will be deposited and an actual microscopic biliary cirrhosis will be produced.

In all types of jaundice, bile pigment is found promptly in the urine but does not appear in the tissues until the serum attains a certain concentration, i.e., 2.0 to 2.5 mg. per cent; only when values above this level are reached is clinical appearance of jaundice evident. Because of this latent period in the clinical appearance of jaundice the determination of the amount of bilirubin in the blood may be a valuable method of identifying occult or latent jaundice and also in following the variations in the degree of jaundice.

Postoperative hemorrhage in jaundice is a more serious and not infrequent complication; it may occur at any time during the first 10 postoperative days but perhaps most commonly between the fourth and the sixth day. Hemorrhage occurs because blood clotting is defective due to the deficiency in the prothrombin content of the blood (Dam, 1935). Although the bleeding and clotting time is usually normal, the clot is defective or fragile because of the diminution in the conversion of fibrinogen to fibrin. This is an indirect result of the prothrombin deficiency (hypoprothrombinemia) which, in turn, is due to a lack of vitamin K. This vitamin is fat soluble and therefore requires the presence of bile salts in the intestines for its assimilation; however, a water soluble synthetic product having vitamin K activity is available for parenteral use. A deficiency follows complete jaundice and also complete external biliary fistula because of the absence of bile in the intestinal tract, thereby preventing absorption of the vitamin from the food. Details of jaundice may be found in publications elsewhere (1, 16, 17).

1. *Hepatogenous Jaundice.* In this group, the disease is primary in the liver, producing so much cellular damage that bile is not being excreted into the ducts which are, indeed, normal grossly and microscopically; at times, edema or fibrous tissue about the bile ducts may be sufficient to exert an additional intrahepatic obstructive mechanism. Hepatogenous jaundice comprises a great variety of conditions; some of them are called infective or toxic jaundice (acute hepatic necrosis), but the cause in many cases is really unknown. The simplest type is virus hepatitis, which is the most common single type of jaundice and has already been discussed. Acute hepatic necrosis may be caused by various chemicals (see p. 660) or endogenous toxins. Of recent years thorazine is a common cause. The appearance of the liver varies considerably, depending upon the type of disease present. In acute hepatic necrosis, the liver is small and presents a striking yellow color. In patients having hepatitis due to infection, the liver is moderately enlarged and swollen, with rounded edges. In cholangiolytic jaundice, the liver is large and, as the disease advances, becomes cirrhotic. The gallbladder and common duct are normal. Enlarged lymph nodes are commonly found at the hepatic hilus. Allied to the examples of primary liver disease discussed above are patients with various types of cirrhosis. Cirrhosis, when it produces jaundice, must be considered in this group, even though the large amount of scar present in the liver may produce a variable degree of duct obstruction. In many instances ascites may also be present, which helps considerably in the differential diagnosis because ascites, though occasionally present in other types of hepatogenous jaundice, is rare in obstructive jaundice except when caused by peritoneal metastases.

The surgical problem in hepatogenous jaundice is largely a diagnostic one, i.e., differentiation from extrahepatic jaundice for which surgery has much to offer. Liver function tests are valuable in differentiating hepatogenous from obstructive jaundice since they are usually positive in the former and negative in the latter. The thymol turbidity test is one of the most valuable since it is usually extremely sensitive. It must be remembered, however, that in patients with prolonged obstructive jaundice, liver function tests may be positive, particularly if infection is present. Only rarely will it be impossible to differentiate the two lesions

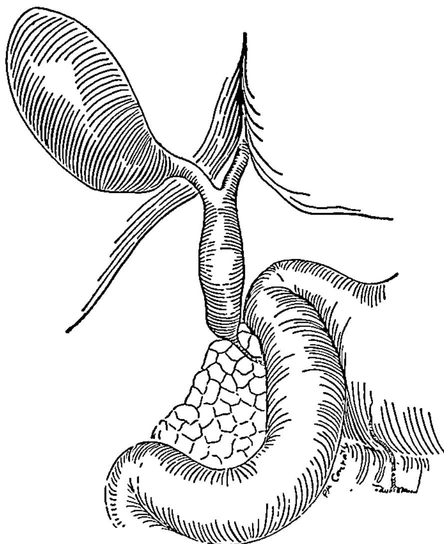

Fig. 12. Diagram to illustrate one of the types of obstructive jaundice. The duodenum has been rolled back to expose the pancreas. In this instance the common duct is distended because of compression of the terminal end of the common duct by the pancreas. The pathologic process in the pancreas capable of producing this compression may be either carcinoma or pancreatitis. In obstruction of this type (absence of infection in the biliary system) the gallbladder is distended, fulfilling part of the requisites of Courvoisier's law (see text).

without operation. It is the possibility that the patient has a stone or a carcinoma for which surgery offers the only hope of relief or cure that often tips the balance in favor of laparotomy.

2. *Obstructive Jaundice.* Obstructive jaundice may be extrinsic or intrinsic. The most common of the former type is carcinoma of the pancreas, which is discussed in Chapter 29. The most common of the intrinsic type is stone in the common duct, which is discussed later in this chapter. In carcinoma of the pancreas (Fig. 12), the manifestations are apt to develop insidiously, pain being present in no more than 20 per cent. When stones in the common duct are the cause of the obstruction, pain will be present in fully 80 per cent of cases; these attacks, including the jaundice and acholic stools are apt to be intermittent, in contrast to carcinoma of the pancreas in which the jaundice and acholic stools are apt to be permanent, once they develop.

Other noninflammatory or aseptic obstructive lesions include carcinoma of the liver, carcinoma of the common duct, congenital strictures, cystic dilatations of the common duct, and other neoplasms which compress the ducts from without. It should be emphasized that certain types of hepatitis,

particularly cholangiolitic hepatitis, are associated with biliary obstruction, primairly in the smaller intrahepatic bile ducts. In "toxic" hepatic or acute hepatic necrosis, the edema within the liver may likewise produce obstruction to the intrahepatic ducts.

Contrary to general opinion, jaundice due to obstruction alone may exist for some time without producing significant damage to the liver. This is particularly true in the slowly developing jaundice which follows an obstruction by carcinoma at the head of the pancreas. However, if there is an accompanying infection, as for example, in the presence of stones in the common duct, there is very obvious and often severe damage inflicted upon the hepatic parenchyma as will be demonstrable by liver biopsy. In chronic obstruction, the liver may become cirrhotic (biliary cirrhosis) giving rise ultimately to severe hepatic insufficiency.

3. *Hemolytic Jaundice*. Jaundice of the hemolytic type has much more relation to the spleen than to the liver. Splenomegalia is fairly consistent. Splenectomy in selected cases is curative. The role of the liver in this disease is limited for the most part to the fact that the amount of bilirubin converted from the hemoglobin (due to excessive destruction of erythrocytes) is so great that the liver is unable to excrete it in a normal fashion. The bilirubin accumulates in the blood stream, resulting in jaundice. The condition is therefore discussed under diseases of the spleen.

DIFFERENTIAL DIAGNOSIS IN JAUNDICE. It is extremely important to differentiate hepatogenous from extrahepatic obstructive jaundice because, in general, the therapy in the former is nonoperative whereas in the latter it is surgical. In general, hepatogenous jaundice is painless in about 80 per cent of cases, whereas obstruction by stone produces pain in about 80 per cent of cases. Pain is usually absent in carcinoma of the head of the pancreas, but epigastric distress of the dyspeptic type is common. (Pain is common, and in fact almost constant, in carcinoma of the body of the pancreas.) The most severe pain of all the groups is encountered in patients with stones in the common duct. The presence of chills may be helpful since they are rarely encountered except in patients with common duct stones, with traumatic strictures, occasionally in obstruction due to carcinoma of the pancreas, or with septicemia accompanying serious sepsis, such as pneumonia.

The age of the patient will frequently be very helpful, since viral hepatitis, which is no doubt the commonest type of hepatogenous jaundice, is usually encountered in young adults, whereas stones in the common duct and carcinoma are usually encountered in later adult life. Sex will be of only slight value in differentiation (Table 1).

The onset of the disease may be very helpful; it is usually acute with severe pain in common duct stone, but in viral hepatitis and carcinoma of the head of the pancreas it is apt to be insidious. Pain occurs in cancer of the head of the pancreas but is rarely severe. The course of the disease frequently establishes the diagnosis with certainty, i.e., allows the surgeon to arrive at the correct decision as to whether or not operation is indicated. For example, if the patient's history reveals a rather sudden onset of relatively painless jaundice, and during two or three weeks' observation shows decrease in symptoms, including a lowered bilirubinemia and more pigment in the stool, the decision to refrain from operative interference will rarely be erroneous on the basis that the jaundice is hepatogenous in origin. In many types of hepatogenous jaundice, the spleen will be enlarged; in obstructive jaundice, it rarely will be enlarged. The size of the liver will not be of much diagnostic assistance, since it will be moderately enlarged in both types of jaundice, though markedly enlarged in most patients with cholangiolytic jaundice. Marked enlargement of the liver is practically never seen in obstructive jaundice due to stone unless a liver abscess is present.

Jaundice tends to be more intense in hepatogenous jaundice than in jaundice due to stones in the common duct. In the former, the color of the stool is variable though usually lighter than normal. In viral hepatitis, the stools are usually acholic for a week or two and then become cholic. In jaundice due to stones in the common duct, acholic stools as well as the jaundice are apt to be intermittent. In carcinoma of the pancreas, bile rarely is found in the stool once it is noted to be absent. *Stool examinations* may therefore be of great value in making a differential

TABLE 1. Important Factors in Differential Diagnosis of Jaundice

It should be emphasized that the features listed represent average data and must not be interpreted dogmatically.

	Extrahepatic Jaundice		Hepatogenous Jaundice	Splenogenous Jaundice
	Stone in Common Duct	Carcinoma of Head of Pancreas	(Toxic* or Infective Hepatitis)	(Hemolytic Icterus)
Age	Usually over 40	Usually over 50	Any age; more frequently young	Variable; may be since birth
Sex	Females predominant	Males predominant	Either	Either
Character of Onset	Sudden	Insidious	Moderate	Variable
Previous Attack	Usually	No	Rarely	Remissions
Pain	Severe and usually colicky; present in over 80%	Pain (usually mild) in about 20%; fairly constant if tumor in body	Rare and mild	None
Degree of Jaundice	Mild to intense, often intermittent	Moderately intense early, usually progressively deepens	Severe, but varies and may be intermittent	Varies
Pruritis	Usually present	Usually present	Absent, usually	Absent
Stool	Intermittently acholic	Acholic and permanent	Acholic for few days only	More pigment than normal
Size of Gallbladder	Usually normal size, but diseased	Always dilated except rarely when gallstones also present	Normal	Normal
Liver Function Tests	Variable to positive	Normal, except serum phosphatase elevated	Strongly positive	Normal
Plasma albumin	Normal to reduced	No change	Low	Occasionally significant
Fever	Intermittent but not common, may have chills	No, except occasionally suppurative cholangitis	May be present early, but variable	None except in severe crises
Serum Amylase	Occasionally elevated day or two following obstruction	Elevated early in disease Serum lipase may be elevated	Normal	Normal
Size of Liver	Variable	Enlarged late in course of jaundice	Usually enlarged	Variable
Blood	Mild to marked leukocytosis at times	Anemia later	Anemia if jaundice is severe and persistent	Spherocytes; anemia in crises
Size of Spleen	Normal	Normal	Occasionally enlarged	Large
Miscellaneous Tests or Data	Stones on x-ray in 20 to 40%		May occur in epidemics	Increase fragility of RBC; Spherocytes; stools hypercholic; no increase pigment in urine

* Cholangiolytic hepatitis, usually associated with jaundice, is probably of toxic origin. It differs from most types of toxic hepatitis in that liver function tests are usually normal.

diagnosis. Urobilin will be present in the urine of patients with hepatogenous jaundice but rarely in patients with complete obstructive jaundice. Pruritis is much more common in obstructive jaundice than in hepatogenous jaundice.

Tests of hepatic function may be extremely helpful, although it should be stated that many clinicians believe their importance has been exaggerated. The *thymol turbidity* test is valuable in differential diagnosis because it tends to be positive (i.e., above 4 units) in hepatogenous jaundice and negative in obstructive jaundice. A positive test depends on an elevation of gamma globulin. It is perhaps the most sensitive test we have for hepatocellular (intrahepatic) jaundice. The *cephalin flocculation* test is also of value in differentiation between the two types of jaundice. Flocculation is negative or 1+ in extrahepatic jaundice and 4+ in intrahepatic jaundice. The *serum alkaline phosphatase* test is elevated (above 10 Bodansky units) in patients with extrahepatic obstruction, due to interference with its excretion. However, it is often elevated in hepatogenous jaundice; this is probably due to obstruction within the liver due to compression of ducts by edema or fibrosis. In severe hepatic damage, *vitamin K* is apt not to restore a low prothrombin time to normal as it will in jaundice with little hepatic damage. A *reversal or a tendency toward reversal in the albumin globulin ratio* is a sign of liver disease, but is not an early test. It usually requires chronic hepatic insufficiency to produce a definite reversal. The *urobilinogen* test is a particularly sensitive test of liver function because this pigment disappears from the urine in complete biliary suppression, i.e., when bile is absent from the intestinal tract. Urobilinuria therefore indicates definite but not complete impairment of bile excretion. The level of *cholesterol esters* may be reduced in hepatocellular disease because esterification of cholesterol is diminished early in hepatic disease; however, low readings are often found in patients who do not appear to have significant hepatic disease (16). The *bromsulphalein* test is very reliable but will not give accurate readings in the presence of jaundice. Ordinarily, a retention is not noted in hepatocellular disease but is fairly constantly elevated in patients with cirrhosis or carcinoma of the liver. Apparently this test is influenced by the blood supply to the liver insofar as there is retention when obstruction to blood flow in the liver is present. Recently the level of *transaminase* in the serum has been utilized as a test of hepatic function (18) since it is high in the acute stage of viral hepatitis and in other patients with obvious severe insufficiency. However, it is also high in acute myocardial infarction and certain other acute serious diseases. The value of liver function tests in surgical diagnosis has been discussed in detail by Hunter (18a).

TREATMENT OF JAUNDICE. Obviously, the first requirement in the treatment of jaundice is to determine and remove the cause. This may require extensive study, including a large amount of laboratory data. Frequently it is extremely difficult to determine the exact cause of the jaundice. On such occasions, exploratory laparotomy may be indicated on the assumption that a lesion will be found which can be effectively treated surgically. If the jaundice is produced by mechanical obstruction, particularly if extrahepatic (e.g., stone), operation is obviously indicated for its correction. On the other hand, if the jaundice is hepatogenous, e.g., due to a diffuse damage or infection of the liver alone (acute hepatic necrosis, viral hepatitis, and so forth), operation will be therapeutically useless and harmful. Operation in patients with acute viral hepatitis may actually be fatal. However, such patients usually have strongly positive liver function tests (thymol and cephalin), making the diagnosis definite. The patients having hepatogenous jaundice of the type difficult to differentiate from extrahepatic type are usually not harmed by celiotomy, because liver function tests are normal or near normal; cholangiolytic jaundice is an example.

Treatment consists of a high carbohydrate intake and an adequate protein intake (8); however, it must be remembered that an excessively high protein intake in severe liver disease may be very harmful (producing nitrogen retention and the like). If oral feedings are impossible, intravenous feedings with glucose and perhaps a moderate amount of amino acids are indicated. Transfusions should be given to bring the hematocrit levels

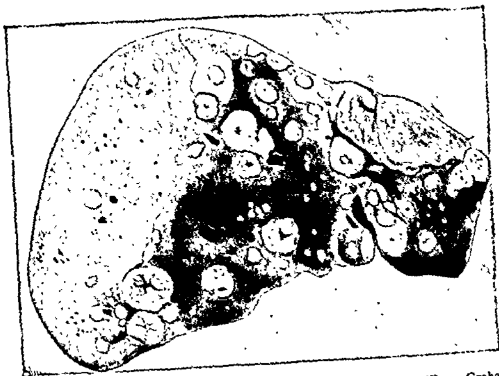

Fig. 13. Metastatic adenocarcinoma, liver, from a carcinoma of the breast. (From Graham. Surgical Diagnosis, W. B. Saunders.)

up to normal. One of the synthetic products, such as 2-methyl-1,4 naphthoquinone or 4-amino-2-methyl-naphthol, with vitamin K activity should be given. Each of these two drugs is given in doses of 5 to 50 mg. per day. The latter drug is soluble in water and the former likewise soluble if combined with sodium bisulphite (hykinone); thus either may be given subcutaneously or intrave- nously. In severe hepatic disease, these com- pounds will not relieve hypoprothrombine- mia; repeated transfusions should then be given.

Neoplasms. The liver is frequently the site of tumors, especially of a malignant type, secondary to a primary focus elsewhere (Fig. 13). Carcinoma of the stomach, intestine, and other intraabdominal organs tend to metastasize first to the liver. Fortunately for the patient, such metastases rarely produce many symptoms other than mild discomfort and tenderness, although the liver on some occasions becomes greatly enlarged. If the metastatic nodules are sufficiently numer- ous, jaundice may be produced. Increasing dyspepsia, weakness, loss of weight, and other systemic manifestations of malignant disease will develop as the disease progresses.

On rare occasions, carcinoma may be pri- mary in the liver, arising in most instances in the bile ducts. It sometimes occurs also in association with or as a complication of atrophic cirrhosis. The clinical manifesta- tions are no different from those encountered in metastatic carcinoma in the liver. At- tempts should be made to arrive at a diag- nosis as early as possible because on rare occasions excision of the tumor in the liver may be possible. Actually the entire lobe (right or left) can be removed (19), but is done only if there is no evidence of disease in the other lobe or elsewhere.

Miscellaneous Diseases of the Liver. The liver may be afflicted with various types of *cirrhosis*, the most important of which surgi- cally is the atrophic (Laënnec) type. When cirrhosis has progressed to the point where the portal circulation has been obstructed sufficiently to produce an ascites, surgical relief may be attempted. Such procedures as implantation of the omentum in the abdomi- nal wall (omentopexy) with scarification of the liver, diaphragm, and spleen were origi- nally used in the treatment of portal hyper- tension caused by cirrhosis, but are not very effective. This procedure has been sup- planted by portacaval shunt (20), spleno- renal shunt, and resection of the terminal end

Fig. 14. Drawing of echinococcus cyst of the liver from sketch made at the time of operation. The gallbladder was normal; its dome may be identified to right of the cyst. The symptoms consist of mild pain in the right upper quadrant of three years' duration and simulated cholecystitis. The cyst was evacuated at the time of operation and drained; the fluid contained hundreds of daughter cysts of variable size. The wound healed after several weeks. Patient was alive and well when last seen, seven years after operation.

of the esophagus as discussed on page 716.

Echinococcus cysts, although rare in this country, occur more frequently in the liver than in other organs. They are apt to develop insidiously, with only a moderate amount of discomfort and pain in the upper abdomen. Examination usually reveals a large liver because of the development of the cyst (Fig. 14). Excision should be performed if possible, but if not feasible, evacuation of the cyst by operative procedures is usually successful in eradicating the disease (see p. 126).

GALLBLADDER

The gallbladder is a pear-shaped organ located *in a fossa on the inferior surface* of the liver between the right and quadrate lobes. The neck of the gallbladder terminates in the cystic duct which empties into the hepatic duct, thus forming the common hepatic duct (Fig. 15). Its blood supply is derived from the cystic artery, which is derived from the right branch of the hepatic artery.

Inflammation of the gallbladder (cholecystitis) and stones within the organ (cholelithiasis) are common diseases and occur with such varied manifestations that they are worthy of special attention. The gallbladder has definite functions, but it is not necessary to life.

The normal gallbladder acts largely as a storehouse for bile, which accumlates within its lumen because of the resistance of the sphincter of Oddi and the relaxation of the gallbladder which occurs between meals.

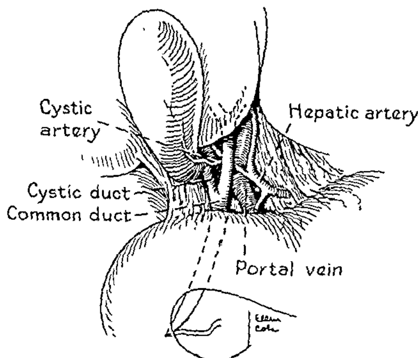

Fig. 15. Anatomy of the gallbladder and bile ducts. The two intrahepatic ducts join in 90 per cent of cases before they leave the liver; on the contrary the portal vein divides in 90 per cent of cases before it enters the liver. Note that the posterior portion of the common duct usually lies in contact with the right branch of the hepatic artery and the portal vein.

Large amounts of bile are thus stored in spite of the small size of the viscus because the normal gallbladder mucosa absorbs water and thereby concentrates the constituents of the bile (Rous and McMaster, 1921). At mealtime and during the process of digestion the musculature of the gallbladder, aided perhaps by breathing, intraabdominal pressure, and so forth, causes expulsion of bile through the relaxed sphincter. Removal of the gallbladder causes dilatation of the extrahepatic ducts (Judd and Mann, 21) and a slight dilatation of the intrahepatic ducts (Counsellor and McIndoe, 22).

Infection is known to be important in the *pathogenesis* of cholecystitis but the inflammation is usually nonbacterial, particularly at its onset. Andrews (23) has called attention to the importance of an increase in bile salts in the bile, in the development of chemical cholecystitis which has been corroborated by Womack and Bricker (24). Likewise Wolfer (1931) has shown that reflux of pancreatic juice into the gallbladder by way of the common duct may instigate cholecystitis. Chronic obstruction of the cystic duct (Fig. 16) may initiate this inflammation because of resultant overconcentration of bile, and the like (Cole and associates, 25); in their experiments, infection was superimposed in 30 per cent of cases, representing about the same incidence of positive culture noted in human cholecystitis. The ability to find bacteria in only a portion of diseased gallbladders has led many observers to doubt that the inflammation is bacterial in origin, particularly at the onset. Therefore it seems possible that, at least on many occasions, the presence of infection may be explained as being superimposed on the initial inflammation as it is in animal experiments. The fact that cholecystectomy can be performed in early acute cholecystitis with almost complete absence of infective reactions likewise supports this view that the initial inflammation may frequently be chemical and the bacterial infection superimposed later. In 100 cases, Illingworth (26) noted that of 62 positive cultures obtained from the wall of the gallbladder, 34 were *Streptococci* and 17 were *Bacillus coli* (*E. coli*). On the other hand, of the 40 instances of positive culture from the bile in the 100 cases, 16 were *Streptococci* and 20 were *Bacillus coli*.

There are four chief ways in which bacteria may reach the gallbladder: *1. hema-*

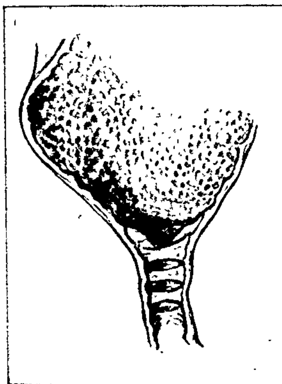

Fig. 16. Partial obstruction of the cystic duct. The transverse bands in the cystic duct of the three gallbladders shown above and to the left represent anomalies (of the valves of Heister) and inflammatory lesions which can partially obstruct the duct. The two photographs and the drawing were made from specimens removed by operation. All three patients had pain in the R.U.Q. typical for chronic cholecystitis. The two gallbladders above concentrated telepaque normally, but the one below did not. Cholecystectomy relieved the pain in all three patients. Lesions of this type are often the important factor in production of cholecystitis (see text).

togenous; 2. lymphogenous; 3. spreading infection from a contiguous organ; and 4. hepatogenous by way of the bile. Of these four methods of development of cholecystitis, the lymphogenous route would appear to be the most important. Years ago (1918), Graham and associates called attention to this mechanism of transmission of infection. Due to the rich anastomosis of the lymphatic vessels between the gallbladder and liver, spread of infection from one organ to the other, and vice versa, is no doubt a common occurrence. On some occasions, the infection perhaps breaks through the mucosal barrier of the intestine and is carried to the liver by the lymphatics or blood stream, particularly

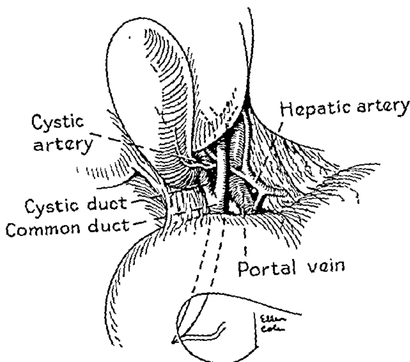

Fig. 15. Anatomy of the gallbladder and bile ducts. The two intrahepatic ducts join in 90 per cent of cases before they leave the liver; on the contrary the portal vein divides in 90 per cent of cases before it enters the liver. Note that the posterior portion of the common duct usually lies in contact with the right branch of the hepatic artery and the portal vein.

Large amounts of bile are thus stored in spite of the small size of the viscus because the normal gallbladder mucosa absorbs water and thereby concentrates the constituents of the bile (Rous and McMaster, 1921). At mealtime and during the process of digestion the musculature of the gallbladder, aided perhaps by breathing, intraabdominal pressure, and so forth, causes expulsion of bile through the relaxed sphincter. Removal of the gallbladder causes dilatation of the extrahepatic ducts (Judd and Mann, 21) and a slight dilatation of the intrahepatic ducts (Counsellor and McIndoe, 22).

Infection is known to be important in the *pathogenesis* of cholecystitis but the inflammation is usually nonbacterial, particularly at its onset. Andrews (23) has called attention to the importance of an increase in bile salts in the bile, in the development of chemical cholecystitis which has been corroborated by Womack and Bricker (24). Likewise Wolfer (1931) has shown that reflux of pancreatic juice into the gallbladder by way of the common duct may instigate cholecystitis. Chronic obstruction of the cystic duct (Fig. 16) may initiate this inflammation because of resultant overconcentration of bile, and the like (Cole and associates, 25); in their experiments, infection was superimposed in 30 per cent of cases, representing about the same incidence of positive culture noted in human cholecystitis. The ability to find bacteria in only a portion of diseased gallbladders has led many observers to doubt that the inflammation is bacterial in origin, particularly at the onset. Therefore it seems possible that, at least on many occasions, the presence of infection may be explained as being superimposed on the initial inflammation as it is in animal experiments. The fact that cholecystectomy can be performed in early acute cholecystitis with almost complete absence of infective reactions likewise supports this view that the initial inflammation may frequently be chemical and the bacterial infection superimposed later. In 100 cases, Illingworth (26) noted that of 62 positive cultures obtained from the wall of the gallbladder, 34 were *Streptococci* and 17 were *Bacillus coli* (*E. coli*). On the other hand, of the 40 instances of positive culture from the bile in the 100 cases, 16 were *Streptococci* and 20 were *Bacillus coli.*

There are four chief ways in which bacteria may reach the gallbladder: 1. hema-

ish color of the contents fades to a gray or grayish brown, due to absorption of the pigment or to bacterial action on it. Empyema of the gallbladder is usually associated with cholelithiasis; it requires operative correction (usually cholecystectomy). The inflammation at the onset of acute cholecystitis may be infectious but more frequently is chemical in origin, infection being superimposed later.

In most instances, acute cholecystitis subsides spontaneously, but occasionally gangrenous or necrotic areas may form in the wall of the gallbladder, thereby leading to *perforation of the organ. Perforation into* the free abdominal cavity is uncommon, but when it occurs is very serious because of the bile peritonitis which inevitably follows. Unless operation is performed within a few hours, fatality is to be expected. The omentum or contiguous organs are usually plastered against the gallbladder in such a way that perforation does not occur into the peritoneal cavity, but rather forms a pericholecystic abscess. On rare occasions, perforation may occur into the liver, the duodenum, the colon, or through the anterior abdominal wall.

Clinical Manifestations. The onset of symptoms in acute cholecystitis is usually sudden, consisting primarily of pain in the right upper quadrant, nausea, and vomiting. Fever soon follows these symptoms, as do other systemic manifestations of severe inflammatory processes, such as tachycardia, malaise, and weakness. Not infrequently there is a history of a chill at the onset. Frequently the pain, which is usually severe, radiates backward to the tip of the scapula. Deep respiration may be painful. Palpation will reveal tenderness and muscle spasm localized over the right upper quadrant, persisting for several days, depending upon the intensity of the attack. The gallbladder will frequently be palpable as a tender mass even in the face of muscle spasm over it. Jaundice induced either by a coincidental obstruction of the common duct or by hepatitis associated with the cholecystitis (Graham) may be present. The leukocyte count is sharply elevated, frequently reaching 25,000 or higher. The acute symptoms, including nausea, vomiting, and severe pain are apt to diminish sharply after the first 24 hours, whereas local muscle spasm and tenderness are more likely to persist. If perforation of the gallbladder occurs, a local abscess is usually formed and the local findings, including tenderness, pain, and muscle spasm, will be much more pronounced.

The disease is perhaps encountered more frequently in a mild form with pain of less intensity and duration (two or three days) and accompanied by only slight fever. Such attacks commonly masquerade as acute dyspepsia or indigestion. It is difficut to decide whether such attacks should be classified as *acute cholecystitis* or *exacerbations* of chronic cholecystitis. Glenn (27) has emphasized the fact that stones are encountered in the common duct in at least 5 per cent of patients with acute cholecystitis.

Differential Diagnosis. The location of the pain and tenderness in the right upper quadrant, combined with the characteristics of the pain which is usually severe and sometimes cramplike in nature, will usually point to the correct diagnosis. Occasionally, it may be confused with acute appendicitis when the appendix is retrocecal and high, but rarely does the tenderness of appendicitis localize itself so definitely in the right upper quadrant. Acute appendicitis is usually a disease of young people, whereas cholecystitis usually occurs in later adult life. Acute cholecystitis may be confused with perforated peptic ulcer, but the onset of the pain, and so forth, in the latter condition is apt to be more sudden and associated with prostration and more generalized abdominal rigidity. Moreover, in perforated ulcer there may be a history of dyspepsia relieved temporarily by food or alkali. X-ray of the abdomen with the patient in a sitting position will rarely fail to reveal air under the diaphragm if a free perforation of an ulcer is present. Frequently, the pain produced by acute pancreatitis is indistinguishable from that of acute cholecystitis but is usually confined to the midline in the epigastrium or to the left upper quadrant. Patients with acute cholecystitis are apt to have a history of previous attacks of a similar character. The pain of acute cholecystitis is similar to renal colic except that the pain in the latter instance is apt to radiate downward, even into the thigh or

Fig. 17. Subacute cholecystitis. Note the enormously thickened wall and the beginning perforation in the fundus. A large stone was present in the neck of the gallbladder.

the latter. It is apparent that a vicious circle may be established by an infection between the gallbladder and liver because of the rich lymphatic anastomosis mentioned above. It may therefore require removal of the gallbladder to break up the vicious circle. Infection of the gallbladder may be acute or chronic.

Acute Cholecystitis. Acute inflammation of the gallbladder is not as common as chronic cholecystitis, but it is of importance surgically because of the acute abdominal symptoms produced. It is usually associated with cholelithiasis. Indeed, in most cases a stone impacted in the neck of the gallbladder, with the consequent production of obstruction of the cystic duct, is frequently an important factor in pathogenesis (Fig. 17). When the organ is the seat of an acute infection the wall becomes thickened and edematous, with a reddened serosal surface upon which fibrin may be deposited. Lymphocytes and leukocytes are found throughout, the number of the latter being dependent upon the acuteness of the process. The external reaction is probably a precursor of the formation of numerous adhesions to other organs (Fig. 18). The cystic duct may also be obstructed by edema and adhesions created by inflammation. When this occurs in the presence of an acute infection, the contents of the gallbladder are apt to become purulent, thereby producing a condition known as *empyema of the gallbladder*. Andrews has shown that, on many occasions, this purulent-like material consists chiefly of mucous and cholesterol crystals and that in such cases the culture is negative, thereby suggesting that on these occasions infection plays a minor role in pathogenesis. The secretion of mucus, the pouring out of exudate, and the production of pus increase the distention and the size of the gallbladder. Within a few days after the production of the obstruction, the green-

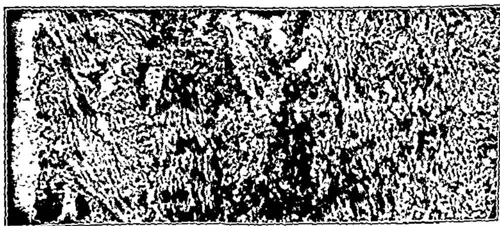

Fig. 18. Photomicrograph of subacute cholecystitis. Note that the mucosa has been eroded away and the submucosa is covered with exudate. The muscularis (M) is comparatively normal. Most of the thickness of the wall consists of fibrous tissue (F), only a part of which is shown.

Fig. 19. Photomicrographs showing chronic cholecystitis. A, diffuse mild lymphocytic infiltration and only slight thickening of the wall; the musoca is intact. B, the wall of this gallbladder is greatly thickened because of numerous attacks of subacute inflammation. Lymphocytic infiltration is more extensive than in A.

ous organs (Fig. 20). If the cystic duct becomes obstructed because of adhesions or a stone, but in the absence of acute inflammation, a condition known as *hydrops* may develop; after several days, the brownish green color of the gallbladder contents fades because of destruction or absorption of bile pigment. The gallbladder becomes distended because of the secretion of mucus by the mucosa and may attain an enormous size, often becoming palpable as a smooth, only mildly tender mass in the upper abdomen. The contents of the gallbladder in such an instance is sterile and is known as *white bile,* since the most important constituent is mucus excreted by the gallbladder and because bile pigments are absent. If the contents become infected, an *empyema,* as discussed previously, will result; in such instances, operative therapy becomes more urgent.

The function of the chronically inflamed gallbladder, as determined by cholecystography, may or may not be seriously impaired. It is quite probable that during the acute attack, the gallbladder function is lost but, when healing takes place, is to a great extent regained. Microscopically, the wall is thickened by fibrous tissue and infiltrated by lymphocytes. Granulation tissue and plasma cells are abundant. The muscle and elastic tissue may be destroyed and replaced by fibrous tissue and fat cells. On rare occasions, the wall of the gallbladder becomes calcified to such an extent that it may be demonstrable by x-ray.

Frequently, the gallbladder mucosa is the seat of polypoid enlargement of the villi. These villi contain yellowish deposits of cholesterol or cholesterol esters which are visible to the naked eye (Fig. 21). The term *strawberry gallbladder* has been applied by MacCarty to this condition (1910), although it was probably first recognized by Moynihan (1909). There is no evidence that this disease has any clinical significance except that stones are frequently associated.

genital organs. Tenderness associated with renal colic is more apt to be acute posteriorly; examination of the urine rarely fails to reveal erythrocytes or pus cells; fever and leukocytosis are usually absent in nephrolithiasis. Occasionally, the pain encountered in gastric crises associated with tabes dorsalis may be similar to that produced by acute cholecystitis. Muscle spasm and abdominal tenderness, however, are usually much less prominent. Moreover, fever and leukocytosis are absent in the gastric crises. Neurologic examination should reveal signs of tabes. Pain of cardiac origin occasionally simulates that of cholecystitis, but rarely indeed will a careful consideration of the manifestations fail to establish differentiation between these two diseases.

TREATMENT. Although the majority of surgeons (27, 28, 29) favor prompt operation for most patients with acute cholecystitis, there are many very competent surgeons who favor conservative treatment (30, 31) unless an acute complication, such as perforation or impending perforation, develops. The high frequency of diagnostic error is one of the important contraindications for prompt operation; however, it is true that immediate operation eliminates much discomfort during resolution of the acute attack and shortens the period of disability. An important disadvantage of delay lies in the fact that, if operation is performed 10 to 14 days after the attack subsides, the gallbladder is still much more seriously inflammed than it is during the first day or two of the acute attack; removal of the organ is therefore more difficult than when performed shortly after onset of symptoms. The authors agree with Boyden (32) that, if the patient is seen within 48 hours after onset of symptoms and the diagnosis appears quite accurate, prompt operation is advised. In our opinion, if the patient is not seen within this period since onset of symptoms, the conservative procedure will usually be indicated. However, if the symptoms do not subside under 24 to 48 hours with conservative therapy, and particularly if there is an increase in such manifestations as pain, muscle spasm, and fever, along with a rising leukocyte count, immediate operation will be indicated on the assumption that a serious complication, such as gangrene or perforation, may be present, thereby demanding surgical relief. Obviously, if signs of peritonitis are present upon admission, emergency operation will be indicated on the assumption that gangrene or perforation has already taken place. At operation, cholecystostomy or cholecystectomy may be performed, depending upon the age of the patient and the condition of the gallbladder. At operation, the surgeon should investigate the common duct because stones will be present in the common duct in 5 to 10 per cent of cases (32).

If the gallbladder is so badly diseased and densely adherent that removal will jeopardize the patient's life, it may be advisable to perform cholecystostomy. However, relief from cholecystostomy is not permanent in that symptoms of more than trivial character will develop within five years following cholecystostomy in 25 to 35 per cent of cases. In seriously ill patients, the risk of operation is greatly reduced by adequate preoperative treatment, including intravenous fluids, transfusion, and combined chemotherapy. This is particularly true in elderly individuals. A study of results in numerous reports will not reveal a significant difference in the mortality rate of patients treated by prompt operation compared to those treated conservatively (33). The mortality rate in acute cholecystitis is much higher (5 to 10 times) in patients over 60 or 65 years of age than in patients under this age (29).

Chronic Cholecystitis. This is an extremely frequent condition, but on many occasions it offers marked difficulty in diagnosis. There is sufficient difference in the manifestations, treatment, and prognosis of patients with cholecystitis due to the presence or absence of stones that the two conditions are considered separately. Cholelithiasis is discussed later in this chapter.

PATHOLOGY. Chronic cholecystitis may develop as a sequel to acute cholecystitis, but more frequently develops insidiously. The gallbladder wall, because of bacterial invasion or a chemical inflammation, becomes thickened, largely because of the deposition of scar tissue (Fig. 19). Adhesions in varying degree are found externally (pericholecystitis) and may involve the contigu-

group of symptoms alone is, therefore, only suggestive evidence of the presence of gallbladder disease. Pain is of much more value in establishing the diagnosis. The pain usually varies in extent, occurring in mild intermittent attacks which in reality may be due to transient acute inflammation and is localized in the right upper quandrant, but frequently radiates toward the tip of the scapula. In a detailed study of over 200 cases made by Harridge and Helsby (34) the attack lasted less than one hour in 42 per cent of cases. Furthermore, in 43 per cent of their cases, the pain, while it lasted, was continuous; it was intermittent or colicky in the remainder. *After an extensive study of patients* at the Mayo Clinic, Smith (34a) noted that 24 per cent of patients with cholecystic disease had pain left of the midline, although many of them had pain also on the right.

Nausea is encountered frequently, but vomiting is uncommon except during severe attacks. Rarely is there any relation of the pain and discomfort to meals, except that fatty food is poorly tolerated. Constipation is a frequent complaint. Fever and leukocytosis are rarely present. Jaundice, if present, is usually associated with a stone in the common duct except that mild jaundice is occasionally produced by an associated hepatitis. Occasionally, patients with chronic cholecystitis have dyspepsia of more or less constant severity without attacks of severe pain. Such a clinical picture, however, offers great diagnostic difficulty since it is produced by so many other diseases.

Examination of the abdomen reveals tenderness over the right upper quadrant, the intensity of which varies with the severity of the disease. Frequently the infection subsides to such an extent that the patient will be free from symptoms or signs for months at a time only to have them recur. Tenderness under the right costal margin (over the liver edge) may be present and is a manifestation of the associated hepatitis (Graham).

Evidence has been presented (Alvarez, 1934) to suggest that allergy may affect the gallbladder. Whether or not it is a true allergy cannot be determined, but it is definitely known that certain foods, such as chocolate or bananas, may initiate attacks of severe right upper quadrant pain.

Differential Diagnosis. It may be extremely difficult to differentiate chronic cholecystitis from peptic ulcer, but symptoms of the former disease are rarely related to meals, whereas in peptic ulcer there is usually a history that discomfort occurs two or three hours after meals and is relieved by eating or ingestion of alkali. The most reliable method of distinguishing peptic ulcer from cholecystitis is by x-ray, especially cholecystography and the barium meal. The two diseases frequently occur together. Recurring attacks of mild acute appendicitis may simu*late chronic cholecystitis if the appendix is* adherent high in the abdominal cavity. However, appendicitis is rarely associated with dyspepsia; pain and tenderness are the chief manifestations. Spastic colitis associated with constipation is perhaps the most difficult disease to differentiate from chronic cholecystitis. Usually the tenderness in spastic colitis is diffuse, limited somewhat to the colon, and not localized to the right upper quadrant. Osteoarthritis of the spine is commonly confused with cholecystitis, and even when the latter condition is present the most annoying symptoms may be due to the spinal lesion. At times, small diaphragmatic hernias (particularly those of the hiatus type, see p. 856) will produce a variety of digestive symptoms including epigastric distress, bloating, and belching so commonly observed in cholecystitis. Intestinal allergy may likewise simulate the manifestations of chronic cholecystitis, but the pain and tenderness are more apt to be diffuse. On rare occasions, tuberculosis of the spine may produce pain, tenderness, and so forth, in the upper quadrant. This condition occurs just often enough to demand inspection of the spine in patients suspected of having chronic cholecystitis. In all these conditions, cholecystography should lead to the correct diagnosis. It should be emphasized, however, that the demonstration of a pathologic gallbladder by cholecystography *does not necessarily mean that the symptoms are of cholecystic origin,* inasmuch as it is known that a pathologic gallbladder may remain silent for years. Moreover, chronic cholecystitis is so common that it will frequently *be present along with some*

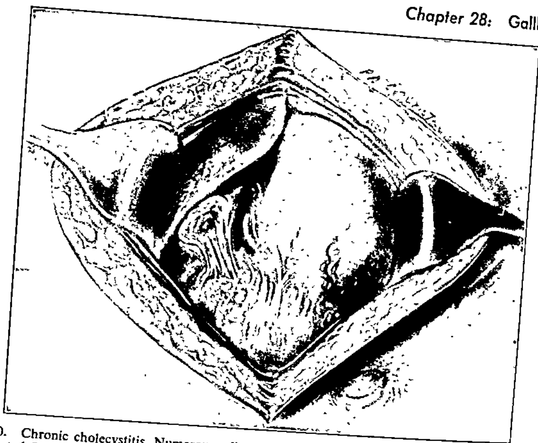

Fig. 20. Chronic cholecystitis. Numerous adhesions to contiguous organs, particularly the omentum, may be noted. There is also a localized area of hepatitis on the superior surface of the liver, adjacent to the gallbladder.

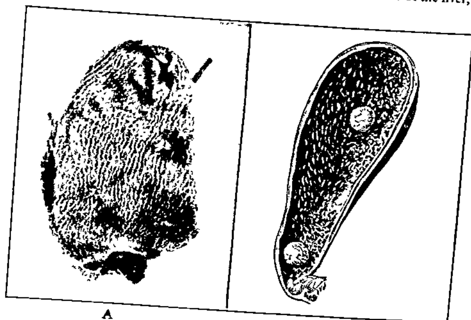

Fig. 21. Cholesterosis of the gallbladder. A, without stones. B, with stones.

Clinical Manifestations. The presence or absence of stones influences the clinical picture as discussed later. One of the most common symptoms complained of in chronic cholecystitis is *dyspepsia*, which may include such symptoms as epigastric distress, bloating, pyrosis (heart burn), flatulence, anorexia, belching, and mild pain. It must be emphasized, however, that innumerable diseases may produce dyspepsia; the presence of this

Fig. 22. Photomicrograph of gallbladder with cholesterosis to illustrate one of the possible mechanisms in the formation of gallstones. The section was made from unfixed frozen tissue and is unstained, but is viewed under polarized light for determination of the presence of cholesterol; the white material in the enlarged villus is cholesterol. It seems logical to assume that the large cholesterol-containing villus might be detached by rupture of the stalk, and become the nucleus of a gallstone.

a criteria of obstruction, Cattell and associates classify all sphincters as obstructed if a 3 mm. probe cannot be passed through it readily. Treatment consists of section of the fibrosed sphincter.

Cholelithiasis. Gallstones nearly always contain cholesterol; many also contain calcium and bile pigments. They may be solitary or multiple. They vary in shape from the round single stone to the faceted multiple stones. Many years ago it was thought that obstruction, stasis, and infection were the important factors in the formation of gallstones. However, Andrews and associates (40) have shown that a reduction in the ratio of cholesterol to fatty acids or bile acids by absorption of bile salts through the gallbladder wall is very important in the etiology of gallstones, particularly the cholesterol type (Fig. 22). Robertson (41) has corroborated this view, adding that hormonal influence may be important; he postulates further that secretion of an abnormal mucoid substance by the gallbladder mucosa might actually act as a binding agent and organic framework for the precipitated elements of the bile. Phemister and associates (1939) have called attention to the role of infection in the formation of calcium carbonate stones.

At least 50 per cent of the gallbladders removed surgically throughout the country contain stones (Fig. 23). In a study of 16,936 autopsies, Robertson and Dochat (42) found gallstones in 31.7 per cent of women past the

Fig. 23. *Cholelithiasis.* The stones in this instance completely filled the gallbladder.

other disease which may be producing the symptoms, and be of much more importance than the gallbladder disease. Duodenal drainage, with study of the centrifuged sediment, is of diagnostic value. The finding of cholesterol crystals, calcium bilirubin, bile pigment particles, and pus cells indicates the presence of stones.

TREATMENT. There is little to offer the patient with chronic cholecystitis other than surgical procedures (cholecystectomy and, rarely, cholecystostomy), except that occasionally changes in the diet, such as elimination of fatty food, will be helpful. It should be emphasized, however, that operation should not be recommended unless the diagnosis is definite and symptoms, especially pain, are sufficient for the patient to demand relief. We wish to emphasize that cholecystectomy will not cure more than 60 per cent of patients when dyspepsia is present without pain, particularly when stones are absent.

Cholecystectomy is much to be preferred over cholecystostomy because of the great tendency for the latter to be followed by recurrence of symptoms at a later date. The *operation* for removal of the gallbladder is associated with certain technical pitfalls which, if not avoided, will lead to deleterious sequelae. During the procedure of cholecystectomy, extreme care must be exercised in the identification of the cystic and common duct lest the latter structure be injured. Such a tragedy is avoided by careful dissection at the neck of the gallbladder, which will facilitate identification of the ducts and thereby minimize the possibility of inflicting injury upon them. The carefully isolated cystic duct is clamped, cut, and the stump ligated. Identification of the cystic artery will also enable its ligation, so that removal of the gallbladder from below upward may then be performed with little or no bleeding. It is advisable to insert a rubber dam drain down to the stump of the cystic duct; if drainage is slight, it is removed in 48 hours. Cholecystectomy is apt to produce more postoperative discomfort (gas pains and the like) than most other types of abdominal operations. For this reason, adequate amounts of morphine or similar hypnotic should be given during the first two or three days. Gastric decompression with a tube for a day or two after operation will minimize the postoperative distress. The use of vitamin K for obstructive jaundice is discussed on page 676. Results of cholecystectomy for gallbladder diseases are very good (80 to 90 per cent) if the diagnosis is correct. Aged people tolerate simple surgical procedures on the biliary tract very well, but in complicated operations the mortality rate will be 5 to 10 times higher in aged patients than in young patients (35, 36). It is for this reason that indications for cholecystectomy may be stronger in aged patients to remove the gallbladder before complications develop.

Poor results following cholecystectomy may be attributed to such factors as error in diagnosis, overlooked stones in the common duct, pancreatitis, technical errors at operation, and fibrosis of the sphincter of Oddi.

Fibrosis of the Sphincter of Oddi. This lesion has been recognized only recently, but for the past 10 or 20 years the term *biliary dyskinesia* has been applied to a partial obstruction at the terminal end of the common duct due to spasm of the sphincter. It is now agreed by most surgeons that fibrosis is the important factor in the obstruction, although spasm may have been a prominent feature in its incipiency. Pain is a prominent manifestation; the pain is similar to that of gallbladder disease, but del Valle (who first performed sphincterotomy for this lesion in 1925) describes the pain of obstruction from fibrosis of the sphincter as radiating toward the first lumbar vertebra and left scapular angle whereas the pain of gallbladder colic radiates to the mid-thorax, right hemithorax, and right scapular area. However, in our experience (37) there has not been a significant difference in the pain encountered in the two conditions. Wise and O'Brien (38) find intravenous cholangiography helpful in making the diagnosis. They postulate that ducts (on x-rays with 30 per cent magnification) measuring 8 to 15 mm. are probably partially obstructed, and ducts measuring over 15 mm. are invariably obstructed; they believe also that density of the shadow is of diagnostic value. Cattell and associates (39) have studied 100 consecutive patients with this condition and noted that 81 had had a previous cholecystectomy. Stones were present in 38 per cent of their series; 30 of them were jaundiced or had a history of jaundice. As

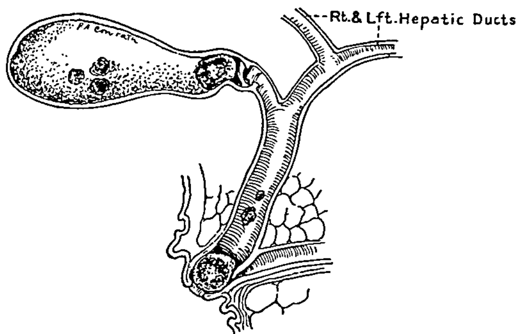

Fig. 24. Drawing to illustrate the common locations of gallstones in the biliary system. Impaction in the cystic and common duct as depicted in the illustration is quite common.

age of 40 years, and in 16.2 per cent of men past the age of 40. Multiple pregnancies have been considered predisposing factors in the development of gallstones; however, in their intensive statistical study, Robertson and Dochat (42) found no greater incidence in women with children than in women who had borne no children. Cholecystitis caused by the typhoid baccillus may be encountered with or without stones.

The *clinical manifestations* produced by biliary calculi vary tremendously. On many occasions the patient may carry gallstones in his gallbladder the greater part of his life without experiencing any symptoms whatever. On the other hand, symptoms may develop as soon as the stones are formed and provoke a wide variety of clinical manifestations.

The clinical picture produced by gallstones *depends on their location* (Fig. 24). When in the *gallbladder*, stones frequently are silent or cause only mild symptoms of dyspepsia. As a rule, however, the pain associated with stones in the gallbladder is more severe and more apt to occur in attacks than it is in chronic cholecystitis without stones. When a stone becomes lodged in the *cystic duct* the pain is usually severe; the clinical picture produced by this condition is frequently spoken of as biliary colic, although a better term is acute cholecystic obstruction. The origin of the pain is uncertain but may be associated with such factors as spasm or contraction of the gallbladder, by distention of the duct, or by the inflammation associated with the stone. The pain is apt to occur in paroxysms with tenderness and pain remaining in the intermissions. These attacks are apt to be of short duration but may last for several days; unlike stone in the common duct they are not associated with jaundice, except when a coexisting hepatitis is present. If the obstruction to the cystic duct does not subside, acute cholecystitis may develop, or the gallbladder distend and its contents become colorless (white bile) because of the disappearance of the bile pigment (hydrops of the gallbladder). If the contents of a hydrops become infected, empyema of the gallbladder results.

When the stones are located in the *common duct* a different clinical picture manifests itself, although stones may occasionally be present and produce very few manifestations. Usually, however, the common duct at the sphincter of Oddi becomes occluded by the stone; more severe manifestations then develop. An intermittent colicky pain in the epigastrium or right upper quadrant is usually present. At the onset of obstruction, nausea

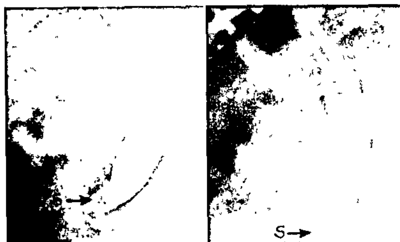

Fig. 27. Postoperative cholangiograms revealing stones. In this patient the surgeon overlooked a stone, an accident which may infrequently happen to any good surgeon. The shadow is relatively the same in the two films, taken on the same day.

fistula is produced (see below). In these patients, it is frequently necessary to institute special preoperative preparations, such as bed rest, high carbohydrate and fluid intake, and the like (see Ch. 9). Extreme precaution must be taken against hemorrhage during and after operative procedures in the presence of jaundice since such patients occasionally have a delayed coagulation time of the blood. Administration of vitamin K with bile salts, intravenous glucose, and transfusions are effective in treatment. (See also p. 676.)

When the stones are producing symptoms, such as pain and troublesome dyspepsia, indications for cholecystectomy are clear cut. However, when few or no symptoms are present, there is disagreement as to whether or not operation is necessary, except that all would agree to removal of a stone from the common duct even though it were producing no symptoms. When stones in the gallbladder are asymptomatic, the authors consider age and life expectancy important in the decision regarding operation. If the stones are asymptomatic and found accidentally in a patient 65 or more years of age, operation would appear not to be indicated. On the other hand, if symptoms are present in the aged, indications for operation (probably cholecystectomy) are actually stronger than in younger patients because old people tolerate complications of gallbladder disease so poorly and complications represent the serious aspects of gallbladder disease. If asymptomatic stones are found by x-ray in a person 30 to 40 years of age, and life expectancy is normal, cholecystectomy would definitely appear indicated since the danger of ultimate development of one or more complications, such as stones in the common duct, hepatitis, pancreatitis, carcinoma, hydrops, and empyema, over a period of many years would appear great enough to justify operation.

Occasionally, gallstones exert a reflex effect deleterious to angina pectoris and make the symptoms and effects of that disease worse. It has been shown by numerous workers (46, 47, 48) that cholecystectomy in such cases will be very beneficial. However, great care must be taken in choosing these patients for operation, particularly regarding time, since an operation within three months following a myocardial infarct is dangerous and, in fact, frequently fatal.

Biliary Fistula. As mentioned above, a biliary fistula is purposely produced after the common duct is opened for exploration and the removal of stones. Ordinarily, such a fistula is of short duration, the T-tube being removed in two or three weeks. Drainage of bile through the resulting sinus tract may continue for a few days, after which time it closes spontaneously; closure is accompanied by a gradually increasing amount of pigment in the stool which changes from an acholic to a pigmented character.

Persistent drainage of bile for more than

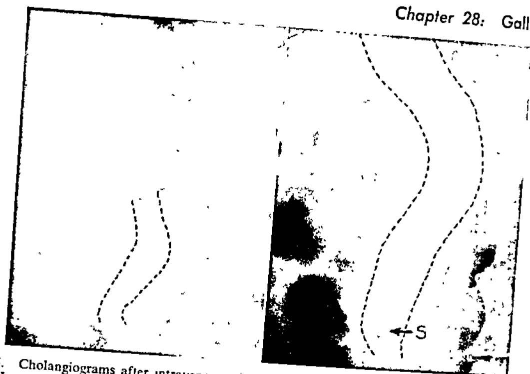

Fig. 25. Cholangiograms after intravenous administration of cholografin. The shadow on the left is normal. However, on the right, the common duct is moderately dilated, and a negative shadow of a soft stone "S" (cholesterol) is observed in the terminal end.

Fig. 26. Postoperative cholangiograms (normal). When choledochostomy is performed, a postoperative cholangiogram utilizing 30 per cent diodrast (or a similar media), is taken before the T-tube is removed (about 12 days postoperatively). Left, no stones were found in the duct, the diameter of which is normal. Right, stones were found and removed; the duct is slightly enlarged. Note that the pancreatic duct is filled. This is not necessarily abnormal; it may be due to temporary spasm or fibrosis of the sphincter of Oddi.

a *preliminary open film of the gallbladder* region, because putty-like material or calcium deposited in the wall may cast a shadow which resembles a normal gallbladder but is not due to administration of dye. One of the most serious pitfalls in cholecystography occurs because asymptomatic cholecystitis is *frequent and because clinicians, on finding* cholecystographic evidence of a diseased gallbladder, may cease searching for other diseases (such as carcinoma of the colon), and thus overlook the lesion which may in reality be producing symptoms.

Nonvisualization of the gallbladder after *cholecystography may mean that the concentrating* power of the gallbladder has been lost or that an obstruction at the cystic duct is present. If a shadow of the gallbladder is obtained, stones will show up as "negative" or "positive" defects in the films, i.e., cholesterol stones displace dye and produce negative shadows, whereas hard calcium stones show up as areas of increased density, which are spoken of as "positive" shadows (Figs. 28, 29). A distortion of the gallbladder shadow which is consistent in more than one film is indicative of adhesions (pericholecystitis). It should be emphasized, however, that the *dye must be excreted by the liver before it* can enter the gallbladder; the presence of jaundice interferes markedly with the production of a gallbladder shadow because of numerous factors, such as inability of the liver to excrete the dye, and edema of the gallbladder wall.

For years tetraiodophenolphthalein and its isomer, phenoltetraiodophthalein, were the substances used in the performance of this test. In 1940, Dohrn and Diedrich (51) introduced another contrast media, β-(4-hydroxy-3,5-diiodophenyl)-α-phenylpropionic acid, known as iodoalphionic acid or *priodax; it is very satisfactory and is given in* a dose of 3 grams orally the night before x-ray pictures are taken. If there is doubt about the accuracy of a test a double dose of priodax may be used. Numerous other compounds have been found suitable for cholecystography. Of those recently introduced 2-(4-hydroxy-3,5-diiodobenzyl)-cyclohexane carboxylic acid (monophen) and 3-(3-amino-2,4,6-triiodophenyl)-2-ethylpropanoic acid (telepaque) should be mentioned. The latter is considered by many radiologists and surgeons to be more satisfactory than the others mentioned above. It is also given the night

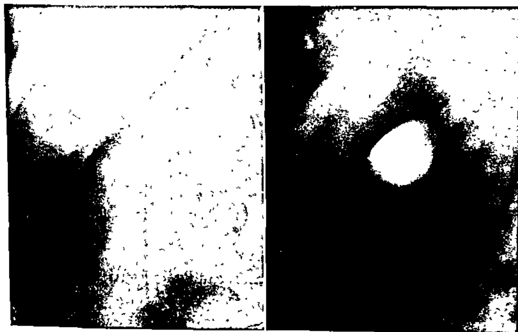

Fig. 28. *Stones revealed by oral cholecystography. In each patient the density of the gallbladder shadow* (after oral ingestion of telepaque) is normal. On the left a negative shadow (cholesterol stone) is observed, whereas on the right a positive shadow (stone containing some calcium) is observed.

several weeks is usually indicative of an obstruction in the common duct distal to the opening made at operation. Injection of radiopaque substances, such as diodrast or sodium diatrizoate (hypaque), into the tract will allow visualization of the larger bile ducts by x-ray. The obstruction can readily be demonstrated by this procedure (cholangiogram); if produced by a stone left in the common duct, the stone can usually be visualized. Regardless of the cause of the persistent obstruction, a secondary operation will usually be indicated, although it has recently been learned (49) that about two thirds of these "stone" shadows will disappear in two to six months. It cannot be proved that these shadows were stones and not air bubbles. The T-tube was clamped to allow bile to flow over the stones. Two to three grams of bile salts were given orally per day to these patients, but it is not clear whether or not this drug was of value. Conservative treatment of this type should not be tried if the patient is jaundiced or there is evidence that the common duct is completely obstructed.

Persistent loss of bile is poorly tolerated by all patients, particularly in males of advanced age. An important symptom is a severe degree of anorexia which may be so marked that it creates a positive loathing for food. Dehydration and hypochloremia are common, especially when the loss of bile is considerable and there is associated vomiting and/or diarrhea. Malnutrition is frequent, developing either insidiously or with rapid loss of weight. There is often a tendency toward spontaneous bleeding due to vitamin K deficiency; the mechanism is the same as in jaundice (see p. 675). *Treatment* is difficult, but the symptoms rapidly improve as soon as bile flow into the intestine becomes reestablished. Bile salts by mouth may be effective, but they induce a further loss of bile since they exert a cholagogue action. Feeding the patient a portion of his own bile is usually very helpful in eliminating anorexia, loss of weight, and other asthenic symptoms, but not all patients will be able to drink it unless it is well disguised. Insertion of a small stomach tube will eliminate this disadvantage but is likewise disagreeable. If the fistula does not close in a few weeks, operation will be indicated to relieve the obstruction. Preoperative preparation, including administration of vitamin K and so forth, as previously described, will be necessary.

A spontaneous biliary fistula is rare but may occur if the gallbladder becomes adherent to the abdominal wall and ruptures to the outside. Rare, also, is rupture of the gallbladder or a large bile duct (usually by abscess formation) through the diaphragm into the lung and bronchus, thereby producing a bronchobiliary fistula, which is characterized by the expectoration of bile-stained sputum. More commonly a stone perforates the wall of the gallbladder into the colon or small intestine, with formation of a fistula which, in time, will usually close. Such stones may actually be large enough to lodge in the small intestine and produce an acute obstruction.

Cholecystography. Cholecystography refers to the visualization of the gallbladder in an x-ray film following the administration to the patient of a radiopaque substance which is carried in the bile to the lumen of the gallbladder and is concentrated there in sufficient amount to cast a shadow on the x-ray film. This diagnostic procedure was discovered in 1924 by Graham and Cole (50). A substance capable of fulfilling such requirements must have two prerequisites, namely, be excreted primarily by the liver and contain elements of sufficient atomic weight (e.g., iodine) to be impervious to the x-ray. In individuals with a normal gallbladder, a shadow of the organ is obtained within a few hours after oral or intravenous administration of the contrast medium. Before the advent of cholecystography, there was no direct clinical method of gaining objective information as to the presence of abnormal changes in the gallbladder, except the demonstration of calcified stones by the plain x-ray plate; the drainage of gallbladder bile through a duodenal catheter (Lyon's test) yields but indirect evidence of disease and often gives equivocal findings.

Production of a dense shadow of the gallbladder (which usually reveals a change in size on successive films) is indicative of a normal gallbladder. Absence of shadow and evidence of stones within the gallbladder shadow (as produced by the dye) are extremely reliable indications of a pathologic gallbladder. It is desirable, however, to obtain

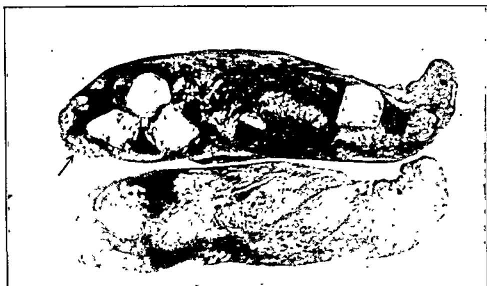

Fig. 30. Carcinoma of the gallbladder. The organ contained stones, and, as is likewise common in carcinoma of the gallbladder, considerable inspissated bile and mucus. The patient had symptoms typical of chronic cholecystitis. Although longitudinal section of the gallbladder revealed an unusual thickening at the fundus, as indicated by the arrow, the presence of the carcinoma was not evident until the microscopic section was obtained. In spite of the performance of a cholecystectomy in this early stage, the patient returned 18 months later with a metastasis in the liver, thereby illustrating the extremely invasive character of carcinoma of the gallbladder.

most common etiologic factor is accidental injury during operative procedures upon the biliary tract. In a recent study of 122 cases by one of the authors and associates (52), 72 per cent could definitely be attributed to operative trauma. An additional 18 per cent were of inflammatory origin, but at least half these were quite certainly related to operative errors. The stasis of bile created by the obstruction encourages infection, and symptoms are apt to occur in attacks consisting of chills, fever, jaundice, pain, malaise, and so forth. The only hope for relief lies in surgical therapy. Such procedures as resection of the stricture with anastomosis of the two ends of the duct over the arm of a T-tube brought out through an opening in the common duct above or below the suture line, implantation of the proximal end of the duct into the stomach or duodenum, implantation of the duct into a loop of jejunum, and implantation of the duct into a Roux Y-arm of jejunum (52) are methods utilized in repair. Perhaps the majority of surgeons favor the latter method although an end-to-end anastomosis is preferred when it is possible.

On rare occasions, such tumors as *carcinoma,* adenoma, and polyp, may be primary in the ducts. Carcinoma may develop at any point in the common hepatic duct or the common duct. More commonly it is located in the *ampulla of Vater.* The symptoms produced by such tumors are similar to those observed in carcinoma of the pancreas (as described later). Important in the differentiation from carcinoma of the pancreas are the facts that, in carcinoma of the ampulla of Vater, the jaundice is apt to be intermittent and that blood is usually found in the stool. Diagnosis is often made with certainty only at the time of operation, especially if the surgeon opens the duodenum for direct inspection of the ampulla of Vater. Since the development of a technic of resection by Whipple and associates (1935), the majority of these tumors are amenable to surgical treatment because they grow slowly. Prognosis is therefore so good that the patient should not be deprived of the benefits of resection if the tumor is operable. *Cysts* of the common duct ai extremely rare and usually are congenital in origin.

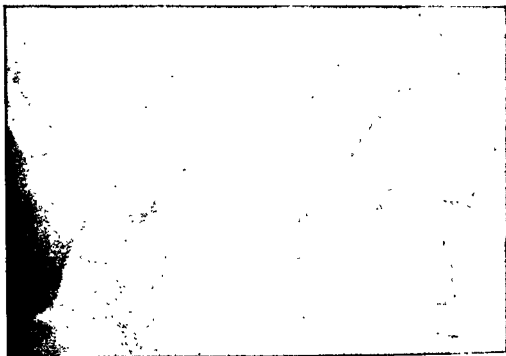

Fig. 29. Multiple stones in gallbladder. Oral administration of telepaque revealed a normally functioning gallbladder, but numerous negative shadows of cholesterol stones are observed.

before (10 hours before x-rays) in a dose of 3 grams; a double dose may be given.

In oral cholecystography x-ray pictures are taken on two or three occasions following the administration of the dye (10 to 12 hours after ingestion of the tablets) so that the presence of stone shadows may be confirmed. An absence of a shadow is 100 per cent evidence of gallbladder disease unless serious hepatic insufficiency exists or the agent was vomited or not taken.

Tumors of the Gallbladder. *Primary carcinoma* of the gallbladder is the most common of these tumors and constitutes about 3 or 4 per cent of all cases of carcinoma. Carcinoma of the gallbladder rarely occurs without the presence of stones in the organ. The relative frequency of carcinoma compared to cholelithiasis varies in different clinics, but on the average 4 to 5 per cent of all patients proved to have stones in the gallbladder by operation or autopsy have associated carcinoma of that organ. Unfortunately, carcinoma of the gallbladder may develop insidiously. The symptoms may occur late and be insignificant; they resemble those discussed under chronic cholecystitis. In the early stages of the disease, pain is usually slight but may be very troublesome later on. The diagnosis is rarely made before operation. If the disease is found to be local at the time of operation, the gallbladder obviously should be removed (Fig. 30). The tumor is so invasive that, even though it is early and small, cholecystectomy is rarely curative.

Small *benign papillomas*, which consist in reality of hyperplasia of the villi, are rather common. Papillomatous structures due to deposition of cholesterol have already been mentioned. Other tumors, such as adenoma and sarcoma, do occur but only on rare occasions. True adenomas have very little clinical importance.

THE BILE DUCTS

Stones in the common duct and infection of the intrahepatic bile ducts (cholangitis) are common and have already been discussed. Infection may also affect the extrahepatic bile ducts, especially when a stone is impacted in the common duct. On such occasions, white bile and even pus may be found in the choledochus at operation. *Strictures* are not uncommon and may occur either in the ductus choledochus or the common hepatic duct, usually in the former. They may be infectious or traumatic in origin. Unquestionably, the

Fig. 1. Demonstration of a common passageway by cholangiogram performed during operation. On the left side a needle has been inserted into the cystic duct (spiraled by the valves of Heister) and opaque material fills the bile duct in liver and down to the junction of common bile duct with pancreatic duct. A metallic bucket on the end of a nasogastric tube is placed to deliver 0.1 hydrochloric acid to the sphincter of Oddi and create spasm of the muscle. Resistance to flow at this point forces the fluid into the pancreatic duct, which is outlined to the tail of the pancreas (arrow).

COMMON BILE DUCT. 1. Many years ago Opie (1) described an instance of acute pancreatitis in which bile had been diverted into the pancreatic duct by a small stone lodged in the ampulla of Vater. The common bile duct and pancreatic duct opened into this ampulla, thus creating a common channel. Archibald (2) some years later proposed that a resistant sphincter of Oddi, which controls the outlet of this ampulla into the duodenum, might divert bile or pancreatic juice from its proper duct system into the other. The actual incidence of a functional common channel is difficult to determine in the cadaver because the sphincter of Oddi during life can extend over both openings and create a common space, whereas the cadaveric position of the sphincter is retracted. In studies with radiopaque materials in the ducts of a large series of patients operated upon for biliary and pancreatic inflammatory disease or by direct observation at operation, a common channel is present in practically all (3) (Fig. 1).

2. Normally both bile and pancreatic juice are delivered to the duodenum as a result of the presence of food. The mechanism of secretion is through the elaboration of the gastrointestinal hormone, secretin, by duodenal mucosa. Secretin is carried by the blood to the pancreas where it acts directly on pancreatic cells. At the same time, the sphincter of Oddi relaxes and juice flows into the duodenum. Resistance to flow by a sphincter which does not relax adequately raises intraductal pressure and brings about distention of the ducts. It can be shown that most of the pain associated with disorders of ductal systems is caused by distention.

3. Experimentally, inflammation of the pancreas can be produced by the injection of bile into the pancreatic duct.

THE PANCREAS

JOHN H. MULHOLLAND

Embryology. A bud of ectoderm pouts out of the primitive duodenum and gives rise to all of the ducts, glands, and appendages of the biliary-pancreatic system. This common origin is the background for complex interdependence and interactions between the two main digestive glands (liver and pancreas) and the upper gastrointestinal tract (duodenum, pylorus, and stomach) in maturity. The pancreas originates as ventral and dorsal lobes which rotate and fuse into the adult single structure. Abnormalities in these processes may give rise to persistent variations which create surgical problems (e.g., annular pancreas).

Anatomy. In the adult, the pancreas is a retroperitoneal organ closely bound to the lesser curve of the duodenum at its head and extending its neck, body, and tail obliquely across the abdomen to the hilum of the spleen. It is a soft, yielding organ which conforms to the rigid curving posterior vertebral bodies and rib cage until the tail extends into the lienorenal ligament. Because of its deep situation and soft consistency, it is not palpable through the abdominal wall in its normal state, and surgical exposure of its entire length is an exacting maneuver. Direct proximity of the neck and body to the rigid vertebral bodies exposes these parts to injury when blunt trauma to the abdomen occurs. Rupture of the pancreas as a result of such forces is a serious event and difficut to diagnose. Depending upon the extent of damage to the pancreas, the outcome may be a rapidly disastrous inflammation or extravasation of pancreatic juice along anatomic pathways defined by peritoneal layers. The latter will be discussed under a consideration of pancreatic pseudocysts below.

Other anatomic features of the pancreas which are of surgical import are the so-called islet cells which produce internal secretions concerned with carbohydrate metabolism (insulin, glucagon) and more obscurely, with gastric acid production. Surgical disorders of these secretions are discussed in Chapter 39.

The acinar and ductal system produces an external secretion which is concerned with intestinal digestion. Acinar cells are large and conical shaped. They are so arranged that the apex of the cone is directed toward the central collecting area of the acinus, which in turn joins to other fine ducts of a lobule. Secondary lobules are groups of acini with loose connective tissue envelopments which carry vessels and nerves. Central collecting ducts join other larger cell-lined tubes at right angles. As the ducts become larger, the lining duct cells change from flat cuboidal to low columnar and finally to columnar epithelium. These duct epithelial cells secrete a mucoid material, and possibly the fluid and bicarbonate portion of pancreatic juice; acinar cells secrete the digestive enzymes.

There are several anatomic and physiologic features of the pancreas which are important in the production of the disease.

RELATIONSHIP OF THE MAIN PANCREATIC DUCT TO THE SPHINCTER OF ODDI AND THE

Fig. 1. Demonstration of a common passageway by cholangiogram performed during operation. On the left side a needle has been inserted into the cystic duct (spiraled by the valves of Heister) and opaque material fills the bile duct in liver and down to the junction of common bile duct with pancreatic duct A metallic bucket on the end of a nasogastric tube is placed to deliver 0.1 hydrochloric acid to the sphincter of Oddi and create spasm of the muscle. Resistance to flow at this point forces the fluid into the pancreatic duct, which is outlined to the tail of the pancreas (arrow).

COMMON BILE DUCT. 1. Many years ago Opie (1) described an instance of acute pancreatitis in which bile had been diverted into the pancreatic duct by a small stone lodged in the ampulla of Vater. The common bile duct and pancreatic duct opened into this ampulla, thus creating a common channel. Archibald (2) some years later proposed that a resistant sphincter of Oddi, which controls the outlet of this ampulla into the duodenum, might divert bile or pancreatic juice from its proper duct system into the other. The actual incidence of a functional common channel is difficult to determine in the cadaver because the sphincter of Oddi during life can extend over both openings and create a common space, whereas the cadaveric position of the sphincter is retracted. In studies with radiopaque materials in the ducts of a large series of patients operated upon for biliary and pancreatic inflammatory disease or by direct observation at operation, a common channel is present in practically all (3) (Fig. 1).

2. Normally both bile and pancreatic juice are delivered to the duodenum as a result of the presence of food. The mechanism of secretion is through the elaboration of the gastrointestinal hormone, secretin, by duodenal mucosa. Secretin is carried by the blood to the pancreas where it acts directly on pancreatic cells. At the same time, the sphincter of Oddi relaxes and juice flows into the duodenum. Resistance to flow by a sphincter which does not relax adequately raises intraductal pressure and brings about distention of the ducts. It can be shown that most of the pain associated with disorders of ductal systems is caused by distention.

3. Experimentally, inflammation of the pancreas can be produced by the injection of bile into the pancreatic duct.

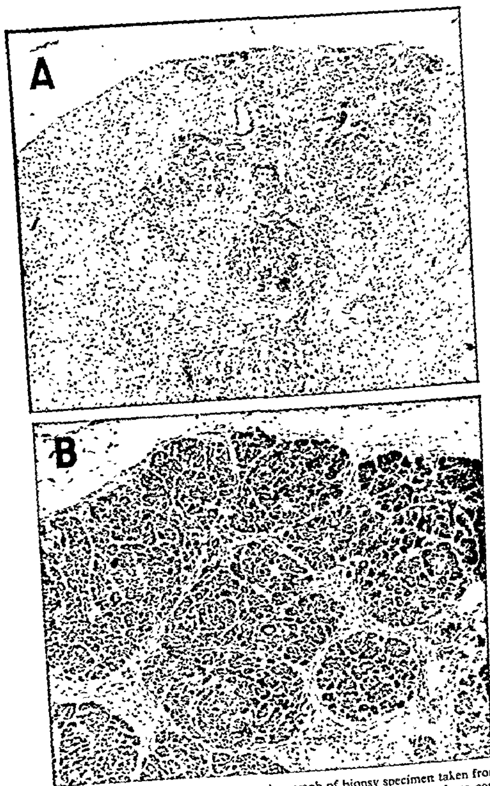

Fig. 2. Regeneration of the pancreas. A, photomicrograph of biopsy specimen taken from the pancreas of a patient who had repeated attacks of pancreatitis for many years. Scar and edema compress a small amount of acinar tissue. B, biopsy from the same site taken four years after sphincterotomy had been performed.

4. When resistance to flow of pancreatic juice is created in any part of the duct system, including the sphincter of Oddi, enzymes freely enter the blood stream. Amylase and lipase are measurable and are an indication of the degree of resistance to flow. In severe inflammation, serum amylase levels may rise to 10 to 15 times normal.

5. The acinar pancreas, like the liver, has remarkable powers of regeneration. When destruction by disease occurs, the regenerative effort may be going on side by side (Fig. 2). Frequently, this regrowth of acinar cells can be adjudged by elevated serum enzyme levels, just as atrophy is manifest by low or absent enzymes in the blood.

6. The bile duct traverses a portion of the head of the pancreas before it joins the pancreatic duct in the ampulla. Obstructions within this portion of the pancreas can create resistance to the flow of bile. Also, the sphincter of Oddi is an influence on bile flow just as on pancreatic juice flow. It is likely that these relationships form some of the basis for the common association of diseases of the two tracts. For example, it is stated that 50 per cent of patients with inflammatory disease of the pancreas also have stones in the gallbladder.

Surgical conditions of the pancreas of importance may be considered as: 1. inflammatory (pancreatitis and its complications); 2. neoplasms; and 3. injury.

Pancreatitis occurs in all degrees of severity from mild recurrent painful episodes, which are transient, to fulminating and rapidly fatal total pancreatic necrosis. Attempts have been made to designate the stage of inflammation as edematous, interstitial, hemorrhagic, or necrotic, but the gradation from one to the other is obscure, and all variations may occur in the same individual from time to time. Pathologic descriptions of the various stages of the inflammatory reaction from edema to necrosis or fibrosis serve little purpose, since the background for all is probably the same. The process may be arrested at any stage, for a characteristic of acute episodes is rapid recovery under proper management. There is also likelihood of recurrence, added destruction, further scarring, and eventual deficiency of pancreatic external secretion.

ACUTE PANCREATITIS

Clinical Features. A typical acute attack of moderate severity begins with abdominal pain, commonly after a heavy, fatty meal. The pain is located in the upper abdomen, sometimes more prominent in either quadrant. It is sudden in onset, severe, accompanied by nausea and possibly vomiting, and frequently radiates straight through to the back.

The upper abdominal wall is held tense when palpated, and there may be tenderness over a diffuse area across the upper abdomen or in any localized segment. In very severe attacks, irritating exudate can burst into the peritoneal cavity and spread downward, so that the signs of generalized peritonitis are evident.

Fever, rapid pulse rate, increased leukocytes in the blood, and other general evidences of acute inflammation are an index of the severity of the disease. One unique event, a helpful diagnostic aid, is that the serum amylase level in the blood rises sharply at the beginning of the attack and very soon begins to decline, so that normal or subnormal levels are reached in three or four days (Fig. 3). This curve of elevated serum amylase is a reflection of the course of the episode. There appears to be an initial, sudden, and violent injury which subsides gradually unless damage to other structures ensues.

Differential Diagnosis. It is most important to distinguish between acute pancreatitis and other diseases which cause severe jolting upper abdominal symptoms because the treatment of one group is considered to be immediate operation and of the other, nonoperative management. Most often considered in the differentiation are perforation of the gastrointestinal tract and acute cholecystitis. Pain, tenderness, nausea, and vomiting may be in all instances precisely the same. Of aid are: past history of ulcerlike pain or the knowledge that an ulcer existed; plain film of the abdomen demonstrating free air in the peritoneal cavity; palpation of a distended gallbladder; serum amylase levels; and analysis of aspirated peritoneal fluid.

Serum amylase determination is such an important diagnostic measure that simple methods for rapid estimations of amylase

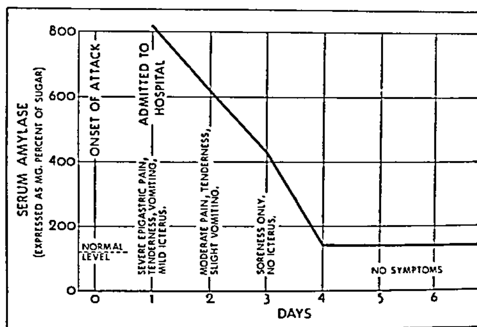

Fig. 3. Amylase levels in the blood during an acute attack of pancreatitis. This curve is characteristic. A blood sample drawn immediately after onset would probably have been much higher.

activity have been developed so that information can be available in a matter of minutes (4). The urgency of establishing a diagnosis is so great that, in occasional questionable instances, it may be advisable to explore the abdomen.

Serum amylase may be elevated as a result of diseases which permit absorption of the enzyme through the peritoneum. For instance, when a duodenal ulcer perforates and a large quantity of duodenal juice comes in contact with parietal peritoneum, amylase may be absorbed at a rate sufficient to elevate the blood level. In high intestinal obstruction with distention, intestinal contents can diffuse through the thin bowel wall into free peritoneum and promote absorption of amylase. In general, the blood level of amylase in these instances is not very high, whereas in acute pancreatitis early in the attack, the blood levels may be 10 to 15 times the normal. Aspiration of peritoneal fluid is a helpful aid in this situation. The fluid can be characterized quickly as containing bile, blood, or hemolyzed blood.

Treatment. It is generally agreed that operation for acute pancreatitis accomplishes nothing and may be detrimental. At one time it was thought that decompression of the biliary tract by draining the common bile duct or the gallbladder was helpful. Experience has shown that active, nonoperative measures can be taken which promptly reverse the chemical derangement and bring about rapid subsidence. These measures are:

1. Suppress hormonal stimulation of pancreatic secretory activity by diverting gastric acid and food from the duodenum. This is accomplished by withholding any oral intake and implanting a nasogastric tube in the stomach to aspirate all gastric juice.

2. Suppression of nervous stimulation of pancreatic secretory activity by the administration of anticholinergic drugs. In most instances, pain will rapidly subside. It is inadvisable to use morphine because it brings about contraction of the smooth muscle in the sphincter of Oddi and duodenal wall, and thus resistance to flow of bile and pancreatic juice.

The events which follow an attack of acute pancreatitis are more difficult to understand and treat. When activated pancreatic juice has spread throughout the peritoneal cavity, digestion of injured structures, erosion of blood vessels, huge fluid and electrolyte losses, and suppuration become the surgical problems. The possibilities of such complications alone or in combination are too bizarre for description. The marks left after recovery from diffuse peritoneal digestion are calcified nodules which result from fat

necrosis. At times roentgenograms will show such areas and thus indicate a previous attack of acute pancreatitis.

The most distressing feature of the disease is the high likelihood of recurrence. This is so common that one conclusion is inescapable. The disease is not accidental or fortuitous, but must be based upon a structural alteration which remains after the acute attack subsides, and is invoked repeatedly under certain conditions.

RECURRENT PANCREATITIS

The term "relapsing" is also used for this characteristic of the disease. The attacks may recur within a short period or after some years. The variability in time between attacks has led to a belief by some surgeons that removal of a diseased gallbladder will prevent recurrences. The association of the gallbladder and biliary tract affections with pancreatitis is significant; 50 per cent of patients who have pancreatitis also have stones in the gallbladder. Symptoms occurring after removal of such a gallbladder have been termed "postcholecystectomy syndrome." It is possible that in many such patients the pain was due to pancreatitis and was not influenced by removal of the more obvious gallbladder and its contained stones. Recurrence often becomes more and more frequent. After repeated injury, repair, attempts at regeneration, and dense scarring, the glands become hard, enlarged, and cylindrical in shape. It rises out of its posterior bed and may become palpable through the abdominal wall. Aortic pulsation can be transmitted through the rigid pipelike organ over a broad area in epigastrium simulating aortic aneurysm.

The end result of attack following attack for a long time is a miserable person with almost constant pain, deficient in external pancreatic secretion to a degree that normal digestion is impossible. In many, there follows diarrhea, spruelike malnutrition, diabetes (because of destruction of islet cells), and narcotic addiction. These patients are among the most difficult in all of medicine to treat.

Treatment. Many operations have been proposed and tried for this condition. Splanchnic nerve resection to interrupt afferent pathways relieves pain but will not influence the course of the disease. Total pancreatectomy, a formidable operation under the circumstances, has also been performed. The most effective and logical operations have been designed to provide free flow of bile and pancreatic juice out of a system which tends to be closed and in which bile and pancreatic juice mix abnormally. The procedures include:

1. *Section of the sphincter of Oddi* (5). Resistance to flow of bile and pancreatic juice can be shown to be created by a hypertonic sphincter muscle or one which becomes spastic for various reasons.

2. *Choledochojejunostomy* (6). In this procedure the closed system is decompressed by anastomosing the common bile duct to the jejunum. Thus, bile flow is free of sphincter resistance and cannot enter the pancreatic duct. However, pancreatic juice must still enter the duodenum against sphincter resistance.

3. *Caudal pancreaticojejunostomy* (7). The tail of the pancreas is sectioned and the main pancreatic duct anastomosed to the jejunum. This procedure is particularly adaptable to situations when the pancreatic duct is obstructed.

All these operations have, in many instances, resulted in relief of pain, regeneration of acinar tissue, and restoration of normal digestion. When the disease is advanced and scarring is so rigid that regeneration is impossible or resistance to flow of secretion is created by multiple obstructions throughout the gland, results are discouraging.

Complications of Chronic Pancreatitis. Associated with recurrence, there may be significant pathologic changes which require special consideration and treatment; they are described below.

DEFICIENCY OF EXTERNAL PANCREATIC SECRETION. Diminution and poor quality of pancreatic enzymes and bicarbonate in the duodenum produce severe gastrointestinal symptoms. Small bowel motility is increased so that food passage through the bowel is hastened and time for absorption shortened. The most prominent defect is in fat absorption. The stools are loose, bulky, foamy, and foul. Fat globules float on the surface. These

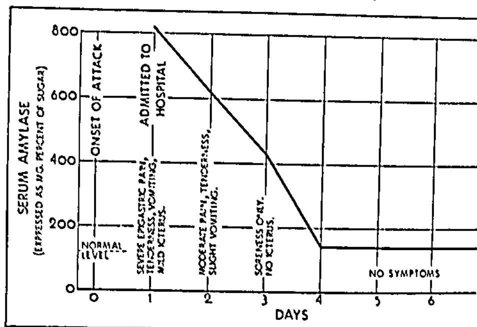

Fig. 3. Amylase levels in the blood during an acute attack of pancreatitis. This curve is characteristic. A blood sample drawn immediately after onset would probably have been much higher.

activity have been developed so that information can be available in a matter of minutes (4). The urgency of establishing a diagnosis is so great that, in occasional questionable instances, it may be advisable to explore the abdomen.

Complications of Chronic Pancreatitis. Associated with recurrence, there may be significant pathologic changes which require special consideration and treatment; they are described below.

DEFICIENCY OF EXTERNAL PANCREATIC SECRETION. Diminution and poor quality of pancreatic enzymes and bicarbonate in the duodenum produce severe gastrointestinal symptoms. Small bowel motility is increased so that food passage through the bowel is hastened and time for absorption shortened. The most prominent defect is in fat absorption. The stools are loose, bulky, foamy, and foul. Fat globules float on the surface. These

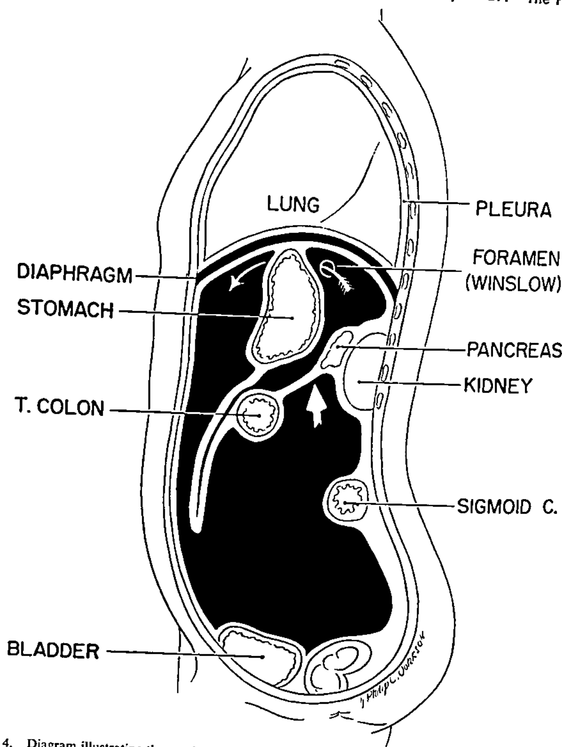

Fig. 4. Diagram illustrating the possible pathways of flow of pancreatic juice in retroperitoneal tissues. When pancreatic juice escapes into the peritoneal cavity, the most common direction of extension is directly anterior obliterating the lesser peritoneal sac and displacing the stomach forward. Pseudocysts may develop following this complication and may be found in numerous areas throughout the body, though usually attached to the pancreas.

symptoms are accompanied by lack of appetite and loss of weight. The deficiency of pancreatic secretion can be measured and the course determined by serial secretin tests (8). The method involves collection of pancreatic secretion through a nasal tube implanted in the duodenum. The hormone secretin is administered intravenously, thus giving a maximal stimulus to the gland. Volume and bicarbonate and enzyme content

Fig. 5. Pancreatogram showing a pseudocyst. Opaque material has been introduced into the pancreatic duct through a small plastic catheter (left). A dilated tortuous pancreatic duct (arrow) is outlined coursing to the tail of the pancreas where a ruptured duct allows the material to flow ino a huge pseudocyst (right).

are measured. Substitution treatment by feeding a potent pancreatic extract will ameliorate the symptoms.

PSEUDOCYSTS. When, in the course of inflammatory disease, a large duct ruptures, the resistance to flow through the tear in the duct is less than that created by the sphincter of Oddi. Under normal stimulation of pancreatic secretion by food and hydrochloric acid in the duodenum, the secretory pressure is maintained. Juice, therefore, flows out into peripancreatic spaces and continues to flow until resistance greater than that of the sphincter is met (Fig. 4). In most instances, the pathway of flow is into retroperitoneal structures anterior to the body of the pancreas. A fibrinous pseudomembrane forms in advance of the fluid, creating the appearance of a walled cyst (Fig. 5). Enlargement is gradual and progressive until a resistant structure is encountered. Most often this is the anterior abdominal wall with the stomach compressed against it. As pressures are being equalized, the patient may complain of pain after eating because of the copious flow of juice at this time. When the rupture is directed into other retroperitoneal areas, lateral or inferior, the cyst may present in the transverse mesocolon about the kidney or into pelvic structures. Unusual pseudocysts have been described traveling around to the anterior retroperitoneal spaces, between the leaves of the broad ligament of the uterus, or even upward into the mediastinum. If there is added to this abnormal flow of pancreatic juice suppuration in the pseudocyst or activation of the trypsinogen in the pancreatic juice, the seriousness of the situation is magnified.

Treatment. A time-honored operation for such a pseudocyst is anastomosis of the cyst to the gastrointestinal tract (9). Flow of pancreatic juice is then directed toward its proper goal. More logical, since the fibrinous membrane is a false one, is to decrease the resistance to flow created by the sphincter of Oddi by sphincterotomy (10). This has been shown to bring about collapse of pseudocysts. Other operations described as "marsupialization," which means simple drainage to the outside, are temporizing procedures which may result in permanent fistula.

CALCIFICATION OF THE PANCREAS. A little understood complication of pancreatitis is the deposition of calcium carbonate in the

finer acini. This precipitation has been noted to occur in a very short period of time and is striking because it may be detected by carefully taken roentgenograms. In some instances, the process is a painless one found accidentally. In most, however, it is associated with severe pain and disability. Hard, spinous, and dendritic particles of solid material clog the terminal ducts and occasionally break off to lodge in the main duct, there producing partial obstruction and painful distention. Treatment is directed toward the basic pathologic process, pancreatitis (11).

TUMORS OF THE PANCREAS

There are two important groups of tumors which occur in the pancreas. One group stems from islet cells and are largely benign. Surgical interest is centered about those which produce internal secretion at a steady or increased rate and therefore create metabolic disturbances. These functional adenomas are discussed in Chapter 39. The other group arises from acinar or duct cells and are mostly malignant.

Carcinoma. The distressing feature of this group is the almost complete hopelessness for cure in spite of well-conceived and technically feasible operations for removal of the tumor. Most arise in the head of the gland where, although the cancer may be relatively small, the common bile duct is obstructed early and visible prominent evidence of their presence is manifested by jaundice. The jaundice is obstructive, the stools acholic, and the gallbladder is distended early. In the Whipple operation, either the head of the pancreas or the whole gland is removed with the duodenum, lower bile duct, and regional lymph nodes. Reconstruction of the gastrointestinal tract, anastomosis of the bile duct and pancreatic duct, if some pancreas remains, to a jejunal limb is carried out, and the functional result is good. The survival time, however, after such successes is little longer than when a palliative anastomosis between bile duct and gut is performed to relieve jaundice. When, less frequently, the cancer arises in the body or tail of the pancreas, it produces few signs or symptoms until it has grown out of the gland itself and pain follows involvement of nerves along the posterior abdominal wall. Prior to such spread, the only manifestations of the tumor are loss of weight and loss of appetite. Early detection is difficult.

Many attempts to devise a method of visualizing the pancreas by x-rays have been made. Most efforts are designed to utilize the normal role of the pancreas in concentrating certain metals, e.g., zinc and copper, within its structure. Molecules containing iodine and zinc have been compounded and investigated, but not perfected for use.

It is probable that the discouraging course of pancreatic cancers is related to the rich lymphatic drainage of the gland directly into large collecting channels, the cysterna chyli and thoracic duct. The portal vein arises by junction of the splenic and superior mesenteric veins practically within the substance of the gland. This means that vascular spread of cancers to the liver is also an early event.

A rare, more hopeful malignant tumor, *cystadenocarcinoma,* is occasionally cured by operation. It results from malignant change in an equally rare benign cystadenoma, also cured by operation. It is detected by its large size as a palpable mass or by pressure on other organs.

Cysts. Other affections of the pancreas of surgical interest are cysts. These are frequently referred to as "true cysts," to distinguish them from the much more common pseudocysts. True cysts have an epithelial lining derived from ducts. They arise most frequently in the head of the gland and manifest themselves by their size through pressure on other nearby organs. Successful treatment is anastomosis of the lining secreting epithelial layer to the gastrointestinal tract.

ANNULAR PANCREAS

This is a developmental defect wherein a segment of the primitive ventral lobe persists anterior to the duodenum. Growth and rotation of the duodenum result in constriction by the fixed ring of pancreatic tissue and partial duodenal obstruction with enlargement of the first portion. It is important because surgical treatment should not be the very inviting maneuver of section of the ring of pancreatic tissue. Duct structures course through the ring, and the danger of leakage

of pancreatic juice after manipulation is grave. A simple anastomosis of the dilated first portion of the duodenum to a nearby loop of upper small bowel is effectively curative.

BLUNT INJURY TO THE PANCREAS

In blunt trauma to the abdomen, such as blows, kicks, and automobile accidents, the pancreas is a vulnerable organ. It may be split directly across in front of the vertebral column or partially split, with rupture of a large duct. The dynamics of flow of juice as described in the discussion of pseudocysts operates here. The difference is that pancreatic juice in the case of trauma is from a normal gland and the enzymes are inactivated and, therefore, less injurious. The manifestations of this rupture of the gland are related to the loss of pancreatic juice, which is a severe electrolyte drain, and fluid collecting in the peritoneal cavity. Retroperitoneal spread, as in pseudocysts, is also a feature when the anterior peritoneum over the pancreas remains intact. Principles of treatment are those used in pseudocyst following pancreatitis.

POSTOPERATIVE ACUTE PANCREATITIS

A rare but distressing complication following operations performed on structures other than the pancreas is fulminating severe hemorrhagic and necrotizing pancreatitis. This disaster is noted to occur most frequently when the operative procedure is on structures adjoining the pancreas and in which there is some likelihood of injury to pancreatic ducts. That this is not the whole story is attested by the same occurrence after operations performed some distance away, notably on the prostate gland. The timing of the onset and its suddenness would indicate that preoperative and postoperative starvation, with cessation of pancreatic juice flow and consequent concentration of enzymes in the acini, is a factor. Use of morphine in the postoperative period causes prolonged smooth muscle spasm, then oral feedings after starvation create a powerful stimulus to flow of concentrated pancreatic juice against resistance. Treatment of this complication is based on early recognition and is as described under acute pancreatitis.

ANNULAR PANCREAS

This is a developmental defect wherein a segment of the primitive ventral lobe persists anterior to the duodenum. Growth and rotation of the duodenum result in constriction by the fixed ring of pancreatic tissue and partial duodenal obstruction with enlargement of the first portion. It is important because surgical treatment should not be the very inviting maneuver of section of the ring of pancreatic tissue. Duct structures course through the ring, and the danger of leakage

in a prompt and marked decrease in the platelet count of the recipient, suggests that autoantibodies are formed by the spleen. The various disease entities resulting from hypersplenism form the most common indications for splenectomy.

Anomalies. Congenital anomalies of the spleen are extremely rare and, for practical purposes, are limited to the relatively frequent finding of accessory spleen. The accessory spleen is a separate encapsulated mass of splenic tissue which is found most commonly in the hilum of the spleen, in the splenic pedicle, or in the tail of the pancreas but also occasionally in gastrosplenic and gastrocolic ligaments and rarely in areas more distant from the spleen. From one to five of these collections of exsplenic tissue have been noted in from 18 to 30 per cent of patients undergoing splenectomy. It is important to find these accessory spleens, particularly during splenectomy for hypersplenism, since unremoved splenic tissue may lead to a recurrence of the hypersplenism. Occasionally, abnormal locations of the spleen are noted but for the most part these are limited to those cases in which there is a generalized visceroptosis.

HYPERSPLENISM

Hypersplenism is a hyperfunction of the spleen, whereby one or more elements of the peripheral blood is decreased because of the splenic overactivity. Regardless of the mechanisms involved in hypersplenism, the decrease in peripheral blood elements delineates several clinical diseases in which splenectomy is usually indicated. These disease entities include thrombocytopenic purpura, hemolytic anemia, neutropenia, and pancytopenia which must be proven of splenic origin. Other causes of these cytopenias must be ruled out by exclusion and the bone marrow should be hyperactive for the specific element or elements which are decreased in the peripheral blood if splenectomy is to give good results.

Hypersplenism is further divided into primary and secondary forms. *Primary hypersplenism* denotes that the spleen is overactive but there is no other associated disease process. The specific clinical syndromes include essential (idiopathic) thrombocytopenic purpura, congenital hemolytic anemia, primary splenic neutropenia, and primary splenic pancytopenia. Splenectomy will give excellent results in these cases and carries a low mortality. *Secondary hypersplenism* differs from the primary form in that the splenic overactivity is due to another disease process which involves the spleen and other reticuloendothelial organs. *The diseases with which* hypersplenism is most frequently associated are leukemia, Hodgkin's disease, lymphomas, Banti's disease, tuberculosis, Boeck's sarcoid, and Gaucher's disease. In these patients, splenectomy will often greatly improve the hematological status of the patient but does not affect the course of the primary disease process.

Results of splenectomy are much better in primary hypersplenism, but it is now known that good results can be achieved in secondary hypersplenism. For example, Zollinger and Williams (5) report 91 per cent good results in primary hypersplenism and 64 per cent good results in secondary hypersplenism, following splenectomy. In their series, the postoperative mortality rate for the former group was 1.1 per cent and 13 per cent for the latter group.

HEMOLYTIC ANEMIA

The most common indications for splenectomy are the several types of hemolytic anemia. Primary hemolytic anemia is more commonly called congenital hemolytic anemia (or congenital hemolytic icterus) and has a familial occurrence. It is characterized by spherocytosis with decreased resistance of red cells to hemolysis. Secondary hemolytic anemia develops as a complication of another systemic disease process, and there may be noted no change in the red cells on routine peripheral smears. A third type of hemolytic anemia is called acquired hemolytic anemia. A family history is lacking, spherocytosis is uncommon, and no other systemic disease need be present. The cause of this form of hemolytic anemia is not always discernable. Autohemolysins and autoagglutinins play a part in the hemolysis as evidenced by the response in many cases to corticosteroid therapy. Splenectomy also gives variable results, probably because the spleen is only a part of

30

THE SPLEEN

Robert M. Zollinger and Roger D. Williams

Although the spleen is not necessary to life, it is associated with numerous diseases, many of which are so serious as to threaten life. Splenic tissue represents a major component of the reticuloendothelial system. Because of its size and vascularity it furnishes a major portion of the venous blood collected through the portal system. This organ is not only often involved with abdominal trauma but also plays an important part in disease processes involving the whole reticuloendothelial system or the liver.

Anatomy. The location of the spleen beneath the left diaphragm, protected by the lower costal margin, makes its palpation difficult unless a significant enlargement has occurred. The spleen usually weighs less than 200 grams. It lies closely attached to the greater curvature of the fundus of the stomach. Two concave medial surfaces border upon the stomach and left kidney, and a single convex lateral surface is often attached in varying degrees to the leaf of the left diaphragm. The blood supply is through the splenic artery which arises from the celiac artery and courses in an irregular fashion just above the more straight vein along the superior border of the pancreas. Several branches develop near the hilum, the most significant of which are the left gastroepiploic and the vasa brevia that form collaterals between the spleen and the stomach.

Functions. The *normal* functions of the spleen are of little real significance since only temporary leukocytosis, thrombocytosis, and erythrocytosis follow its removal. Like other portions of the reticuloendothelial system, the hemoglobin of destroyed red blood cells is converted to bilirubin and often much iron is stored in the spleen. Lymphocytes, monocytes, and some antibodies are formed by the spleen, but these functions are readily assumed after splenectomy by the remaining reticuloendothelial organs. The reservoir function of the spleen in some other mammals is apparently not of clinical significance in man.

The *abnormal* functions of the spleen are of more clinical significance. Overactivity of the spleen, which has been called *hypersplenism,* results in a decrease in the peripheral blood of the platelets, red cells, white cells, or of all three of these elements. The bone marrow also shows changes, usually a marked overactivity in the production of one or more of the cellular elements. There is evidence that three mechanisms may play a part in this splenic hyperfunction: 1. Increased splenic phagocytosis and cellular destruction (Doan and associates, 1); 2. the liberation of humoral factor from the spleen, affecting the bone marrow (Dameshek and associates, 2); and 3. the formation of antibodies by the spleen, which affects the destruction of the peripheral cellular elements (Evans, 3 and Harrington, 4). The demonstration by Harrington and associates (4) that transfusion of blood from patients with thrombocytopenic purpura to normal individuals results

thelial system. Spherocytosis and increased hemolysis in saline are not found, but the bone marrow must be active for good results to be obtained by splenectomy. Removal of the spleen does not affect the course of the primary disease but often produces dramatic hematological results.

Acquired Hemolytic Anemia. This form of hemolytic anemia differs in several ways from primary (congenital) and secondary hemolytic anemias. The familial tendency is absent. The osmotic fragility of the red cells is not significantly changed and the survival time of red cells transferred to a normal person is normal (100 to 120 days).

Loutit and Mollison (6) were perhaps the first to prove the difference between the hereditary and acquired types of anemia; they found that transfusion of red cells from patients with hereditary anemia into normal recipients survived only 20 to 50 days, whereas erythrocytes from patients with acquired anemia transfused into normal recipients survived the normal length of time, i.e., 100 to 120 days. The factors responsible for increased hemolysis may be multiple. Although no other chronic systemic disease is present with acquired hemolytic anemia, hemolysis may begin as a result of exogenous hemolysin. When no cause for the increased hemolysis can be found, the hemolytic anemia may be called idiopathic acquired hemolytic anemia. In other cases, autoantibodies, autohemolysins, isohemolysins, and autoagglutinins may be discovered by special immunoserological studies.

The symptoms do not differ greatly from those of primary congenital hemolytic anemia but are more apt to occur later in life and to be more severe. Spontaneous recovery occasionally occurs, a phenomenon not encountered in primary hemolytic anemia The spleen is not as enlarged but is palpable in over half the patients. The Coomb's human serum antiglobulin test, which is positive for autoagglutinins in acquired hemolytic anemia, is the best diagnostic test.

The results of splenectomy are variable, only 50 to 65 per cent of patients having a good hematological response. This may be due to the fact that the spleen is often only one of several factors in the causation of hemolysis and the remainder of the reticuloendothelial system can perpetuate the hemolytic process. Many patients will give excellent temporary or even permanent remissions after the use of corticotropin (ACTH) or cortisone. Even when these drugs fail to give a satisfactory remission, steroid therapy after splenectomy may give good results. If splenectomy is advised, blood transfusions should be deferred until after the splenic artery has been ligated because of the danger of producing a hemolytic crisis. If the patient has been receiving steroid therapy before surgery, even though it may have been discontinued for several months, cortisone should be given on the day of surgery and for *several* days thereafter.

PRIMARY THROMBOCYTOPENIC PURPURA

Primary (essential or idiopathic) thrombocytopenic purpura is a common indication for splenectomy. The usual manifestations of this disease are bleeding from the mucous membranes, body orifices, or into various organs, including the skin and subcutaneous tissue. The disease is more common in children and young adults. The possible etiologies for the peripheral thrombopenia have been mentioned (hypersplenism). The studies of Harrington and associates who have noted thrombopenia in normal patients following the transfusion of citrated blood from patients with thrombocytopenic purpura, are interesting.

The platelet count drops from normal of 300,000 to 400,000 down below 100,000 and occasionally below 10,000 per cubic millimeter. Thrombopenia alone, however, does not produce all the signs and symptoms seen with thrombocytopenic purpura. The bleeding time is prolonged but the clotting time is unaltered. The clot which forms in a test tube fails to contract. There is increased capillary fragility, which is an important factor in the causation of purpura. The prothrombin time is usually normal, but prothrombin consumption is increased.

An anemia develops which varies in severity with the amount of blood lost and, when severe, is associated with the appearance of nucleated erythrocytes. The bone marrow shows a myeloid, erythroid, and

the reticuloendothelial system involved in this type of hemolytic anemia.

Diagnosis. The hemolytic anemias involve a differentiation of the various causes of anemia and jaundice. Hemolytic anemia should be suspected as the cause of jaundice when anemia is noted or there is a familial history of anemia and jaundice. The spleen is enlarged, chills and fever may occur with a rapid increase in jaundice with pain in the upper abdomen (hemolytic crisis), there is an absence of bile in the urine, and the indirect van den Bergh is elevated without an elevation of the direct van den Bergh. If hemolytic anemia is considered as a cause of jaundice, its differentiation from hepatocellular and extrahepatic (obstructive) jaundice is usually not difficult.

Hemolytic Crisis. Hemolytic crisis is a severe exacerbation of symptoms occurring in any of the forms of hemolytic anemia. There is a rapid breakdown of red cells, jaundice and anemia develop, often being associated with fever, nausea, vomiting, and abdominal pain. The spleen is enlarged and tender. This complication represents one indication for immediate splenectomy. Because of the danger of precipitating a hemolytic crisis, blood transfusions are usually contraindicated in patients with hemolytic anemia until after the splenic artery has been ligated.

Primary (Congenital) Hemolytic Anemia. Congenital hemolytic icterus is one of the most common indications for splenectomy. The clinical features of this form of hemolytic anemia are anemia with spherocytosis of the red cells and jaundice without bile in the urine. A familial tendency is helpful in suspecting the diagnosis but symptoms vary widely with the severity of the disease. While one member of a family may have all the classical symptoms including splenomegaly, another may have only mild anemia with no complaints. This disease most often makes its appearance in early life, but the wide variation in severity of symptoms may delay diagnosis as late as the fifth decade. The symptoms in more severe cases include weakness, a dull discomfort in the upper abdomen, splenomegaly and splenic tenderness, and jaundice. Hemolytic crises may be severe.

The diagnosis is dependent upon a familial history of anemia, peripheral spherocytosis, and an erythroid hyperplasia of the bone marrow. Although excessive urobilinogen is found in both urine and feces, due to the increased formation of bile from an increased red cell hemolysis, bile does not pass into the urine (acholuric jaundice). The red blood cells are small and ovoid with an increased susceptibility to hemolysis in salt solutions which do not usually cause hemolysis of normal blood cells (i.e., normal hemolysis begins in 0.5 per cent saline but the cells of patients with congenital hemolytic anemia may begin at concentrations as high as 0.65 per cent). Because of the more rapid breakdown of red cells there is a compensatory hyperplasia of the bone marrow. This is exhibited peripherally by a reticulocytosis, with the reticulocyte count rising as high as 20 per cent.

The diagnosis should not be confused with other causes of jaundice. Anemia is more severe than that usually seen with either hepatitis or obstructive jaundice. Liver function is normal. Absence of bile in the urine and failing to note a yellow foam should suggest the need for ascertaining a familial history and obtaining more hematological evaluation. The frequent occurrence of pigment-cholesterol gallstones may suggest the possibility of obstructive jaundice due to a stone, but with hemolytic anemia there is marked splenomegaly and an absence of biliary pain.

Splenectomy is indicated in patients with primary hemolytic anemia and gives excellent results. Although the spherocytosis continues, hemolysis is stopped in over 95 per cent of patients after removal of the spleen.

Secondary Hemolytic Anemia. This is a form of secondary hypersplenism in which hemolytic anemia develops during the course of another chronic disease process. The spleen is usually enlarged. Since patients with lymphoma, leukemia, and other debilitating diseases are those in whom secondary hypersplenism most often occurs, the diagnosis is not often confused with primary hemolytic anemia. The anemia occurs in patients in an older age group. The symptoms may be similar to those of primary hemolytic anemia but more often they are overshadowed by those of the primary chronic disease. The diagnosis should be suspected when anemia becomes difficult to control in the various chronic systemic diseases affecting the reticuloendo-

thelial system. Spherocytosis and increased hemolysis in saline are not found, but the bone marrow must be active for good results to be obtained by splenectomy. Removal of the spleen does not affect the course of the primary disease but often produces dramatic hematological results.

Acquired Hemolytic Anemia. This form of hemolytic anemia differs in several ways from primary (congenital) and secondary hemolytic anemias. The familial tendency is absent. The osmotic fragility of the red cells is not significantly changed and the survival time of red cells transferred to a normal person is normal (100 to 120 days).

Loutit and Mollison (6) were perhaps the first to prove the difference between the hereditary and acquired types of anemia; they found that transfusion of red cells from patients with hereditary anemia into normal recipients survived only 20 to 50 days, whereas erythrocytes from patients with acquired anemia transfused into normal recipients survived the normal length of time, i.e., 100 to 120 days. The factors responsible for increased hemolysis may be multiple. Although no other chronic systemic disease is present with acquired hemolytic anemia, hemolysis may begin as a result of exogenous hemolysin. When no cause for the increased hemolysis can be found, the hemolytic anemia may be called idiopathic acquired hemolytic anemia. In other cases, autoantibodies, autohemolysins, isohemolysins, and autoagglutinins may be discovered by special immunoserological studies.

The symptoms do not differ greatly from those of primary congenital hemolytic anemia but are more apt to occur later in life and to be more severe. Spontaneous recovery occasionally occurs, a phenomenon not encountered in primary hemolytic anemia. The spleen is not as enlarged but is palpable in over half the patients. The Coomb's human serum antiglobulin test, which is positive for autoagglutinins in acquired hemolytic anemia, is the best diagnostic test.

The results of splenectomy are variable, only 50 to 65 per cent of patients having a good hematological response. This may be due to the fact that the spleen is often only one of several factors in the causation of hemolysis and the remainder of the reticuloendothelial system can perpetuate the hemolytic process. Many patients will give excellent temporary or even permanent remissions after the use of corticotropin (ACTH) or cortisone. Even when these drugs fail to give a satisfactory remission, steroid therapy after splenectomy may give good results. If splenectomy is advised, blood transfusions should be deferred until after the splenic artery has been ligated because of the danger of producing a hemolytic crisis. If the patient has been receiving steroid therapy before surgery, even though it may have been discontinued for several months, cortisone should be given on the day of surgery and for *several* days thereafter.

megakaryocytic hyperplasia. Leukopenia is not common in this disease and, if present, should suggest atypical leukemia or aplastic anemia for which, of course, splenectomy is not indicated. The spleen is rarely enlarged; splenomegaly should suggest that the purpura is due to another disease.

ACTH and cortisone are effective in decreasing symptoms and in some patients actually produce a remission; however, this remission is usually of short duration. Accordingly, these drugs are most useful in preparing the patient for splenectomy. This is particularly true since the beneficial effect of a second course of steroid therapy is not as marked as the first. Ultimately, following several courses of therapy, the steroids become ineffective, except in the occasional mild case which may sustain a prolonged remission. Results following splenectomy for idiopathic primary thrombocytopenic purpura are good to excellent in about 85 per cent of cases (Table 1). Following splenectomy or steroid therapy, bleeding usually ceases even in those cases where there is little rise in the peripheral platelet counts.

SECONDARY THROMBOCYTOPENIC PURPURA

Thrombocytopenic purpura may develop during the course of a number of chronic systemic disease processes (secondary hypersplenism). The signs and symptoms are similar to those of primary thrombopenic purpura, but the patients are usually more seriously ill and suffer the additional symptoms of their primary disease. The spleen is usually enlarged. Occasionally the spleen is removed with a preoperative diagnosis of primary thrombopenic purpura and, after examination of the spleen and sections of abdominal lymph nodes or the liver, another systemic disease is discovered, changing the diagnosis to secondary thrombopenic purpura. Secondary purpura due to hypersplenism should be differentiated by history and bone marrow studies from purpura due to toxic substances. In the latter cases, the bone marrow is hypoplastic and splenectomy will be of no value. Until a few years ago it was thought that splenectomy was not indicated in secondary purpura. However, in 10 patients with secondary purpura, Elliott and Turner (7) reported complete arrest in six and fair results in three. All of these had a low platelet count. Steroid therapy may be required postoperatively in an occasional case or when the platelet count is not promptly elevated.

Role of Steroid Therapy in the Treatment of Splenic Diseases. Steroids (ACTH or cortisone) are very useful in the treatment of many splenic diseases but should be used primarily in the preparation of patients for operation. They have a beneficial effect in the hemolytic anemias and purpuras. Their mechanism of action is not fully understood. In the hemolytic anemias, the benefit is obtained presumably through one of two mechanisms: either the steroid affects the red cell in such a way that the antibody cannot attach itself to the cell, or it has a neutralizing effect in the source of the antibodies. Steroids are most effective in the acquired types of hemolytic anemias. They are effective in the hereditary type only when there is an associated acquired component; Cooley's (Mediterranean) anemia is an example of hereditary anemia which occasionally is benefited by steroid therapy. Benefit is sustained in both types of purpuras, but it is more marked in the idiopathic type possibly because in this

type, circulating antibodies are more common (perhaps 50 per cent). Steroids are of benefit in purpura of childhood, but even without this therapy, purpura at this age regresses satisfactorily without splenectomy, with rare exceptions. The reaction of the various types of splenic disease to steroids regardless of the responses cannot be used as an indication or contraindication for splenectomy.

As mentioned above, steroid therapy results in benefit in several types of splenic disease, but since it is not curative, the chief value is in preparing patients for operation. Often, indeed, the patient is too ill to allow splenectomy safely. This is exemplified in patients with hemolytic crisis or severe thrombocytopenia with hemorrhage and anemia. In such patients, marked temporary benefit can usually be achieved by a course of ACTH or cortisone. However, it must be emphasized that a second course of steroid therapy will be less effective, and as the treatment is continued, the disease becomes more resistant. Accordingly, the patient with hemolytic crisis may be markedly improved with steroid therapy, but if splenectomy is not performed during the remission (when the expected mortality is practically zero), the "golden" opportunity may be missed. This is true because splenectomy may have to be performed later as an emergency for a recurrent critical state for which no medicinal therapy is effective; under such circumstances, the expected mortality rate may be very high. It must also be emphasized that, if steroids have been given preoperatively, they must be continued postoperatively: this is true even though several weeks or months have elapsed since discontinuance of the therapy.

Not infrequently steroid therapy is helpful after operation when the effects of splenectomy have been unsatisfactory. Accordingly, this phase of steroid therapy may be very important.

PRIMARY SPLENIC NEUTROPENIA AND PANHEMATOPENIA

Wiseman and Doan (8) have described a rather uncommon disease consisting of splenomegaly and leukopenia for which splenectomy is curative. This condition actually represents a selective type of hypersplenism in which only one of the cellular elements (neutrophils) is involved. The bone marrow may be normal or slightly hyperplastic. Occasionally, fever and pain in the splenic area are present. There is often an increased susceptibility to infection, and preoperative antibiotics are indicated. The disease usually leads a cyclic course. Splenectomy is considered safer when the white blood count is highest and infection less likely to develop after surgery.

If all three of the blood elements (erythrocytes, neutrophils, and thrombocytes) are involved, the condition is known as pancytopenia. Bone marrow studies show a panmyeloid hyperplasia. Pancytopenia may be primary or secondary to some other disease, such as Gaucher's or Banti's disease and leukemia. With few exceptions, an enlarged spleen is found in all patients with pancytopenia of splenic origin. Splenectomy is very effective in relieving the hypersplenism but will not alter the course of the primary disease. ACTH and cortisone are not often of much value.

FELTY'S SYNDROME

The most important manifestations of this disease are splenomegaly, chronic rheumatoid arthritis, leukopenia, and anemia. Thrombocytopenia may also be present; under such circumstances the disease may be classified as secondary pancytopenia. Occasionally, lymphadenopathy and a yellowish-brown pigmentation of the skin are noted. The bone marrow is hyperplastic with granulocytic elements predominating. Splenectomy usually relieves the pancytopenia and occasionally the arthritis is also greatly improved.

GAUCHER'S DISEASE

Gaucher's disease is a rare disease affecting the spleen secondarily and occurring most commonly in young girls. The spleen is enlarged and the lipid material (cerebroside) is present in the spleen, bone marrow, and lymph nodes. Foam cells in the bone marrow are diagnostic. Common manifestations are splenomegaly, anemia, and pigmentation of the skin. Hepatomegaly occurs late in the disease. Occasionally the splenomegaly pro-

duces pancytopenia; still less commonly, rupture of the spleen may develop with little or *no trauma.* Pressure symptoms caused by the enlarged spleen are not uncommon. Any of the complications mentioned above may justify splenectomy.

RUPTURE OF THE SPLEEN

Lacerations of the spleen are serious because the resultant hemorrhage rarely stops spontaneously. Accordingly, rupture of the spleen usually necessitates operation, indications for which may be very vague because of the difficulty of diagnosis. In a series of 102 cases reported by Terry and associates (9), about half were caused by penetrating injuries and half by nonpenetrating injuries. In a series reported by Musselman and associates (10), contusion of the chest over the spleen was noted in about half and fractured ribs on the left in about one third of the cases. Since hemorrhage is the major process involved in injuries to the spleen, the systemic manifestations of injuries will be related to blood loss producing tachycardia, drop in blood pressure, and other changes of shock as described in Chapter 13.

The symptoms and local abnormal signs of splenic rupture vary considerably. On some occasions, there is marked tenderness with a fair degree of muscle spasm in the left upper quadrant. Pain may be referred to the left shoulder as evidence of irritation of the diaphragm. This pain may at times be made to occur by placing the patient in the Trendelenberg position. On other occasions, pain is minimal and tenderness is only moderate and somewhat diffuse. Under such circumstances, evidence of loss of blood may represent the indication for operation.

A diagnostic peritoneal aspiration and abdominal x-rays should be obtained in all patients suspected of having a splenic rupture. Utilizing a small syringe and a No. 20 needle, there is little danger from aspiration in all four abdominal quadrants in doubtful cases unless intestinal distention is present. If blood is found, the diagnosis is confirmed; however, a negative peritoneal aspiration should not be considered as evidence that splenic rupture has not occurred. Abdominal and chest x-ray films may show one or more of several changes. Wang and Robbins (11) have emphasized the incidence of an abnormality of the splenic shadow, particularly an enlargement as an indication of an injured spleen. This enlargement is presumably due to blood clots surrounding the spleen. Bollinger and Fowler (12) have called attention to a shadow in the left lower thorax in patients with an injured spleen. Elevation of the left diaphragm, separation of the gastric and colon gas shadows with serration of the gaseous shadow along the greater gastric curvature, and absence of psoas shadows may occasionally be noted.

Delayed rupture, with signs manifested 48 or more hours after injury, is not uncommon. The mechanism of delayed rupture is probably either renewed hemorrhage after temporary tamponade by omentum or surrounding structures or subcapsular hemorrhage which later ruptures the capsule. In the series by Terry and associates (8), 11 per cent were delayed splenic ruptures. As a consequence, patients with abdominal injury must be observed rather carefully for several days to discover the early manifestations of blood loss.

The treatment for rupture of the spleen is splenectomy, since ligatures applied to a lacerated spleen do not control the bleeding effectively. Usually it is necessary to match the patient with several donors and administer several hundred cubic milliliters of blood rapidly to improve the patient's condition sufficiently to allow operation. If the signs of shock disappear rapidly with the administration of one or two pints of blood, delay in operation may be permissible, and, in fact, operation not performed unless local signs represent indications for celiotomy. The mortality rate from splenectomy performed for an uncomplicated rupture of the spleen obtained soon after injury is almost zero. However, complicating injuries may be extremely serious. In the series by Terry and associates (9), the mortality rate was 12 per cent for patients having blunt trauma and 25 per cent for patients having injury of the spleen due to penetrating injuries.

BANTI'S DISEASE

This disease is characterized by splenomegaly, anemia, leukopenia, and portal hypertension. The portal hypertension and changes due to hypersplenism are the usual

indications for splenectomy. The portal hypertension is due to venous portal obstruction either proximal to the liver or as a result of cirrhosis of the liver. The anemia may be due to bleeding, or all the cytopenic changes may be the result of secondary hypersplenism. The disease affects children as well as adults.

The patient commonly notices a gradually increasing weakness, anorexia, and abdominal discomfort. Pallor is noted and examination of the blood shows an anemia; but the resistance of the erythrocytes is apt to be increased. The liver may be enlarged, but as the disease progresses the liver becomes cirrhotic in most cases and ascites may develop. About 15 per cent of patients do not develop cirrhosis and the portal hypertension and splenic changes are the result of extrahepatic portal obstruction from thrombosis or congenital abnormalities of the portal system.

Upper gastrointestinal hemorrhage may be the first indication that portal hypertension exists. Considerable difficulty may be encountered in differentiating esophageal from gastric or duodenal hemorrhage. Transfusions should be started immediately, but definitive therapy will have to be delayed until the diagnosis is established. Delay is necessary because the treatment of bleeding peptic ulcer (the most common cause of gastric hemorrhage) is very different from that for bleeding varices. Important in the differentiation is the history of peptic ulcer and the presence or absence of an enlarged spleen; about two thirds of patients bleeding from a peptic ulcer will have an ulcer history, whereas about 80 per cent of patients with bleeding varices secondary to portal hypertension will have an enlarged spleen. Liver tests will also be of value since they will be normal with peptic ulcer and abnormal in the majority of patients with portal hypertension. If the diagnosis is in doubt, a barium swallow with x-ray studies of esophagus, stomach, and duodenum should be made as soon as the patient's condition will allow.

As soon as the diagnosis of bleeding esophageal varices is established, an attempt should be made to stop it by passage of a Patton (or similar type) tube into the stomach and inflation of the attached balloons to obtain pressure against the bleeding point. If utilized correctly, this tube will stop the hemorrhage unless the bleeding point is located within the stomach or in the esophagus above the larger balloon. The air pressure in the balloon is maintained, according to the directions for the type balloon used, in combination with slight traction on the tube for 24 hours, following which pressure is released to prevent pressure necrosis of the esophagus and cardia of the stomach. After release of the air in the balloon, the tube should be left in situ for 24 to 48 hours lest removal dislodge the clot. If one or two attempts to control the hemorrhage are unsuccessful, operative interference, consisting of transection of the cardiac end of the stomach (with ligation of all bleeding points and approximation of the cut ends by suture), or suture of all bleeding paints through a longitudinal incision in the esophagus may be indicated.

The patient's condition with bleeding varices is usually too critical to justify the performance of a portocaval or splenorenal venous shunt. These procedures are usually reserved for elective use after the bleeding has ceased and after the patient's condition has improved. However, if there is no history of bleeding, but hypersplenism is rather pronounced and prominent varices are demonstrated by x-ray, it may be justifiable to perform a splenectomy and splenorenal shunt. Although the results of portocaval shunt are a little better than those of splenorenal shunt, the latter operation is justifiable when splenectomy has to be performed because a splenorenal shunt can rarely be performed in patients who have had a splenectomy performed at a previous operation.

It should be emphasized that not all surgeons believe that the benefit obtained from a venous shunt justifies the high mortality incident to the operation. If liver function tests show significant liver damage with jaundice and ascites present, most surgeons consider a shunt operation contraindicated.

MISCELLANEOUS

Porphyria is not a disease affecting the spleen primarily but, during the past few years, good results have been reported following splenectomy (see p. 814). The etiology of this disease is unknown. *Infarcts* of the spleen, *cysts* and *tumors* of the spleen,

and *aneurysms of the splenic artery* are rare but constitute indications for splenectomy. *Mediterranean anemia* (Cooley's anemia), a chronic anemia apparently due to a defect in the formation of hemoglobin, was, until recently, not considered an indication for splenectomy. Glenn and associates (13) have shown that these patients, although not cured, may require fewer transfusions to maintain a respectable blood level after splenectomy.

THE ALIMENTARY TRACT

The alimentary tract is probably more commonly the site of disease, both functional and organic, than any other system. For the sake of completeness, the entire alimentary tract (including the oral cavity, which is in part the sphere of the dental specialty), will be considered in this chapter. Several disciplines and technics are involved in the diagnosis and treatment of disorders of the intestinal tract. The use of radiology for the indirect inspection of the gut and the use of esophagoscopy, gastroscopy, and proctosigmoidoscopy for direct visualization are of obvious importance, and the pathologic examination of removed tissues is often essential. This chapter must necessarily deal with some purely medical aspects of disease of the gut as well as with those lesions which are the problem of the surgeon. While acute appendicitis, perforations, and carcinoma are primarily of surgical, sometimes urgent surgical, importance, other conditions may be either medical or surgical in nature. Indeed, many diseases, such as chronic peptic ulcer and idiopathic ulcerative colitis, straddle several fields and thus require the closest cooperation among general practitioners, internists, surgeons, radiologists, pathologists, and even psychiatrists. Often it is found that only by cooperation among the specialists thus implied will the best therapeutic program for the patient be chosen.

Because of the complexity of the problems of intestinal obstruction, this matter will be discussed in a separate chapter.

ORAL CAVITY

The mouth is the concern of general, dental, and plastic surgeons. Oral lesions are frequently but local manifestations of more widespread disease. The teeth are important contributors to the diseases of the mouth. Much of this material in this section is based on the text by McDowell, Brown, and Fryer, to which the student is referred for greater detail (1).

The Mouth. Congenital Clefts. Congenital cleft lip (harelip) and cleft palate are probably the most common severe congenital deformity amenable to surgical correction. They vary widely in degree, may occur alone or in combination, and may be unilateral or bilateral. According to Fogh-Andersen (2) this deformity is found to some degree in one of every 660 babies in the white race; certain varieties definitely follow Mendelian genetic patterns. While clefts may be produced in experimental animals by such influences as severe nutritional deficiencies, cortisonelike drugs, and certain virus infections during early gestation, it is not certain that they are identical with the human lesions (Fig. 1).

Treatment is surgical, and requires careful planning and meticulous technic in order to achieve the optimum effect both as to appearance and to speech. The lip is best repaired at about three months of age, the objective being to produce a full and loose, protruding, smooth lip, and a symmetrical yet nondrooping nostril (3). The palate is usually operated on at about 18 months of age, with the objec-

Fig. 1. Double harelip before and after operative repair. A, at four months of age just before repair of the lip. B, at one year of age; a cleft palate was repaired at this time. (St. Louis Children's Hospital)

tive of complete closure, maximum flexibility with minimum scarring, sufficient length for nasopharyngeal closure, and preservation of the muscles with the nerve and blood supply to them. In general, narrow clefts are closed earlier than 18 months and wide clefts a year or two later. Early orthodontia may be required for proper molding of the dental arch, some speech training, and limited prosthodontia for missing teeth. The better the surgical repair, however, the less will be the need for these additional services.

Other congenital clefts are rare and include the lateral facial clefts, which are oblique from the upper lip to the orbit and even within the eye, and macrostomia, which is persistence of an open cleft from the angle of the mouth toward the ear.

INFECTIONS. The mucosa of the mouth is the site of several types of inflammation called, collectively, stomatitis. Specific local agents, such as infected teeth, chemical or physical irritants, or certain bacterial or viral invaders, are usually the cause. Many are secondary to such systemic diseases as blood dyscrasias, avitaminoses, diabetes, pemphigus and other skin disturbances, virus infections, poor hygiene, malnutrition, digestive disturbances, and metallic poisoning. While Vincent's spirochetes and fusiform bacilli can be recovered from most chronic mouth ulcers, the etiological significance of them is uncertain.

Clinical manifestations vary, but consist mostly of pain, tenderness, visible lesions (macular, papular, vesicular, or ulcerative), foul breath, and systemic evidences of infection. Treatment will be effective if the underlying cause can be found and removed. Prolonged chemotherapy may be an etiological factor due to the development of resistant bacteria or the conversion of oral saprophytes to pathogens, which become virulent and attack the mucosa. Addition of an effective antibiotic, or change to another antibiotic to which the causative organism is sensitive, is often successful. Local treatment includes simple cleanliness, liberal use of warm saline, and the removal of local irritants. Strong chemicals or escharotics must never be applied. Some lesions are on the allergic basis, any may respond to cortisonelike therapy.

Thrush is a superficial infection of the mucosa occurring in infants and in the aged, especially when debilitated and in unhygienic surroundings. It is characterized by white patches which can be removed easily, exposing a bleeding surface. The fungus, *Candida albicans*, is the causative agent. Treatment is of the underlying cause, plus local use of 10 per cent glycerine or 5 per cent gentian violet and specific antibiotics (nystatin).

Fig. 2. Fig. 3.

Fig. 2. Acute dento-alveolar abscess of the upper jaw. The patient was a 40-year-old woman. The swelling began nine days previously, 48 hours after the extraction of a left upper molar which had been painful for two weeks. The abscess opened into the mouth spontaneously shortly after the above picture was taken; a large amount of greenish, foul-smelling pus escaped. (Barnes Hospital.)

Fig. 3. Acute dento-alveolar abscess of the lower jaw. One week after onset. Incision and drainage of the abscess were followed by rapid healing with no evidence of osteomyelitis.

Noma is an extremely rare progressive gangrene, usually starting about the mouth and spreading to involve the face and neck, often fatal. The etiology is unknown, but is probably a combination of two or more of such factors as acrodynia, poisoning, chickenpox, typhoid, meningococcemia, measles, blood dyscrasias, or drug sensitivities. Treatment is based on thorough investigation to find and eliminate the cause or causes. In some cases, the local lesion is widely excised by electrosurgery, with plastic repair later if the patient survives.

The Jaw. Tumors have been discussed elsewhere (p. 418). This leaves jaw infections, most of which are of dental origin.

Acute Alveolar Abscess. This lesion, often called gumboil or root abscess, follows an acute exacerbation in a chronic dental root granuloma, the portal of entry being usually a dental cavity (Figs. 2, 3). The first symptom is pain, which is boring and pounding as the infection invades the jaw bone from the tooth root out to the gum surface. There may be edema of the overlying soft tissues, extreme tenderness to percussion of the tooth, spasm of the masseter muscles (lockjaw), fever, prostration, and leukocytosis. These manifestations differentiate it from ordinary toothache (pulpitis), in which the inflammation is entirely within a tooth. Within 12 to 48 hours after the onset, an abscess usually presents at the gum surface or through the outside of the face and should be promptly opened to prevent further spread. Antibiotic and other systemic treatment should be started promptly after the onset, but the tooth should not be extracted during the acute phase for reasons mentioned below.

Pericoronitis. This term applies to an infection under the gum flap overlying a partially erupted third molar. The clinical picture is much the same as in an alveolar abscess, with even greater tendency for the infection to invade between the masseter muscles and the ramus of the mandible to form a deep jaw

Fig. 4. Acute dento-alveolar abscess followed by chronic osteomyelitis. Three lower molars had been extracted several weeks previously. The two photographs are taken four days apart before and after incision and drainage. Foul-smelling pus was evacuated containing many types of mouth organisms. (Barnes Hospital.)

abscess (see below). Here, too, the offending tooth should not be extracted during the acute phase, but chemotherapy and surgical drainage should be instituted.

JAW ABSCESS. This deep abscess in the upper neck, or around the ramus of the mandible, is usually secondary to an alveolar abscess or pericoronitis. The usual evidences of abscess are present, plus severe trismus (lockjaw), and sometimes difficulty in swallowing or breathing. Fluctuation can seldom be elicited until very late, due to the overlying muscle mass; indeed, the swelling may be stony hard. Although local manifestations may be masked or altered by chemotherapy, surgical drainage is usually indicated on about the third or fourth day after onset. Respiratory difficulty demands immediate drainage; if pus cannot be found, relief may not follow and tracheostomy may then be necessary. However, pus is usually located between the ramus and internal pterygoid, or between the ramus and masseter muscle, or in the submaxillary triangle, or in two or more of these locations. In the older literature this condition was often called Ludwig's angina, which was assumed to be a diffuse cellulitis without pus. It is probable, however, that in most instances pus was present but just was not found.

OSTEOMYELITIS OF THE JAW. Much more frequent in the mandible than in the maxilla, this serious infection is most commonly secondary to alveolar abscess or pericoronitis, especially when a tooth has been extracted during an acute phase (Fig. 4). In reality, every alveolar abscess is associated with a slight osteomyelitis, which premature extraction of the tooth may convert into an extensive bone infection. The onset of widespread osteomyelitis is heralded by a chill, high fever, extreme prostration, and delirium, including evidence of sepsis, plus an increase in all local signs. Radiological changes do not appear until two or three weeks later, after sufficient time for decalcification or sequestration has elapsed. Treatment requires complete rest, good nutrition, attention to the airways, transfusions and oxygen if needed, adequate chemotherapy, and surgical drainage of any soft-tissue abscesses. Any bone operations should be postponed until the late chronic stage, and even then is limited to removing detached sequestra. Rapid and complete regeneration of the mandible is common, even after many sequestra have been removed.

THE TONGUE. *Tonguetie*, a common congenital deformity, is due to extreme shortness of the frenum which may interfere with nursing. While the frenum is often severed, which can be done readily, it usually stretches spontaneously in a few years without treatment. In the rare cases where surgery is necessary, a plastic procedure is performed, consisting of switching flaps of mucosa.

Simple ulcers of the tongue are usually part of a general stomatitis, or due to local mechanical trauma. Any ulcer persisting more than three weeks should be biopsied to establish or exclude a more serious diagnosis. *Tuberculous ulcers* are usually deep, painful fissures and are associated with extensive pulmonary cavitation. *Syphilitic ulcers* include the chancre, mucous patch, and gumma, all of which are now quite rare. Any nodular mass in the tongue of a syphilitic should be biopsied, as carcinoma is more common than gumma in this location. *Leukoplakia* of the tongue is a firm white plaque and is a true precancerous lesion requiring removal. *Glossodynia*, or painful tongue, is a common complaint in middle aged or elderly patients. There are no local physical findings, and the situation is commonly associated with other neurosthenic manifestations, with poorly fitting dentures, avitaminoses, or derangements of the temporomandibular joint.

Lingual thyroid represents a rare type of aberrant thyroid tissue. The tumor is located at the foramen cecum at the base of the tongue. If symptoms are produced by it, excision may be indicated. However, one should first test for the presence of functioning thyroid elsewhere in the neck, which can now be readily done with scintillation counting after administration of radioactive iodine.

Tumors of the tongue include the common *squamous carcinoma*, the less common *adenocarcinoma*, and a variety of benign tumors such as *hemangiomas* and *fibromas*, which have been discussed elsewhere (Ch. 20). Diffuse enlargement of the tongue (*macroglossia*) may be seen in cretinism, or may be due to diffuse lymphangioma.

Tonsils and Pharynx. *Peritonsillar abscess* and *retropharyngeal abscess* are now rather uncommon due to the wide and early use of chemotherapy. Symptoms and signs are those of an abscess in the local area and are usually sequelae of some upper respiratory infection. In addition to local pain, the patient may be unable to swallow or to open the jaw widely and exhibit excessive salivation. Inspection will reveal a bulging of the anterior pillar with deviation of the uvula. In *retropharyngeal abscess*, there is not only difficulty in breathing and swallowing but respirations may be of the snoring type. The mouth is usually held open. Diagnosis is made by palpation and inspection of the throat. Treatment is incision and drainage with caution to avoid aspiration of pus into the lungs.

The Salivary Glands. There are three pairs of salivary glands; the parotid and submaxillary, each draining through a single duct, and the sublingual gland, draining through a series of ducts. Tumors and cysts have been considered previously (Ch. 20). Infection and obstruction will now be discussed, under two headings depending upon the presence or absence of stone.

SIALOLITHIASIS. Stones are most common in the submaxillary gland (Fig. 5) but also occur in the parotid gland. Obstructive symptoms are produced when a stone becomes impacted in the main duct and consist of painful enlargement of the corresponding gland (usually more pronounced during or after eating), and of redness of the duct opening, from which a trickle of pus can be manually expressed. Diagnosis may be confirmed by probing the duct, or by radiography. The latter, to be most accurate, requires special soft-tissue exposures on small intraoral films. If there is just one stone in the duct, surgical removal and enlargement of the duct opening are indicated. If the submaxillary gland proper is full of stones, however, with just one in the duct, surgical extirpation of the entire gland is usually advisable, in order to relieve symptoms.

INFECTIONS WITHOUT STONES. In the absence of stone, infections of the salivary gland consist of either purulent invasion of bacterial nature, or parotitis (mumps). The latter is to be differentiated from surgical parotitis, which as a third type is described separately. In *mumps* the saliva is clear though scarce, the white blood count shows a leukopenia and a shift to the right, and there is nearly always a negative past history for mumps. Associated orchitis, oophoritis, or pancrea-

Fig. 5. Obstruction of the submaxillary duct due to stone (sialolithiasis). The patient, aged 60, had been aware of a mass, more or less tender, under the left jaw for many years. It enlarged during and following meals; occasionally it disappeared entirely. A lump under the left side of the tongue was also noted; the symptoms had become more pronounced the past few months. Note the swelling under the angle of the left side of the mandible. The photograph shows the enlarged submaxillary gland, and the x-ray reveals the stone. A photograph of part of the calculus after removal is also included in the lower right hand corner of the illustration.

titis may be present. The disease is common in childhood. Pain on salivary stimulation from acid or sweet drinks or food is well known. Mumps usually infects one or both parotids, but may involve one or both submaxillary glands. The disease is transient and requires no therapy. Cortisonelike drugs are effective in controlling the complications of orchitis, oophoritis, and pancreatitis.

Purulent salivary infections are usually limited to one gland, with pus exuding from the duct. Blood counts show leukocytosis and a shift to the left. The absence of stones is confirmed by probing or by radiography. In otherwise healthy individuals, such infections are often associated with strictures or anomalies of the main or lesser ducts, which may be shown by sialography. Treatment consists of dilatation or surgical resection and plastic repair of any strictures, or, in extreme cases, of extirpation of the entire gland. Simpler measures, such as chemotherapy, repeated probing of the duct to dislodge mucous plugs, natural salivary stimulation as with citrus fruits, or artificial stimulation with pilocarpine plus manual stripping of the duct, may suffice in moderately severe cases.

Surgical parotitis is really a misnomer applied formerly to purulent parotitis without stone occurring as a postoperative complication (Fig. 6) in extremely debilitated patients. The high mortality was probable due to the low resistance of the patient to his own mouth organisms. Because of this, radical surgery was often, though erroneously, recommended. Treatment is largely prophylactic in that this infection rarely occurs in patients kept in a good general condition and given routine and adequate mouth hygiene. Chemotherapy is now quite effective. The sooner the patient can take a normal oral diet, the sooner parotitis will subside.

Mikulicz's disease, and *Sjogren's disease* are both rare and diffuse swellings of the salivary and lacrimal glands. The pathogenesis is poorly understood. In some instances they may be associated with uveitis or other eye disturbances. The disease is usually asymptomatic except for the visible and palpable chronic nontender swellings. Saliva is

THE TONGUE. *Tonguetie*, a common congenital deformity, is due to extreme shortness of the frenum which may interfere with nursing. While the frenum is often severed, which can be done readily, it usually stretches spontaneously in a few years without treatment. In the rare cases where surgery is necessary, a plastic procedure is performed, consisting of switching flaps of mucosa.

Simple ulcers of the tongue are usually part of a general stomatitis, or due to local mechanical trauma. Any ulcer persisting more than three weeks should be biopsied to establish or exclude a more serious diagnosis. *Tuberculous ulcers* are usually deep, painful fissures and are associated with extensive pulmonary cavitation. *Syphilitic ulcers* include the chancre, mucous patch, and gumma, all of which are now quite rare. Any nodular mass in the tongue of a syphilitic should be biopsied, as carcinoma is more common than gumma in this location. *Leukoplakia* of the tongue is a firm white plaque and is a true precancerous lesion requiring removal. *Glossodynia*, or painful tongue, is a common complaint in middle aged or elderly patients. There are no local physical findings, and the situation is commonly associated with other neurosthenic manifestations, with poorly fitting dentures, avitaminoses, or derangements of the temporomandibular joint.

Lingual thyroid represents a rare type of aberrant thyroid tissue. The tumor is located at the foramen cecum at the base of the tongue. If symptoms are produced by it, excision may be indicated. However, one should first test for the presence of functioning thyroid elsewhere in the neck, which can now be readily done with scintillation counting after administration of radioactive iodine.

Tumors of the tongue include the common *squamous carcinoma*, the less common *adenocarcinoma*, and a variety of benign tumors such as *hemangiomas* and *fibromas*, which have been discussed elsewhere (Ch. 20). Diffuse enlargement of the tongue (*macroglossia*) may be seen in cretinism, or may be due to diffuse lymphangioma.

Tonsils and Pharynx. *Peritonsillar abscess* and *retropharyngeal abscess* are now rather uncommon due to the wide and early use of chemotherapy. Symptoms and signs are those of an abscess in the local area and are usually sequelae of some upper respiratory infection. In addition to local pain, the patient may be unable to swallow or to open the jaw widely and exhibit excessive salivation. Inspection will reveal a bulging of the anterior pillar with deviation of the uvula. In *retropharyngeal abscess*, there is not only difficulty in breathing and swallowing but respirations may be of the snoring type. The mouth is usually held open. Diagnosis is made by palpation and inspection of the throat. Treatment is incision and drainage with caution to avoid aspiration of pus into the lungs.

The Salivary Glands. There are three pairs of salivary glands; the parotid and submaxillary, each draining through a single duct, and the sublingual gland, draining through a series of ducts. Tumors and cysts have been considered previously (Ch. 20). Infection and obstruction will now be discussed, under two headings depending upon the presence or absence of stone.

SIALOLITHIASIS. Stones are most common in the submaxillary gland (Fig. 5) but also occur in the parotid gland. Obstructive symptoms are produced when a stone becomes impacted in the main duct and consist of painful enlargement of the corresponding gland (usually more pronounced during or after eating), and of redness of the duct opening, from which a trickle of pus can be manually expressed. Diagnosis may be confirmed by probing the duct, or by radiography. The latter, to be most accurate, requires special soft-tissue exposures on small intraoral films. If there is just one stone in the duct, surgical removal and enlargement of the duct opening are indicated. If the submaxillary gland proper is full of stones, however, with just one in the duct, surgical extirpation of the entire gland is usually advisable, in order to relieve symptoms.

INFECTIONS WITHOUT STONES. In the absence of stone, infections of the salivary gland consist of either purulent invasion of bacterial nature, or parotitis (mumps). The latter is to be differentiated from surgical parotitis, which as a third type is described separately. In *mumps* the saliva is clear though scarce, the white blood count shows a leukopenia and a shift to the right, and there is nearly always a negative past history for mumps. Associated orchitis. oophoritis, or pancrea-

free of voluntary control. As might be expected, diseases of the esophagus produce clinical manifestations by interfering with normal deglutition. Difficulty in swallowing is called dysphagia, which varies in severity from transient interference with the ingestion of solid food to a complete inability to swallow even liquids. Complete obstruction is usually associated with regurgitation of esophageal contents, which must be distinguished from true vomiting, in which gastric content is lost. In true vomiting, the patient usually recognizes the sour taste of the gastric contents. The liquid regurgitated in esophageal obstruction may merely be swallowed saliva, or may consist of fluids taken just a few minutes before or of food eaten many hours previously. Regurgitation of food taken hours previously is particularly characteristic of fusiform dilatation of the esophagus or of the presence of a large diverticulum.

Difficulty in swallowing may be sudden or gradual. Sudden dysphagia is usually due to the immediate effects of swallowing corrosive chemicals, to bulbar paralysis, to a foreign body, to irritation by a rubber nasal tube, or acute lesions in the neck or mediastinum, such as abscess, thyroiditis, and lymphadenitis, which may involve the esophagus by contiguity. Chronic dysphagia may be produced by strictures and tumors within or by aneurysms, vertebral disease, mediastinal tumors, or other masses by pressure from without. Occasionally, dysphagia is due to paralysis of the ninth and twelfth cranial nerves. *Gradually increasing dysphagia in an otherwise healthy person, particularly in a male, is nearly always due to carcinoma.*

Special examinations are usually essential for accurate diagnosis. These special methods include (*a*) fluoroscopic and radiologic study during and after the ingestion of a barium meal and (*b*) direct inspection of the interior of the esophagus by the esophagoscope. These types of examination usually suffice to establish the diagnosis but are most effective in the hands of those expert in the use of them. On the other hand, the passage of a bougie or tube into the esophagus in a patient with dysphagia is apt to be a dangerous procedure should an acute ulceration or an aneurysm be present, and should not be performed unless such lesions are definitely excluded.

Diverticulum of the Esophagus. Also called pulsion diverticulum, this lesion is really located in the *pharynx* and is a hernial sac through the posterior pharyngeal wall, presumably due to a congenital defect (Fig. 7). *Traction diverticulum* represents a different type, small in size, and without clinical significance, being usually noted only by radiography or at autopsy. Traction diverticula are asymptomatic, usually located in the midportion, and are the result of traction by scar following an inflammatory process such as a suppurating lymph node. *Pulsion diverticulum* develops at a point just above the cricoid cartilage where the inferior constrictor fibers merge with the circular musculature of the esophagus to form the circopharyngeus muscle. The neck of the sac is thus in the mid-line, but the mass usually presents to one side or the other, nearly always the left, as it increases in size. It rarely becomes large enough to be visible as a definite swelling. Symptoms of slight difficulty in swallowing may date back to childhood. More severe manifestations, however, do not occur unless the sac attains a fairly large size and contains food which may be retained for considerable periods of time. The patient may then be conscious of peculiar sounds or slight discomfort associated with swelling. The soured or foul food retained in this diverticulum may be regurgitated. Accidental aspiration of some of the foul content of the diverticulum into the respiratory tract during sleep, or even when the patient is awake, may lead to development of lung abscesses. Finally, the sac may become large enough to produce definite mechanical obstruction, leading in severe cases to gradually increasing malnutrition. Diagnosis is usually obvious by radiographic visualization of the sac, especially in the lateral view after the ingestion of a barium meal. *Treatment* consists of surgical excision, which is now usually performed in one stage. This condition has been well reviewed and analyzed by Lahey and Warren (4).

Cardiospasm. Slight spasm of the cardiac end of the stomach is usually functional and produces only transient difficulty in swallowing related perhaps to the condition popularly known as "globus hystericus," which, however, may occur in any part of the gullet. Cardiospasm, when it is severe and of long

Fig. 6. Acute parotitis. The patient is a 35-year-old woman upon whom a rectal operation had been performed 10 days previously under general anesthesia. The swelling began on the seventh postoperative day; five days later the opposite parotid became similarly involved. The patient was treated conservatively and several days later small abscesses were incised; recovery was eventually complete.

clear. Microscopic study shows diffuse round cell infiltration with many plasma cells and eosinophiles. In syphilitics, the lesions sometimes improve on specific therapy. Since there is evidence that these lesions may be allergic, improvement may follow prolonged cortisonelike therapy.

Deep Surgical Infections. Most of these have already been discussed under the heading of jaw abscesses (see above), originating from infections of the oral cavity which have already been described. Occasionally, however, the nature of the primary port of entry is difficult to demonstrate, although careful search should always be made. The infection may be the local manifestation of agranulocytosis (agranulocytic angina) or of leukemia. These deep surgical infections usually offer no difficulty in differentiation from the more superficial infections of the neck so commonly due to skin lesions or subcutaneous lymphadenitis. Acute diffuse cellulitis of the deep tissues involving also the floor of the mouth often is called Ludwig's angina, as already described on page 124. The typical deep cervical infections are much more localized and assume a less diffuse form than Ludwig's angina, exhibiting, moreover, localized redness, induration, and often a brawny edema confined first to one side of the neck, but not infrequently spreading across the mid-line. As in other infections, systemic manifestations may accompany a local lesion which may produce pressure symptoms sufficient to embarrass respiration and require emergency tracheotomy.

Treatment is the same as outlined above for jaw abscesses. The relation between chemotherapy and surgical incision requires accurate timing, as has already been discussed.

ESOPHAGUS

The esophagus or gullet is a muscular tube concerned with swallowing, or deglutition. In the upper portion, the musculature is striated and largely under voluntary control. In the lower portion the musculature is smooth and

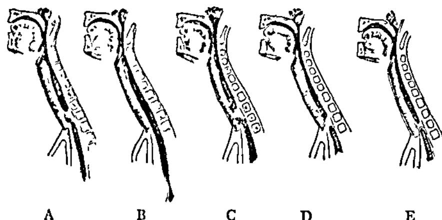

Fig. 8. Types of congenital malformation of the esophagus. A, the type in which the proximal portion ends blindly, the distal portion communicating with the trachea; this type is found in from 80 to 90 per cent of the anomalies; B, constriction without atresia, usually occurring at the distal end of the esophagus; C, communication between the trachea and each segment of the esophagus; D, communication between the trachea and the proximal segment (rare), and E, atresia of the esophagus without a tracheal fistula. (From W. H. Cole. Arch. Surg.)

available, but each requires close cooperation between the surgeon and the esophagoscopist to achieve the best results. In many instances, a functioning gullet will result, particularly if dilatation is repeated at intervals and particular attention is paid to the diet and to thorough mastication in order to avoid swallowing large particles. Eventually, the gastrostomy may be closed. In the more severe cases, an abdominothoracic operation yields the best results. Resection of the involved esophagus or a by-passing anastomosis between the stomach and the esophagus above the stricture is performed (7). The early use of cortisone to reduce the degree of scarring has been tested experimentally but lacks adequate clinical support.

Congenital stricture and other anomalies of the esophagus are rare but are apparent immediately after birth. The varieties which have been observed are shown in Figure 8. Without surgery, and even with simple gastrostomy, death may occur from inanition or more rapidly by aspiration of gastric contents into the lung because of the existence of a fistula between the respiratory and the gastrointestinal tract. Correction of the anomaly by operation is indicated and should be performed within a few hours after birth. Detailed studies and description of various surgical procedures may be found as listed in the references (8). Survival and normal development may be expected in about one third of the cases. The greatest handicap to greater success is the presence of other severe malformations. The awareness of doctors and nurses caring for newborn infants of the possibility of this condition, their alertness in recognizing the symptoms, the promptness with which patients are referred for surgery, the preoperative and postoperative care, and the technical details of the operation all play a decisive part in salvaging these patients.

Foreign Bodies in the Esophagus. A history of the accidental swallowing of a foreign body, such as a toy, can usually be obtained in this condition although, in many instances, the first intimation of trouble may be pain and inability to swallow, followed by regurgitation. If cough and respiratory disturbances occur, the foreign body is probably in the trachea or a bronchus. If the patient is seen immediately after the accident, a sedative, such as morphine, is given as soon as possible to allay apprehension and muscle spasm. After sedation of the patient, the object is frequently swallowed and reaches the stomach, where its presence may be of much less concern. Fortunately, the object is sometimes regurgitated spontaneously. If neither occurs, the child should be brought to the hospital, where a radiograph is taken in order to reveal objects which may be radiopaque (Fig. 9). If the object is sharp, the removal is urgent, lest esophageal perforation occur, with mediastinal infection as a serious complication.

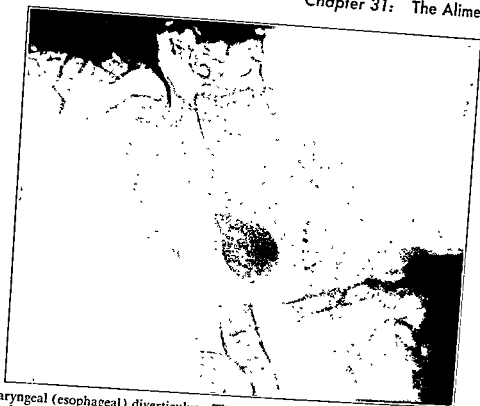

Fig. 7. Pharyngeal (esophageal) diverticulum. The roentgenogram is an oblique view after the ingestion of barium and shows the pouch well outlined. The patient, a 63-year-old male, first noted regurgitation of food following meals, especially when lying down; often a gurgling sound preceded the vomiting. Excision was performed in one stage with uneventful recovery. (Courtesy, Dr. V. P. Blair.)

standing, leads to a fusiform dilatation of the esophagus above the cardia. When long continued, dilatation may become so pronounced as to lead to retention of considerable amounts of ingested food and liquids. The patient may seem to eat and drink normally, but when regurgitation occurs it may be so profuse as to be mistaken for vomiting. Despite severe obstruction, sufficient food may still pass through to maintain the patient's normal weight. In this regard, cardiospasm stands in contrast to other types of esophageal obstruction, such as stricture and carcinoma, which lead to severe cachexia. Cardiospasm may, however, be associated with esophagitis (see below). For therapy, it must be distinguished from carcinoma and stricture which is usually possible by radiographic and fluoroscopic studies.

Treatment may be instituted from above by means of procedures designed to dilate the cardia by means of various manipulative devices, or by an operative procedure designed to divide the cardiac sphincter (Heller operation) (5, 6). In severe cases, the obstruction becomes organic and the term *achalasia* of the esophagus is often used. In such a case, more complicated and extensive abdominal or thoracic procedures may be necessary in order to relieve the obstruction (6).

Stricture of the Esophagus. Fibrous tissue may be deposited in the esophageal wall in response to previous ulceration usually due to the accidental ingestion of corrosive chemicals, the most common example of which is the swallowing of lye by young children. If the patient escapes fatal poisoning or perforation, the cicatricial contraction of the resulting scar will gradually lead to difficulty in swallowing, followed by regurgitation. Stricture formation may also follow other ulcerative lesions, such as esophagitis (see below) and carcinoma; a good history, however, will differentiate these lesions. Many patients may suffer only mild disability because of esophageal stricture; but in most instances, the dysphagia becomes severe as stenosis becomes more and more complete.

Treatment in the severe cases consists of a preliminary gastrostomy for feeding purposes, followed by gradual dilatation of the stricture. Many methods of dilatation are

Fig. 10. Carcinoma of the esophagus. The filling defect following ingestion of barium was marked in each patient; they were able to swallow liquids, but no solid food.

mucous glands. The tumor is not common, comprising only about 5 per cent of all malignant disease. It rapidly ulcerates and later, by growth or fibrous tissue contraction, produces stricture and obstruction of the lumen. The disease is far more frequent in males than in females, and in individuals of more advanced years. The tumor may occur at any level of the esophagus, but it is more common in the distal portion. Perforation may occur; metastases, unfortunately, may be widespread when the patient is first seen. The *clinical picture* is one of gradually increasing difficulty in swallowing, first of solid food and later even of liquid. Regurgitation of food and drink develops as stenosis becomes complete. Loss of weight is progressive and rapid because of starvation; pain is entirely absent. Diagnosis is made by finding a characteristic radiological picture after the ingestion of barium meal (Fig. 10) and/or by the direct visualization of the lesion through the esophagoscope. Examination of a biopsy specimen will often enable a certain diagnosis to be made.

Treatment is usually surgical. In the absence of metastases, operation should be planned for resection of the tumor, followed by primary anastomosis to restore continuity between the remaining esophagus and stomach or jejunum. In the presence of severe malnutrition, a preliminary gastrostomy or jejunostomy for feeding may be advisable. Several surgical procedures have been recommended and the choice in any case will depend on the location of the tumor. Radical resection aimed at removing all the carcinoma should be the procedure of choice and is sometimes within reach, based upon the good results reported by Sweet (15), and by others. In most cases, however, the patient is seen too late for the possibility of cure. In such cases, a palliative resection, using a plastic prosthesis has been recommended (16), but in the hands of some of us the results have been almost uniformly catastrophic because of spread of infection from the junction of plastic and esophagus. A more successful palliative method has been the placement of a plastic tube (17) through the un-

Fig. 9. Open safety pin in the esophagus. The above roentgenogram was taken immediately after admission to the hospital. The patient, a two-year-old child, had swallowed the pin a few hours previously. A few minutes after this x-ray was taken the child swallowed several times and the pin passed into the stomach (see Fig. 18).

On the other hand, the manipulations incident to removal may lead to a perforation unless performed by an expert. The use of solid food to aid the esophagus in carrying the object into the stomach may be useful in some instances, but only when there is no danger that a sharp point may lead to perforation.

Esophagitis. The lower end of the esophagus may become the site of inflammation and ulceration, leading even to fibrous stricture and stenosis, due presumably to the effect of regurgitated irritating gastric secretions. In fact, the terms reflux and peptic esophagitis are often applied (9, 10). Thus the mechanism presumably involves a relaxation of the cardiac sphincter—the opposite of cardiospasm, although the latter may occur secondarily by reflex action. Thus cardiospasm may be associated with esophagitis. However, the mechanism is far from clear even when changes in the esophagus are pronounced and the symptoms severe. A sliding hiatus hernia is often associated and is the causative factor. In a few cases, the esophagus is unusually short. The diagnosis is usually made on the basis of the history, expert radiographic study, and esophagoscopy.

The clinical picture is one of severe pain, usually substernal, and is frequently mistaken for angina pectoris. Often the pain is similar to that of gastric and duodenal ulcer in that it responds to antacid and antisecretory drugs. Obstructive symptoms occur later. In some cases, an associated duodenal ulcer is found, and adequate gastric resection leads to cure of the esophagitis, and thus emphasizes the importance of controlling acidity (10). Pyloroplasty has also been effective (11). In many of these patients, however, severe complications demand more radical procedures and several operations have been advocated (12, 13, 14). However, further study of this disease is needed.

Carcinoma of the Esophagus. Usually of the squamous cell type arising from the mucous membrane, a few of these neoplasms may be adenocarcinoma arising from the sub-

Fig. 11. Benign gastric ulcer. The patient, a man aged 58, had epigastric pain of four years' duration. Arrow points to the crater defect, which is larger than average. Gastric resection was performed.

is less clearly understood. Gastric ulcer is of special importance because it is a potential cancer, whereas duodenal ulcer has not been *observed to undergo malignant changes.* The transition from gastric ulcer to cancer has been proved in many cases, although it is likely that in most instances gastric cancer is confused with gastric ulcer because it starts as an ulcer. The possibility of cancer means that operation in gastric ulcer is more definitely indicated than as if this risk were absent, and medical therapy is potentially dangerous, as discussed below. About 15 per cent of gastric ulcers are malignant (Fig. 12). *A few (less than 5 per cent) appear to develop into carcinomas,* but proof is not definite.

Clinical Manifestations. Peptic ulcer in either the stomach or duodenum should be considered essentially as a chronic disease, with long or short periods of remission or exacerbation, even though severe acute complications may occur. Gastric ulcer, though

Fig. 12. Malignant ulcers of the stomach. Left, the x-ray defect in this patient suggested a benign ulcer; the hyperplastic area was not visible on x-ray. Right, the arrow points to the ulcer which is filled with fibrin and tumor. The crater was noted on x-ray four months ago, then disappeared (under medical treatment) as if it had healed. Nevertheless, gastric resection was performed; a typical malignant ulcer was found microscopically.

resected tumor to provide continuity for swallowing as originally suggested by Souttar many years ago. Because of the high mortality rate following resection and esophagogastrostomy for lesions in the middle third of the esophagus, some surgeons are performing the resection at one stage and the repair at a second stage, using the colon or jejunum anterior or posterior to the sternum to bridge the gap between the esophagus and stomach. Radiotherapy has also been used, particularly since the surgical results in general have proved to be disappointing. Although the benefits following x-ray radiotherapy have been disappointing, results following use of the betatron are definitely encouraging, insofar as the local lesion can be destroyed.

Gastrostomy. This procedure is necessary in esophageal obstruction, whether benign or malignant, whenever the amount of food passing through is insufficient to maintain the patient's nutrition. Gastrostomy is also sometimes indicated as a preliminary to other operative procedures, as already mentioned. If there is an esophageal stricture to be dilated, the opening is made as near the cardiac orifice as possible through a high right rectus incision so as to facilitate bouginage from the gastric side. On the other hand, if resection of a low lying carcinoma with primary anastomosis is planned, the opening is made into a more distal portion of the stomach or into the jejunum. Many types of gastrostomy have been described, but they fall into two general groups, depending upon whether the opening is to be permanent or temporary. In the latter case, a large catheter is inserted into the stomach through a small incision, and the gastric wall infolded with concentric purse-string sutures around the tube, which is brought out through the abdominal wall by a separate small incision. The Witzel technic is similar, except that the infolded stomach wall extends in linear fashion rather than concentrically. In either case the tube, when it is removed, leaves a connective tissue-lined fistula, which rapidly closes. If a permanent gastrostomy is desired, an operation of the Janeway type must be performed. In this procedure, a flap of gastric wall is fashioned into a mucosa-lined tube around the catheter, and the opening in the stomach is closed. The external end of the flap is sutured to a part of the abdominal incision, mucosa to skin. Thus there is created a short tunnel leading from the gastric lumen to the outside, lined by mucosa and easily entered with a catheter. As long as the mucocutaneous border is intact, the fistula will remain open.

STOMACH AND DUODENUM

The clinical history, examination, and usual laboratory studies will reveal the existence of surgical diseases of the stomach and duodenum. However, an accurate diagnosis is often possible only after special examinations. The most important are fluoroscopic and radiologic examinations after the ingestion of a barium meal. As with other radiologic examinations, however, this must be carried out by an expert in order to get the full advantage of the best technic. Interpretation of radiologic findings is not always easy in terms of a specific diagnosis and often involves a certain degree of both positive and negative errors. Direct visualization of the interior of the stomach by means of a flexible gastroscope may also be indicated. With these procedures, the diagnostic accuracy of gastroduodenal disease has been greatly increased, but as with other so-called laboratory procedures, must only be used in conjunction with a clinical evaluation of the patient. The tendency to rely entirely upon such special examinations is to be deplored. Test meals of various kinds to measure gastric secretory function, formerly used as routine, are now seldom employed except in clinical research. Gastric secretory activity may also be estimated by the uropepsin excretion in the urine. Gastric acidity can also be estimated by the urinary content of quinine or methylene blue which are released by ion-exchange resins containing them, following ingestion of them (so-called tubeless gastric analysis). These may prove of value for routine clinical use but as yet are mostly research tools requiring further study.

Gastric Ulcer. Most gastric and duodenal ulcers (the latter is discussed separately) are called *peptic ulcers* for reasons to be discussed below. This remarkable lesion is often located in the pyloric region or along the lesser curvature (Fig. 11). The pathogenesis, though apparently similar to duodenal ulcer,

they have a tendency to heal and recur, and occasionally to be multiple. In the simplest cases, the mucosa alone is denuded, but in more severe cases the necrosis or digestion extends more deeply, so that more of the wall becomes involved. If, in the process, a blood vessel is eroded, *hemorrhage* follows. *Perforation* of the entire duodenal wall follows when the lesion reaches the serosa. Should the ulcer be located on the posterior wall, the perforation encounters the head of the pancreas, which becomes the site of chronic induration. More commonly, however, the ulcer is in the anterior duodenal wall so that perforation reaches the peritoneal cavity, resulting in a diffuse peritonitis unless operation is promptly performed, or unless the right lobe of the liver, omentum, or gallbladder becomes adherent and seals it off, or permits the formation of a small walled-off cavity.

The propensity of peptic ulcer to undergo intermittent healing undoubtedly explains the clinical behavior in many of these patients. What probably happens is that tiny erosions or even ulcers are frequently formed in the stomach and duodenum from the mechanical effects of hard or harsh foods, or from other factors, most of which probably heal without being noticed. Even when definite symptoms are present, the frequent spontaneous remissions enjoyed by these patients indicate healing. Such a healing process has also been noted by radiologists; and surgeons have frequently seen an old scar shining through the serosa of the first part of the duodenum in patients with a previous "ulcer history." Such scar has clinical interest only in that it may be sufficient to produce an *obstruction*, which at the pylorus may lead to serious symptoms, as discussed under complications.

The *pathogenesis of peptic ulcer*, though only partly understood, is undoubtedly associated with the presence of the proteolytic ferment in the gastric juice which permits digestion of the mucosa. At least it is true that a peptic ulcer does not form in the absence of gastric juice. Moreover, gastric mucosa is always adjacent to or at least a few centimeters proximal to the site of the ulcer. This applies to marginal ulcer which, as described later, is chiefly on the jejunal side of the gastroenterostomy stoma. This is also true in the ulcers found in Meckel's diverticulum, a rare lesion which is described on page 747, which is also associated with the presence of aberrant gastric mucosa in the pouch. Finally, experimental peptic ulcer likewise occurs just beyond the secreting gastric mucosa. It appears, therefore, that not only is the proximity of gastric mucosa necessary for the formation of peptic ulcers but that they form very close to the point where secretion first comes in contact with the ulcerated tissue.

A high acidity is probably just as important if not more important than the presence of pepsin. Indeed, a high gastric acidity has long been found on examination of the gastric contents of many ulcer patients. At any given moment, however, the gastric acidity may be low or absent, even in the presence of an ulcer. Because of the wide variations normally found, measurement of gastric acidity is now seldom used in the diagnosis. Nevertheless, the beneficial effects of alkaline therapy in those patients emphasize the importance of a high gastric acidity, not only in producing symptoms of pain but also in preventing ulcers from healing. Operative procedures in general are more effective when they lead to low or no gastric acidity. It seems logical, therefore, to suppose that not only is the healing process interfered with by high gastric acidity but that high acidity favors digestion or necrosis. Much of this evidence has been summarized in detail by Dragstedt (19). Faulty regulation of gastric acidity, therefore, would seem to play an important part in the pathogenesis of peptic ulcer.

The control of gastric secretion is equally shared by neurogenic and humoral influences. The former is spoken of as the cephalic phase of gastric secretion and is mediated through the vagus nerve. The latter is called the gastric phase and resides in a hormone produced by antral cells in the distal third or half of the stomach. There is also a humoral intestinal phase, but this is quantitatively small. These factors in the control of gastric secretion and acidity are of importance in surgical therapy, as discussed below. Another secondary factor in the control of gastric acidity should also be mentioned because it may be of significance in certain cases, and that is the neutralizing effect of alkaline pancreatic juice

similar to duodenal ulcer, usually presents a less definite clinical picture. Epigastric distress or pain, while periodic and definitely related to food intake, is more likely to be variable even when severe. Ingestion of food or alkali often relieves the pain, but in some cases the former may aggravate it. Such symptoms as dyspepsia, which includes sour eructations, bloating, and heartburn are not infrequent. Vomiting is not uncommon. Diagnosis is usually readily made radiologically after a barium meal by the demonstration of a characteristic niche in the outline of the stomach. In many cases, certain manifestations enable the expert radiologist to distinguish a benign ulcer from carcinoma. There is, however, a considerable margin for error; what usually happens is that, in order to avoid the mistake of calling a malignant lesion benign, most radiologists will tend to err in the reverse direction by calling a benign lesion malignant. Even gastroscopy may fail to make a definite differential diagnosis. These considerations are important in that the clinical picture plays a lesser part in deciding the question of therapy than it does in the case of duodenal ulcer. Gastric ulcer is occasionally associated with gallbladder and appendiceal disease, and may be overlooked in the presence of them not only clinically, but also at operation. Unlike duodenal ulcer, gastric ulcer is as common in women as in men. The complications of gastric ulcer, such as hemorrhage, obstruction, and perforation, are similar to those of duodenal ulcer and will be discussed under complications (see p. 737).

TREATMENT. The therapeutic problem in gastric ulcer is dominated by the possibility that the lesion may be malignant, a diagnosis which can be made with certainty only by microscopic study after removal. For this reason, many surgeons advocate immediate operation as soon as the diagnosis is made. However, on certain occasions (e.g., young patients, acute short history), the diagnosis of benign ulcer can be made with fair certainty, and at least a trial of medical therapy for three or four weeks is justifiable. When clinical, radiologic, or even gastroscopic evidence suggests cancer, an operation should unquestionably be carried out at once; even when all evidence points to a benign ulcer, it is wiser to keep in mind the possibility that cancer may be lurking in a few such cases, as emphasized by Eusterman years ago (18). Thus, the likelihood of cancer places a grave responsibility on the physician who prescribes nonoperative therapy even if there is some radiologic sign of healing, particularly in the older age group. If medical therapy is used, the patient should preferably be under observation in the hospital and released only if the ulcer has shown unmistakeable clinical and radiologic evidence of complete healing within a two- or three-week period. Even then, subsequent radiologic examinations at intervals of three to six months are advisable, and operation should be carried out if the lesion recurs even in the absence of symptoms. Persistent pain may call for operation in any case. The difficult ulcers are those high on the lesser curvature close to the esophagus, impossible to excise short of complete gastrectomy. In such a case, control of gastric acidity by a traditional gastric resection may permit the ulcer to heal if it is benign. In all other cases, gastric resection (see below) including the ulcer, the greater omentum, and a wide area of lymphatic tissue, is the procedure of choice, lest the lesion contain malignant cells. Microscopic (frozen) section of a portion of the lesion at operation carries the danger of spread and is not advisable or necessary, in general. The complications of gastric ulcer, such as perforation and hemorrhage, are similar to those of duodenal ulcer and will be considered under that heading.

Duodenal Ulcer. The duodenum is more often the site of peptic ulcer than the stomach, in the ratio of five to one. However, the ulceration frequently occurs so close to the pyloric ring that it may be difficult to decide whether the lesion is duodenal or gastric. Ordinarily the difference is easily demonstrable at operation, since the pylorus can be located by the transverse pyloric vein. Ulcers distal to this vein are duodenal, those proximal to it are gastric.

PATHOLOGY. The location of duodenal ulcers nearly always is the first portion of the duodenum, just beyond the pyloric ring at the site where gastric contents first strike the duodenal mucosa which may be of some significance in the pathogenesis. The lesions vary considerably in gross appearance, for

than the acute phase of the disease. During the acute phase, rest in bed with the exclusion of all disturbing outside influences may be important for spontaneous healing of the ulcer.

Duodenal ulcer becomes a surgical disease primarily because of the complications, which are described below. However, elective operation is indicated even in uncomplicated peptic ulcer when symptoms persist or recur despite competent medical treatment. The success of operation under such circumstances depends upon many factors, including careful selection. Patients with a long history of vague digestive disturbances, who are neurotic, and who happen to show a duodenal deformity on one examination are not good subjects. On the other hand, those with severe disability and repeated evidence of unquestioned ulceration, and who do not wish to or cannot live on a restricted though successful dietary regimen, are, in general, apt to enjoy freedom of symptoms and to enjoy a normal dietary intake after an adequate operation.

The operation, to be successful, is one which, in general, best controls gastric acidity without postoperative symptoms. Gastroenterostomy, once the procedure of choice, is now seldom used except in poor risk patients with advanced pyloric obstruction (or in conjunction with vagotomy). While 90 per cent of patients used to enjoy immediate relief of symptoms following gastroenterostomy, the percentage rapidly dropped with the passage of time so that within five years after operation more than a third were found to be suffering from their old symptoms. In many instances, the recurrence of pain was due to the formation of a new ulcer in the jejunum just beyond the operative stoma (jejunal or marginal ulcer, which is described later).

The most commonly used operation now is partial gastrectomy, a procedure which has long been known to result in a more persistent lowering of gastric acidity than is the case following a gastroenterostomy. The Billroth II pattern may be used, in which the residual gastric pouch is anastomosed to the duodenojejunal junction to re-establish enteric continuity, and the duodenal stump at the pyloric amputation site is closed blindly, thus taking the duodenum out of the main enteric stream. Under these circumstances, the gastrectomy, to be effective, must remove all antral cells, known to produce a hormone (gastrin) stimulatory to acid secretion by the remaining portion of stomach. Antral cells extend further along the lesser than the greater curvature so that the line of resection must be at least two thirds of the distance from the pylorus to the cardia on the lesser curvature of the stomach, and well above the junction of the left and right gastroepiploic vessels on the greater curvature. In most hands this amounts to removal of approximately 75 per cent of the stomach. The gastrojejunal anastomosis may be made either antecolic or retrocolic; the latter is preferred by most who have run carefully controlled series because it permits utilization of an extremely short duodenal loop, a factor minimizing the incidence of later recurrent ulceration.

The Billroth I pattern, largely abandoned until a few years ago, is now regaining acceptance; in this operation, the remaining upper gastric pouch is anastomosed to the cut end of the duodenum or antrum, thus leaving all elements in enteric continuity. With retention of the antrum in continuity, the hormonal hypersecretion seen after the Billroth II procedure does not occur (Dragstedt, 21 and Thal, 22). There is good evidence for the production of an acid suppressing hormone by the antral cells under these conditions (23). Wangensteen (24) has adopted a sleeve resection which divides the vagi in mid-stomach and preserves the antrum, coupled with pyloroplasty to forestall the poor gastric emptying otherwise seen after vagal section. The Billroth I pattern tends to give better results in women and in thin subjects (25) and is less likely to lead to postgastrectomy dyspepsia.

Resection of the vagus nerves just below the diaphragm, as advocated by Dragstedt, is now usually performed only together with gastroenterostomy (26) or pyloroplasty (27) but neither combination has received wide acceptance.

The high mortality which followed gastric resection in the past has been steadily reduced within the past decade, due largely to more adequate preoperative preparation and postoperative care. Nutritional deficiencies are frequent in these patients as in others with

when, as, and if it enters the stomach or even in the duodenum.

Another element in the pathogenesis of peptic ulcer is undoubtedly the motor function of the stomach and duodenum. An increased gastric motor activity has actually been observed in many patients with ulcer. Presumably this enables highly acid content chemically to produce or aggravate mucosal ulceration. Spasm of the pylorus, in many instances, may interfere with adequate control of gastric acidity, diminishing the regurgitation of alkaline duodenal contents, a factor which may play an important part in the control of gastric acidity.

The autonomic nervous system, which controls both secretory and muscular activity, is therefore probably involved in the pathogenesis of peptic ulcers. Indeed, it has long been known that worry, fatigue, and tension greatly aggravate the clinical severity of peptic ulcers, presumably because of the influence of these factors on gastroduodenal secretion and motility via the autonomic nerves, particularly the vagus. This concept of autonomic derangement was advanced greatly through the well-known observations of W. B. Cannon (20). Moreover, the role of stress is indicated by recent observations showing that adrenocortical stimulation may lead to peptic ulceration.

Other etiological factors, while important, are less readily explainable. For example, ulcer symptoms are apt to be worse during the spring and fall and are aggravated by respiratory and oral infections, especially about the teeth.

CLINICAL MANIFESTATIONS. Entirely apart from the complications which are discussed separately, duodenal ulcer produces a characteristic type of upper abdominal pain varying from a sense of hunger and distress to a dull, gnawing, boring pain, which may be severe and disabling. The pain is not due to the presence of the ulcer per se, but to the spasm and cramping which are provoked. The pain is not only variable but essentially chronic, yet intermittent, and may disappear for months or years, being aggravated by the factors already mentioned above, particularly mental stress.

The pain is often described as a hunger pain because it occurs characteristically when the stomach is empty, i.e., two or three hours after meals. Moreover, it is usually relieved by eating. Patients soon learn of this and carry food with them or keep it at the bedside because of the relief it affords. Relief is also achieved by taking alkalis, but the effect is not as lasting. Other symptoms, such as heartburn and belching, usually referred to as dyspepsia, are not characteristic since they occur in many other conditions. Vomiting is frequent in the severe cases, especially when pylorospasm is persistent or actual pyloric obstruction has developed.

Abdominal examination may be entirely negative or may reveal deep tenderness in the epigastrium, presumably over the lesion. More superficial tenderness, or hyperasthesia, is due to the same mechanism which produces referred pain and can often be elicited along the costal margin. An accurate diagnosis of duodenal ulcer, however, depends in most cases upon the findings of the expert radiologist following the ingestion of a barium meal. Collection and examination of gastric contents is of value when it reveals a high acid titer, particularly in patients who also show evidence of hypersecretion. However, high acidity may be found in patients without anatomic evidence of ulcer, either radiologically or at operation. These patients, however, may suffer the same type of pain as described above, and it is usually explained as being due to pylorospasm. The more serious manifestations of duodenal ulcer are due to the complications which are described below.

TREATMENT. Medical therapy is successful in most patients with uncomplicated duodenal ulcer. Drugs are employed to decrease gastric secretion and to reduce gastric acidity. Attention must, of course, be directed toward the control of psychosomatic disorders, particularly those based on emotional strain and the stress of "high pressure" living. Dietary measures are based upon modification of the regimen popularized decades ago by Sippy and consists essentially of a bland, liquid diet usually containing a large fat (cream) content. The fat tends to slow gastric peristalsis. Unless such a diet contains sufficient protein, vitamin C, and iron, it may lead to nutritional deficits. Severe diets are, in general, losing favor in medical therapy, especially as a means of controlling more

cicatricial contracture just as peptic ulcer elsewhere.

The *clinical manifestations* of marginal ulcer are generally severe and are similar to those of duodenal ulcer, i.e., "gnawing" pain, anorexia, nausea, epigastric distress, and occasionally vomiting. The pain may be located to the left of the mid-line and may be associated with local tenderness at the same point. Should the marginal ulcer perforate into the free peritoneal cavity, sudden and acute manifestations are produced similar to those of a perforated duodenal ulcer, as discussed later. Perforation into the colon produces a gastrocolic fistula, the manifestations of which are less acute but nonetheless severe, and include great wasting, severe diarrhea, fecal vomiting, and bleeding, which may be severe. The ulcer may at times be associated with severe hemorrhage; hematemesis is not as common as tarry stools, but anemia may be prominent. Diagnosis is best made radiologically, but the ulcer can be thus demonstrated in only a little more than half the cases.

Treatment of a dietary nature, such as is used in duodenal ulcer, is tried, but operation in most cases becomes necessary sooner or later (34). The operations for marginal ulcer consist chiefly of excision of the stoma with closure of the opening in the stomach and the re-establishment of the original continuity of the jejunum, followed by the production of a new stoma or of subtotal gastric resection or bilateral vagotomy. In a few cases developing after a Billroth II operation, resection of the duodenal stump is indicated to remove antral mucosa which may have been left inadvertently. In certain cases, the cause of the persistent gastric hypersecretion and ulceration will be found in remarkable islet cell tumors of the pancreas which remain unnoticed because they do not produce hypoglycemia (Zollinger and Ellison, 35).

Complications of Peptic Ulcer. The three most important complications of peptic ulcer are perforation, severe hemorrhage, and obstruction. Hourglass stomach is rare and occurs, of course, only in gastric ulcer. Carcinoma development is a fourth complication, but is a problem only in gastric ulcers, being observed with extreme rarity in duodenal ulcers. The treatment of carcinoma complicating peptic ulcer is discussed elsewhere.

Perforation. Ulcers which perforate slowly into a solid viscus, such as liver or pancreas, tend to produce rather indefinite, though severe, local tenderness and pain of the latter, often going through to the back. More commonly, the perforation of duodenal ulcer is of dramatic suddenness, occurring practically only in males. The patient may have had previous digestive disturbances suggestive of ulcer, but frequently the perforation seems to be the first intimation of trouble. It rarely occurs while under treatment, whereas in untreated patients 20 per cent are said to perforate at one time or another. The pain is of excruciating severity and precipitates immediate prostration or collapse due apparently to the intensity of the pain. The patient lies on his side with his knees drawn up and will not move for fear of aggravating the pain. He often breaks out into a cold sweat and his brow and extremities may be covered with beads of perspiration. However, there is usually no other evidence of surgical shock, for the pulse and blood pressure are normal. In the occasional case with pronounced fall in blood pressure, the immediate prognosis is grave (J. D. Stewart). Vomiting commonly occurs. On abdominal examination one finds the most pronounced muscular rigidity, aptly called "boardlike." Moreover, the slightest pressure elicits exquisite pain, and the resistance of the spastic muscles cannot be overcome. It is most evident, however, over the right rectus, particularly in the epigastrium. The patient's face is anxious, but only because of pain. Laboratory examination reveals only a leukocytosis characteristic of peritoneal irritation. After a few hours, a radiograph taken in the upright position will in 80 per cent of cases reveal air under the diaphragm (pneumoperitoneum, as illustrated in Fig. 14). Differential diagnosis from other abdominal diseases is discussed elsewhere.

Treatment of perforation of an ulcer into the free peritoneal cavity represents a surgical emergency. Moreover, the mortality increases with the period elapsing between perforation and operation. If the patient is operated upon under two hours, mortality is very low; under 12 hours, slight; between

chronic gastrointestinal disease. Correction of deficiencies, particularly hypoproteinemia, dehydration, lack of vitamins C and B_1, has been found to lower operative risk tremendously.

The *results* of adequate gastric resection are excellent, as shown by a permanent restoration to health in up to 90 to 95 per cent of subjects. An important requirement is sufficient attention by the surgeon to psychosomatic factors, which he is often much more able to treat than the patient's own physician or even a psychiatrist. The most serious but rare hazard of gastric resection is recurrent ulcer, which is discussed below. The end results of gastric resection are occasionally marred by the variable incidence of annoying and sometimes persistent sequelae called "postgastrectomy" syndrome or dyspepsia or "dumping." These consist of a variety of symptoms including epigastric distress, flatulence, discomfort after meals followed by an empty feeling, faintness and asthenia, and failure to gain. It appears probable that these symptoms are due to rapid introduction of hypertonic fluid into the jejunum, with secondary withdrawal of huge volumes of water from the circulating blood (Randall, 28). There are other factors which contribute to the picture, including a faulty selection of patients for operation. Creation of a small gastroenterostomy stoma lessens the incidence of dumping (Waugh, 29). An important factor also is the tendency up until recently toward removal of too much stomach. In a 5- to 15-year study (30) in nearly 1,000 cases, the incidence of postgastrectomy disturbances increased strikingly as more and more stomach was removed, presumably to lower the incidence of recurrent ulcer, which, however, remained constant at 4.5 per cent. The over-all restoration to complete health in this series was 85 per cent. Everson (31) has conducted numerous animal and clinical observations determining the physiologic differences between the various operations on the stomach.

Much can be done to help most patients with symptoms of dumping. Hypnosis has been strikingly successful in some (Wangensteen, 32). Use of a solid diet containing largely meat, fish, and other protein and fat-containing food, but little carbohydrate, has been helpful in some hands. Free administration of salt-containing fluids, especially beer, in the few minutes before meals has also proved effective, presumably because it bolsters the blood volume sufficiently to minimize the systemic effects of withdrawal of large volumes into the duodenum (Poth, 33). Occasionally, operation to convert a gastrojejunostomy to a gastroduodenostomy will be successful in curing the dumping syndrome, as will also a revision of the anastomosis simply to delay gastric emptying (Poth). The tendency without operation is for the symptoms gradually to subside over a period of months.

Recurrent (Marginal) Ulcer. This distressing postoperative complication usually follows a gastroenterostomy, less frequently an adequate gastrectomy. Islet cell tumor of the pancreas may be responsible (see below). It is a true peptic ulcer whose formation, no doubt, is due to the persistence of a high gastric acidity because of the failure of the operation favorably to influence the secretory or neutralizing mechanism (Fig. 13). Such an ulcer may bleed, perforate, or lead to

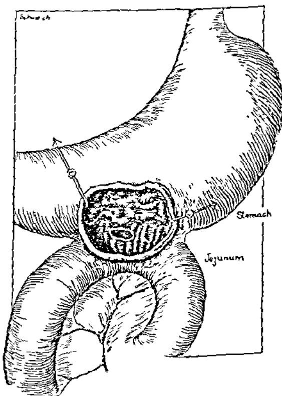

Fig. 13. Jejunal ulcer following gastroenterostomy. Ulcer is not marginal but is actually distal to the stoma and in the jejunum.

such a case, the term *massive hemorrhage* should be applied, limited, however, to patients who have lost sufficient blood (at least 1 to 2 liters) to produce an anemia of 2.5 million red cells per cu. mm. (7 grams per cent) or less, plus unmistakable signs of surgical shock, including persistent hypotension. Fatalities are, in general, limited to this category, yet really all can be prevented by adequate emergency therapy. Hemorrhage is usually evident by hematemesis, in about three fourths of the cases, but in all melena is always seen sooner or later after the bleeding.

Treatment of the mild cases presents no particular problem. Although a mild hemorrhage may produce an anemia, it does not lead to signs of shock. Threat to life is therefore practically nil, hence nearly all patients recover with or without transfusion. Massive hemorrhage, on the other hand, because of the threat to life, has always presented a difficult problem. One of the most difficult aspects of the problem is establishment of the cause of bleeding. Hemorrhagic diatheses must first be eliminated. Usually a good history and an emergency bromsulphthalein test will eliminate bleeding from esophageal varices. There remain peptic ulcer, gastritis, superficial erosions, cancer of the stomach, ulceration of leiomyoma of the stomach, and bleeding of unknown origin. Statistically, peptic ulceration is the most common of these factors. The emergency care of any patient with massive gastroduodenal hemorrhage is of great importance, regardless of the hour of the day or night; it will play a large role in determination of success. This implies thorough and repeated examination, including vital signs (temperature, blood pressure, pulse, state of consciousness, and so forth) and laboratory examinations, including hemoglobin or red cell count and, if possible, circulating red cell mass (usually by hematocrit and total blood volume determinations).

Several patterns of therapy have been recommended and have been assayed from the practical standpoint by Dennis and associates (36). In *one* the patient is transfused vigorously until out of shock or until it appears unlikely that transfusion alone will handle the shock, and subjected to operation without delay (Stewart, 37). Blood should preferably be administered until the hemoglobin level is above 10 grams per cent. The danger of transfusions is open to question, Andresen (38) being fearful, and Costello (39) not fearful if the blood is given slowly. The rate of transfusion may be fast in this pattern of management only until the blood pressure begins to approach normality.

In a *second* pattern of management (Dunphy and associates, 40), an effort is made to permit those who will do so to cease to bleed on conservative care. The thesis is that, even though the surgical mortality of those gastrectomied late after failure of conservative therapy will be higher than the surgical mortality of early cases, nevertheless so many will cease spontaneously that the over-all mortality will be lower than as if all are subjected to early operation. Rhoads (41) outlines a pattern of transfusion rates, utilizing operation at once if three units of blood fail to relieve initial shock, or if, after relief of initial shock, a slow, continuous drip of blood at the rate of one unit every eight hours fails to maintain the patient in a shock-free state.

A *third* pattern consists of extreme conservatism. This pattern was first suggested by Andresen (42), and was adopted with modifications by Meulengracht. Transfusions are feared because of the risk that the enhanced blood pressure will lead to resumption of bleeding and because of fear of loss of some clotting factors by dilution of the patient's blood with bank blood. During observation, blood is administered in amounts of 100 ml. or less, and only for air hunger or for very profound blood pressure drops, is a formula containing gelatin, milk, and added protein given at frequent intervals.

Certain factors pervade thinking in regard to management of massive gastroduodenal hemorrhage. Attention to an adequate food intake is important, particularly when the bleeding has stopped and immediate surgery is not contemplated. The empty stomach was originally assumed to be at rest, without realizing that the ulcerated stomach actually contracts much more when empty than when it contains food. Thus, starvation has harmful effects which are now well known for other reasons, although Lenhartz, as long

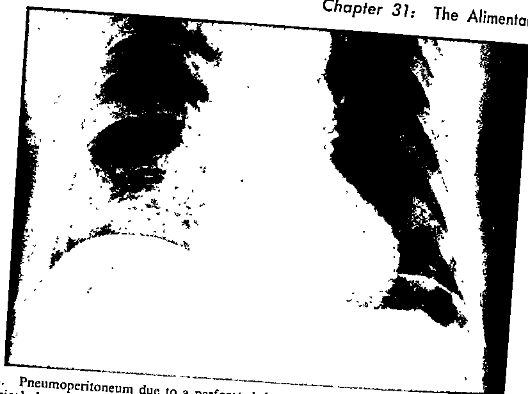

Fig. 14. Pneumoperitoneum due to a perforated duodenal ulcer. The patient, a young man aged 28, gave a typical ulcer history of several years' duration with development of severe epigastric pain six hours before admission. The x-ray reveals air under the diaphragm on each side. Operation revealed a perforation of the ulcer on the anterosuperior portion of the duodenum near the pyloric ring. Closure was effected by an omental tag. Convalescence was uneventful.

12 and 18 hours, considerable; whereas after 24 hours, the prognosis may be grave. Gastric suction and chemotherapy may therefore be justified in the late cases, but most surgeons would deny that such therapy is sufficiently safe in the early hours when the risk of operation is so low. The minimum requirement at operation is closure of the perforation. Gastric resection, however, has been carried out, and may be justified in patients with a previous gastric ulcer history, operated upon in excellent general condition within a few hours after the perforation.

HEMORRHAGE. Although hemorrhage from peptic ulcer (Fig. 15) is frequent, only seldom is it severe enough to threaten life. In

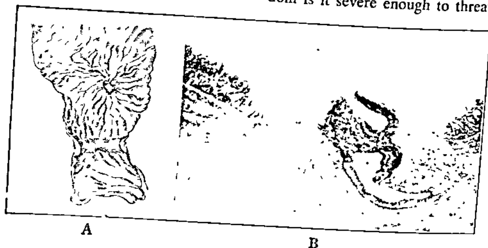

Fig. 15. Gastric ulcer leading to a fatal hemorrhage. A, the gross appearance of the specimen of stomach opened along the greater curvature. Note the "pipe-stem" artery projecting into the base of the small ulcer; B, photomicrograph showing cross-section of the artery which was responsible for the hemorrhage. Operation in this patient, a 26-year-old male, would have been the only way of controlling the bleeding from such a vessel.

passed the pylorus. Should vomiting become profuse, usual signs of water and electrolyte disturbance will occur unless losses are adequately replaced.

Treatment will depend to a considerable extent upon the degree of obstruction and how much of it is due to pylorospasm, how much to edema, and how much to actual stricture formation. Occasionally, gastric atony due to potassium deficiency simulates or is associated with gastric retention. The answer to these questions usually follows a period of careful observation and simple therapy which includes small, frequent feedings, alkali and antispasmodic drugs as indicated, and daily gastric lavage. The program is used merely as a therapeutic test. Progressive decreases in the amount of 24-hour retention indicate a favorable response, which indicates that part of the obstruction was due to edema, to spasm, or to both. Even if surgical therapy is indicated on the basis of past history, such preliminary therapy serves a useful purpose by decreasing operative difficulty through relief of edema of the gastric wall and of inflammation at the pylorus and duodenum. Should the patient be able to take an adequate diet after such therapy, the correction of some of the nutritional deficits will be almost automatic. In other cases, adequate preparation requires the parenteral replacement of water and electrolyte deficits as determined by careful history and examination of the patient. Occasionally, gastric atony due to potassium deficiency simulates or is associated with pyloric obstruction and requires the addition of potassium chloride to the parenteral fluids. In any case, with adequate preparation under these conditions, operation may be carried out with practically no risk and with a minimum of technical difficulties.

Gastric Cancer. Not only is carcinoma of the stomach common, it is also frequently "silent," producing relatively few symptoms in the early stages, during which surgical excision offers a chance of cure. Cancer, masquerading as an ulcer, as discussed already, is an exception and therefore offers a much more favorable prognosis. Of some theoretical interest are recent observations showing that certain blood groups have an influence in increasing the susceptibility to gastric cancer (46). In a large percentage of patients with gastric cancer, the disease has progressed beyond the stage of excision at the time operation is performed. This is due, of course, to the difficulty in early diagnosis, based in turn upon the fact that the symptomatology varies widely. Moreover, the more rapid the growth, the earlier the symptoms and the less favorable the prognosis, as discussed below. Cancer may occur in any portion of the stomach and, except for the fact that a peptic ulcer may be associated, may give no warning. The tumor may take the form of a surface growth which ulcerates and bleeds, or a more fungating type (Fig. 16). Others develop scirrhous characteristics. Unfortunately, the tumor often penetrates the stomach wall and metastasizes to adjacent lymph nodes and even to the liver before symptoms occur.

Cancer of the stomach should always be suspected in any individual, middle-aged or older, who develops digestive symptoms or anemia without apparent cause or precedent. These may be ever so slight, perhaps only an epigastric discomfort or anorexia; but if they persist, the patient should consult his physician, and, if the symptoms are not readily explainable, radiographic studies after a barium meal should be performed (Fig. 17). This examination will be of value only when carried out by an expert, and really constitutes our chief objective method of early diagnosis. Routine radiologic examinations of large numbers of patients have been carried out (similar to mass chest x-rays) in an attempt to detect early lesions. Unfortunately, the findings did not justify the tremendous expense and effort involved. Gastroscopic examination may be useful in some of the more doubtful cases. Less important is the examination of gastric contents which, in general, show abnormal findings only late in the disease. Anacidity, formerly considered of diagnostic value, is not always found in patients with gastric carcinoma. Moreover, normal individuals may have no acid in their gastric contents at the time of a single examination. Gastric analysis is, however, a useful screening test for cancer detection centers. Vomiting of food taken several hours previously is generally indicative of obstruction regardless of the cause; how-

ago as 1906, recommended the liberal feeding of bleeding peptic ulcer patients. Meulengracht popularized this form of therapy in 1935, following Andresen; Levy (43) extended it by adding protein hydrolysate to a mixture of milk and cream. The hydrolysate, he showed, maintains gastric anacidity much more effectively than other means, whereas the cream slowed gastric motility and seems to have a definite influence on increasing the coagulation of the blood (44).

To eliminate permanently the threat to life from a dangerously bleeding ulcer, it is considered best by most surgeons to perform gastrectomy with ligation of the bleeding point or excision of the bleeding point. The mortality of this procedure is low when the principles mentioned above have been observed. While it is true that operation is best performed during a quiescent period after an acute episode has subsided, since the mortality then can be as low as 2 per cent, operation is also reported to be relatively safe if performed early during the acute phase of bleeding, mortality rates being reported as low as 10 per cent. The factor to emphasize, however, is that operation becomes highly dangerous if carried out as a last resort, after several days of recurrent or continuous bleeding, particularly if during this period the patient has suffered continuing hypotension and/or anemia because of inadequate blood replacement. In such cases a mortality of 50 per cent has been reported by Welch (45), an experience in accord with that of the authors.

Several technical features of the operation may be mentioned. In some cases it may be difficult to find the bleeding site, but the search is aided if the operation is performed during an episode of active bleeding. Apparently in over half the cases a frank ulcer or superficial peptic erosion is the source. If no source of bleeding is found on exposure of the gastric and duodenal mucosa, a gastric resection is nevertheless usually advisable to remove difficultly recognizable tiny erosions and to control gastric acidity, either or both of which may have provoked the hemorrhage.

In a statistically controlled series of 110 cases of massive gastroduodenal hemorrhage with a circulating red cell mass below 18 grams per kilogram (normal is 30 grams per kilogram) or with a red cell count below 2.5 million per cu. mm., types 1, 2, and 3 of management, as outlined above, were found to give survival rates not statistically different from one another, although all three, after the study had been instituted, provided striking improvement over that observed prior to concentration on this problem. The extremely conservative management was accompanied by somewhat lower mortality than the operative methods, and immediate operation was slightly more effective than operation in selected cases only; a larger series is being assembled to achieve numbers of true statistical significance (Enquist).

Massive gastroduodenal hemorrhage, in summary, may be treated in any of several fashions, but, regardless of the fashion chosen, the patient must be kept under constant accurate scrutiny day and night, a factor of greater importance by far than the particular pattern of therapy chosen.

Obstruction. The history of a patient with duodenal ulcer will often reveal the development of pyloric obstruction. As long as no obstruction exists, the patient is usually relieved of symptoms after a meal or with alkali. However, as obstruction develops, vomiting becomes more prominent and less and less relief is obtained from eating or taking alkali; indeed eating usually aggravates distress after the obstruction becomes significant. The site of the obstruction is usually at the pylorus, thus may follow both gastric or duodenal ulcers located at this point. Indeed, such ulcers are often spoken of collectively as pyloric ulcers. Gastric ulcer may rarely lead to an obstruction higher up, producing what is known as an hour-glass contracture.

Pyloric obstruction is always suspected when the patient recognizes in the vomitus food eaten 24 hours or more before. The amount remaining in the stomach at intervals after a barium meal yields accurate information as to the degree of obstruction. In complete occlusion no barium will be found to leave the stomach, even after 24 hours. A simpler bedside method is first to empty the stomach by tube, then measure each 24-hour intake, empty the stomach again, and calculate by difference the amount which has

Fig. 17. Carcinoma of the stomach. The entire distal third of the stomach is deformed because of the tumor. Considerable obstruction is present as indicated by the film which was taken six hours after ingestion of the barium. At operation, the tumor was resectible, but diffuse edema of the tissues thereabouts suggested it was not curable.

nosis. Thus in the long survivals, symptoms had been present an average of 16.6 months, and the involved nodes in the specimens removed were located within 3 cm. of the tumor. By contrast, in the short survivals, the symptoms had started only 5.8 months before, and 83 per cent had involved nodes beyond 3 cm. from the tumor. Other differences were also described, but the distance between the line of resection and the tumor was not significant.

Other Gastroduodenal Lesions. *Foreign bodies in the stomach* occasionally require removal by operation, though on most occasions the foreign body is usually passed spontaneously. Even open safety pins are disposed of in this way without perforating the intestinal wall. The progress of a radiopaque foreign body may be determined by periodic x-ray examinations; however, if the object is sharp and becomes lodged for several days at some point, operation for removal is sometimes indicated, lest perforation occur (Fig. 18). Professional debris-swallowers are sometimes operated upon for the removal of glass, nails, chains, and other objects when they produce gastrointestinal symptoms. Food balls represent another type of foreign body most often developing around tough vegetable fibers, such as those in persimmons. These are called *bezoars*—if of vegetable origin, phytobezoars, and if of animal origin, usually hair, trichobezoars. Bezoars are generally discernible during radiologic examination after the barium meal, produce a variety of symptoms, including those of ul-

ever the presence of "coffee-ground" material in the vomitus is evidence of extensive ulceration and bleeding which is usually associated with gastric retention. Abdominal palpation may occasionally reveal the tumor, but only when it has reached a considerable size. Anemia and loss of weight are usually late manifestations. Often gastric carcinoma is detected first by noting occult blood in the stools.

Treatment of carcinoma of the stomach, to be curative, means radical gastric resection well beyond the pylorus into the duodenum and proximally, including excision of the greater omentum, often the spleen, and the associated lymph nodes, followed by some type of gastrointestinal anastomosis. Preoperative nutritional preparation and continuous gastric lavage to relieve edema due to obstruction are obviously necessary. The presence of metastases to the liver precludes chance of cure, unless it is single and can be excised widely. In the face of hopeless spread, palliation of obstructive symptoms may be achieved through gastrojejunostomy and thus life is prolonged for months—rarely for years—although resection even in the presence of metastases is frequently preferable because of the better symptomatic relief which follows the successful elimination of the infected bleeding tumor. Radiotherapy has been disappointing.

Linitis plastica is a special type of gastric carcinoma producing a diffuse scarring of the entire stomach, which assumes the appearance of a tough woodlike pouch, hence the name. Although total gastrectomy must be performed in order to eliminate all of the diseased tissue and permit a successful anastomosis, the end results are uniformly poor.

The long-term results of resection in gastric cancer have been disappointing and have not been appreciably improved by more radical operation, including total gastrectomy (47). While wide resection is essential, a careful study (48) of two groups of 34 cases, each with similar gross lesions, one surviving over five years and the other less than one year, show that it is the rate of growth of the tumor which is decisive in the prog-

Bezoars are generally discernible during radiologic examination after the barium meal, produce a variety of symptoms, including those of ul-

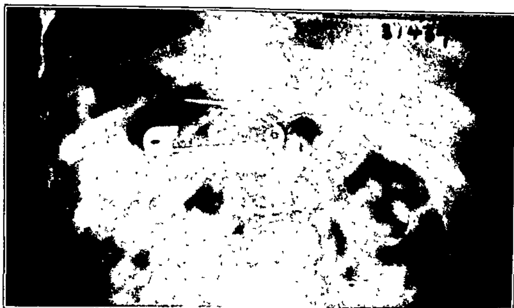

Fig. 18. Foreign body (safety pin) in the stomach. This roentgenogram was taken six days after the ingestion of the pin which first lodged in the esophagus (see Fig. 9). The pin remained at the same point during the six days, although the child, aged two years, suffered no symptoms. Laparotomy was performed and the pin removed through a gastrostomy opening; recovery was uneventful.

cer, and are usually so disabling as to demand operative removal of the foreign body by gastrotomy.

Polyps of the stomach occur and frequently are multiple. Diagnosis is made by x-ray or gastroscope in most cases. Excision by operation should probably be carried out even if the symptoms are not severe because of the danger of malignant degeneration. Occasionally, a polyp will be carried through the pylorus and produce a characteristic filling defect and symptoms simulating duodenal ulcer. The multiple adenomatous polyps seen in patients with pernicious anemia are so often a precursor of cancer as to justify excision, which may require total gastrectomy. *Leiomyoma, lipoma, carcinoid* (49), and other tumors including *aberrant pancreas*, though rare, may occur in the stomach and duodenum as they do elsewhere. The surgeon must be prepared to encounter any of them, often when least expected, since preoperative diagnosis is seldom made. *Lymphosarcoma*, when it occurs, is usually less invasive than carcinoma of the stomach, yielding better results following gastrectomy than carcinoma. Carcinoid occurs anywhere in the gastrointestinal tract and is discussed in detail elsewhere.

Syphilis of the stomach produces a thickening of the wall and a variety of mucosal ulcerations with a clinical picture and radiologic findings similar to those of cancer or peptic ulcer. The differentiation is difficult even at the time of operation, particularly since a patient with definite ulcer or carcinoma of the stomach may also have a positive Wassermann (see p. 116). Operation is nevertheless usually indicated since gastric syphilis produces symptoms due to scarring even after adequate antisyphilitic therapy.

Gastritis, as a pathologic and clinical entity, rests upon definite observations of the gastric mucosa with the flexible gastroscope. Various types have been observed and are supposed to be associated with definite clinical manifestations. Massive hemorrhages from gastritic stomachs have been frequently observed (Enquist). Otherwise, gastritis is largely of medical interest. Gastritis in the past was said to be significant in peptic ulcer, and many European observers maintain that gastritis precedes and is an etiological factor in ulcer. It is likely, however, that the gastritis is secondary to the ulceration. Phlegmonous gastritis, a rare disease, is due to extensive and severe infection of the stomach with systemic manifestations and a rapid fatal course. Treatment is palliative.

Acute dilatation of the stomach has been

discussed elsewhere. It occurs practically always as a postoperative or post-traumatic complication. The entire stomach gradually becomes more and more dilated with liquid and gas and produces more or less obvious upper abdominal distention and serious embarrassment (by pressure) to the heart and lungs. The patient is usually free from pain but vomits continuously, though in small amounts. Hiccup is often present and persistent. Diagnosis is generally easy if the condition is suspected; treatment is simple and effective. The passage of a stomach tube will yield one or more liters of stomach contents, and produces an immediate and marked improvement in the patient's local and general condition. It is usually necessary to leave the tube in place for a day or two or until external drainage from the stomach becomes insignificant. Indeed, the use of continuous gastric suction for 24 hours or more after operations will prevent the development of acute dilatation of the stomach.

Diverticulum of the duodenum is probably a congenital defect and is not infrequently noted by roentgenologists during an x-ray examination following a barium meal. The clinical significance is not great because it rarely produces symptoms and/or leads to serious disease. *Duodenitis* is a poorly understood lesion which is sometimes diagnosed only by the radiologist. *Annular pancreas* produces duodenal atresia and obstruction which often requires surgical relief, usually by gastroenterostomy.

Duodenal fistula is a rare, but distressing, postoperative complication following surgical procedures about the duodenum, stomach, and pancreas. The destructive action of the discharge from the opening on the tissues is due to the presence of active trypsin, which also produces the same changes in any high intestinal fistula. Treatment consists of drainage to the exterior and suction at the skin margin with some type of sump-pump to minimize digestion of the skin, which should be protected with a stiff ointment or powdered aluminum.

SMALL INTESTINE

Considering the great length of the small intestine (average 6.5 with a range of 3 to 8.5 meters), it is the site of relatively few surgical diseases. Polyps, adhesive bands, congenital anomalies(Fig. 19), intussusception, and postoperative adhesions, which cause intestinal obstruction, are described in Chapter 33. Cancer of the small intestine is rare. Acute infection, usually called gastroenteritis, may result from the ingestion of contaminated food and is of interest surgically only because it may be confused with acute appendicitis and lead to an ill-advised operation.

Regional Ileitis. Apparently first described by Combe and Saunders (49) in 1813, and named and brought to the attention of the medical profession by Crohn, Ginzburg, and Oppenheimer in 1932 (50), this rather remarkable granulomatous lesion, usually of the terminal ileum, is of unknown etiology. Anatomically, it consists of a subacute or chronic inflammation which leads to ulceration of the mucosa, edema, and connective tissue proliferation of the remaining portion of the wall. The diagnosis is often first made at operation, performed usually for suspected acute appendicitis. The involved ileum is found to be thicker and more boggy than normal; edema and hyperemic or cyanotic areas are noted in the serosa with visable beaded lymphatics draining into the mesentery therefrom. The mesentery is thickened and contains enlarged lymph nodes. Although usually located in the terminal ileum, there may be similar and independent ("skip") areas in other portions of the small intestine, and even in some cases in the large intestine.

The disease occurs at all ages, but usually starts in early adult life and runs an essentially chronic or intermittent course, producing symptoms for many months or longer, and then clinically subsiding, usually only to recur after an interval of apparent good health. The clinical manifestations vary considerably, but in the severe cases consist of fever, diarrhea, continuous loss of weight, and progressive anemia, thus resembling ulcerative colitis. Stenosis of the bowel may produce a typical picture of partial or complete intestinal obstruction, particularly in the later stages of the disease. Perforation of the ulceration, depending upon the rapidity with which it occurs, may rarely lead to general peritonitis, more commonly to a localized abscess, or to a persistent fecal fis-

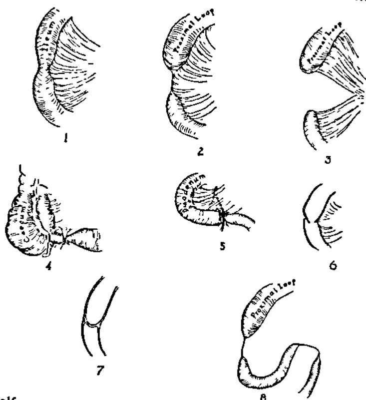

Fig. 19. Congenital malformations occurring in the small intestines. 1, stenosis with partial obstruction; 2, occlusion with blind loop; 3, blind loop with a gap in the mesentery; 4, obstruction by a fibrous band (found usually in the third part of the duodenum or the terminal ileum); 5, obstruction at the ligament of Treitz; occasionally an anomalous superior mesenteric artery is the chief factor in producing the obstruction at this particular site; 6, cross-section of intestine showing perforated diaphragm; this occurs usually in the duodenum or the terminal ileum; 7, cross-section of imperforate diaphragm, and 8, multiple occlusion of the ileum or jejunum; this constitutes about 15 per cent of the atresias of the intestine. Clinically, the dilatation of the proximal loop with collapse of the distal loop, is usually even more pronounced than shown in the illustrations. (From W. H. Cole. Arch. Surg.)

tula, either to the outside, to the vagina, urinary bladder, or the colon. Diagnosis during the chronic stage may often be made radiologically because of the characteristic findings at the site of the diseased bowel after the ingestion of a barium meal. Thickening and contraction of the gut wall typically lead to a stenotic area described on barium roentgen examination as the "string sign." However, carcinoma, tuberculosis, and actinomycosis of the cecum may produce similar manifestations and therefore must be considered in the differential diagnosis.

Treatment depends on the stage of the disease, the severity, and the presence of complications. Nonoperative therapy varies and occasionally leads to improvement of symptoms and even objective disappearance of the local and radiologic signs. Opinion is divided as to the place of operative intervention in regional ileitis. Some clinics believe medical management is indicated in cases with localized disease of short duration without complications and in cases with uncomplicated but widespread disease which might necessitate resection of too much bowel. Early surgical intervention is felt by some to decrease the chance of extension and the rate of severe complications (Dennis and Lear, 51). When medical management is employed, it may include adequate physical rest, proper nutrition, reduction of intestinal activity, correction of chemical imbalance by parenteral administration of blood, protein, and electrolytes, cortisone, psychotherapy, and antibiotics to control secondary infection. There is no evidence to indicate specific usefulness of any antibiotic for the primary disease.

After the abdomen has been opened and the nature of the disease established, closure of the abdomen without resection should be

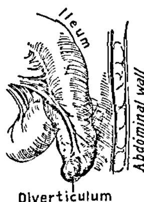

Fig. 20.

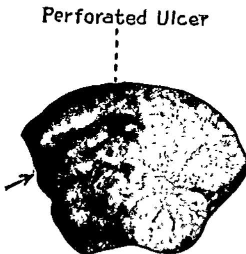

Fig. 21.

Fig. 20. The usual form of Meckel's diverticulum. Drawing of an intact specimen. Note that the proximal portion of the original vitelline duct persists, but having become closed at its end and detached from the umbilical region, it appears as a pouch hanging free from the convex border of the ileum. The omphalomesenteric vessels run up to its tip. (Redrawn from Kelly. The Vermiform Appendix, J. B. Lippincott.)

Fig. 21. Meckel's diverticulum showing a perforated peptic ulcer. Photograph showing the inside of the specimen which has been opened and laid flat. The patient was a six-year-old girl and was operated on for manifestations thought to be a general peritonitis of appendiceal origin. However, at operation the appendix was normal but there was a perforation in a Meckel's diverticulum, which was resected, the child making an uneventful recovery. The arrow points to the line of division between the ileal (above) and gastric mucosa (below), each verified by microscopic section. Note that the perforated ulcer is at the juncture of the two types of tissue. Another tiny ulcer can be seen in the middle of the aberrant gastric mucosa. (St. Louis City Hospital.)

restricted to those cases so hopelessly involved that surgical resection would be fatal. Simple short-circuiting of the diseased area once enjoyed a vogue, but has been abandoned because of the late poor results. The choice otherwise lies between exclusion of the involved segment and resection with end-to-end anastomosis. By exclusion is meant division of the gut proximal to the involved segment, closure of the end then in continuity with the involved segment, and end-to-side anastomosis of the cut end of the proximal bowel to healthy gut below the disease. Although the recurrence rate with resection is reported by some to be lower than with exclusion (Colp, 52 and Garlock, 53), the differences are not statistically significant. One series of 35 cases subjected to resection and followed up to 10 years shows a recurrence rate just under 10 per cent (Lear and Dennis, 51). The trend appears to be toward primary resection of involved areas (Crohn, 54). Truly curative therapy will be possible only when the cause of the disease has been found.

Meckel's Diverticulum. Originally described by the German anatomist, John Frederick Meckel, over a century ago, this congenital anomaly is an outpouching of the ileum about one to three feet from the ileocecal valve (Fig. 20) and in reality is a remnant of the obliterated vitelline duct of embryonic life (see p. 782). It is found in 2 per cent of individuals, and usually produces no symptoms. Associated lesions, however, may produce manifestations similar to acute appendicitis, or cause acute intestinal obstruction, or both. The diverticulum sometimes contains aberrant gastric mucosa (Fig. 21), which commonly produces a true peptic ulcer in the adjacent ileum. Such an ulcer may bleed or perforate. A band attached to it may produce intestinal obstruction or the diverticulum proper may lead to intussusception. Any or all of these complications usually occur in early childhood. Occasionally, however, Meckel's diverticulum first produces trouble in the form of acute intestinal obstruction in the later decades of life. Per-

foration produces acute, severe, abdominal pain, nausea, and vomiting not unlike peritonitis due to other causes. The correct bedside diagnosis will only rarely be made, unless one remembers to get a radiograph and finds a pneumoperitoneum. However, the acute abdominal sign will demand exploration during which the true nature of the lesion will be revealed. The peptic ulcer in Meckel's diverticulum may bleed and produce *anemia slowly*; but commonly, the bleeding is profuse, and shock follows. The ulcer may produce chronic abdominal pain of variable severity located in the right lower quadrant or about the umbilicus; a diagnosis of recurrent appendicitis is often made. When symptoms are vague or bizarre, radiography sometimes, but not always, may reveal changes suggestive of the correct diagnosis. During operations for unexplained abdominal pain the surgeon should always look for a Meckel's diverticulum.

Treatment is urgent in perforation, obstruction, or massive hemorrhage; the presence of abdominal pain, particularly if accompanied by persistent bleeding, will also justify operations in the patient with chronic manifestations, Excision of the sac with reestablishment of intestinal continuity is performed. For further details the reader is referred to a recent review of 60 cases (55).

Intestinal Fistula. Abdominal incisions which fail to heal should always be suspected of being intestinal fistulas. The diagnosis is, of course, obvious if fecal material can be recognized escaping from the wound. A direct identification of the fecal nature of drainage from the fistula is provided by a positive test for urobilinogen (Baronofsky, 56). If necessary, a colored substance, e.g., carmine, can be given by mouth; it will appear in the wound if a fistula is present. The higher the fistula, the sooner the color will appear, and the more irritated the skin about the wound will become. Most intestinal fistulas have a natural tendency to heal spontaneously. When closure does not occur within a few weeks or months, a specific cause must be established, such as one or more of the following: 1. an obstruction present distal to the fistula; 2. continuity of intestinal mucosa with the skin; 3. presence of a granulomatous infection, such as tuberculosis, actinomycosis, or regional ileitis; and 4. colloid cancer of the cecum. Indeed, these lesions may lead to spontaneous fecal fistulas.

The best *therapy* is adequate preparation by complete gastrointestinal rest, including gastric or gastrointestinal decompression if indicated, during which nutrition is maintained and deficits corrected by intravenous infusions, followed by excision of all diseased intestine, including parts of the abdominal wall if necessary with primary intestinal anastomosis and closure without drainage. Two or more staged procedures, including "exclusion" of the fistulous area, are no longer indicated as they were decades ago.

Acute Mesenteric Lymphadenitis. This condition occurs chiefly in children and is of surgical interest only because it produces abdominal pain, tenderness, nausea, and vomiting, and therefore simulates acute appendicitis. There is usually more fever than with early appendicitis, and the abdominal findings are more apt to be diffuse. The disease may follow or accompany various types of epidemic infections or of acute upper respiratory infection or poorly delineated types of enteritis. If the patient is operated upon, the appendix will be found to be normal or only slightly injected; the mesenteric lymph nodes are enlarged, often to a size 2 to 3 cm. in diameter. Microscopic section of these nodes reveals only a *diffuse* hyperplasia. Treatment is symptomatic; the abdominal manifestations usually subside spontaneously in a few days.

Typhoid fever sometimes causes perforation of the Peyer's patches in the small bowel, which, of course, represents an acute surgical emergency (p. 125). *Chronic mesenteric lymphadenitis* is usually tuberculous and is described under tuberculous peritonitis (p. 808).

THE APPENDIX

Although this small cecal appendage is the site of a few neoplasms, the most important disease of the organ is acute appendicitis.

Acute Appendicitis. Acute appendicitis is not only common, it presents many diagnostic problems, and leads to serious complications. A monograph by Boyce (57) contains valuable and detailed information and his-

torical data on the appendix. Acute appendicitis, despite the dramatic reduction in mortality in the past two decades, is still a frequent and serious surgical disease and respects no age, although it is more prone to occur in the teens and twenties. In children, it is especially serious because of the more rapid, though often atypical course, and the tendency for early perforation. In the elderly, it is also a problem diagnostically, for here again it fails to provide the typical clinical picture seen in young adults. Before the days of chemotherapy it accounted for nearly 20,000 fatalities a year in the United States alone. This high toll of life has been reduced to less than 5,000 (in 1950), despite the increased population, and can be lowered even more provided a prompt diagnosis can be made and appendectomy can be carried out in every case. Undoubtedly, the widespread use of cathartics, stimulated by ignorance and unethical advertising, is an important obstacle. Chemotherapy aimed at avoiding operation may also prevent further reduction in mortality.

The enigma of the *pathogenesis* of appendicitis has been approached from many angles. Van Zwalenberg (1904) first demonstrated that sustained intraluminal pressure in the cecal appendage of the dog leads to necrosis of the wall and ultimate perforation. Wangensteen and Bowers (58) noted that in clinical human appendicitis with gangrene or perforation there is invariably complete organic obstruction of the lumen. Laboratory studies have shown that, of the readily available animals, only the rabbit, the chimpanzee, and man have appendices which regularly secrete fluid at pressures high enough to lead to gangrene and perforation following ligation obstruction with preservation of the blood supply (Dennis, Buirge, and Wangensteen, 59). Although it has been speculated that blockage of the large blood vessels to the appendix is a factor, such blockage experimentally fails to produce the picture seen clinically. Ligation obstruction of the lumen regularly produces the clinical and pathologic findings of appendicitis in the chimpanzee, the rabbit, and man (Wangensteen and Dennis, 60; Dennis, Buirge, and Wangensteen). The precise stages in which pathologic changes develop after obstruction have been delineated in the rabbit and are parallel to those seen clinically (Dennis, Buirge, Varco and Wangensteen, 61).

The factors which lead to luminal obstruction have also been studied. The roentgen-cinematographic studies of Wildegans (62) showed the normal appendix of man to fill from and empty into the cecum every few hours. The facts that the fecaliths frequently found in association with appendicitis usually contain identifiable vegetable seeds at the centers and that a few well-studied cases of appendicitis, including those of D. P. D. Wilkie (63), who first postulated the obstructive origin of appendicitis, have been observed in which ingested bird shot have been found in the lumina—both sustain the thesis that irritation of luminal content is a factor. Swelling of the abundant lymphoid tissue within the circular musculature appears occasionally capable of production of sufficient obstruction; Bowers found in army personnel six times the incidence of appendicitis in the period after immunization injections against typhoid fever than in a control group.

The musculature of the appendiceal wall is an important factor also. A generous share of cases less severe than gangrene has been found to exhibit an elevation of measured resistance to flow through the lumen, which is obliterated by permitting the muscle to relax by the lapse of an hour after removal. The usual partial relief of symptoms seen in clinical appendicitis and the occasional abortion of an attack by administration of 0.5 ml. of adrenalin (1:1,000), which acts by marked relaxation of the circulatory musculature, also testify to the importance of this tissue (Dennis, 64).

Summarization of observations indicates that, initially, irritation of the appendiceal wall by material entering from the cecum leads to a localized area of inflammatory reaction and secondary mucosal edema and muscular contracture. Pressure rises distally from continued secretion of fluid at 3 to 4 ml. per day in a space normally less than 0.1 ml. Secretion continues until the muscular component of the obstruction is overcome or relaxed by the degree of inflammatory reaction, and empyting into the cecum occurs. Subsequent bouts occur, but residual fibrosis from preceding attacks renders spontaneous

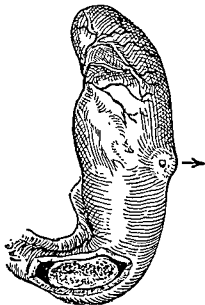

Fig. 22. Gross specimen of an acutely inflamed, perforated appendix, removed eighteen hours after the onset of acute abdominal pain. Note the fecalith impacted at the base of the rather short appendix, producing an acute obstruction to the lumen, and the tense swollen part distal to it in the middle of which is the site of perforation indicated by the arrow.

decompression progressively less likely until ultimately complete organic obstruction results in gangrene and perforation.

An attempt to evaluate this thesis, made by interview of 150 patients with gangrene or perforation of the appendix, shows that 83 per cent of them gave histories of previous bouts, and more than half of these of bouts of progressively increasing severity until gangrene or perforation occurred.

In the occasional case found to have complete organic obstruction without gangrene or perforation, the mucosa is fragmented and thin, and apparently the response to previous attacks has been mucosal destruction alone without full-thickness gangrene. In these cases, the mucosa recovers in one to three weeks, again to cause trouble.

In review of the clinical implications, pressure rise secondary to continued secretion in the face of luminal obstruction (e.g., fecalith, as shown in Fig. 22) appears conclusively to lead to ischemic necrosis of the mucosa and secondary invasion by whatever bacteria happen at the moment to be in the lumen. The experiment of ligation obstruction of the lumen in the rabbit shows well-developing changes of ischemic necrosis at three to four hours, at which time no febrile or leukocytic response has occurred and no pathologic infiltration into the appendiceal wall is yet fully developed. The initial pain, tenderness, nausea and vomiting, and even apparently localization to the right lower quadrant, can be induced in man under local anesthesia. It is possible, therefore, that the very alert physician may suspect and diagnose acute appendicitis by these historical and laboratory items and localized right lower quadrant tenderness in advance of fever and leukocytosis, and possibly even before development of pathologic changes which can be found by examination of the removed appendix.

Clinical Manifestations. Abdominal pain, nausea and vomiting, and tenderness in the right lower quadrant are the three chief abdominal manifestations which should lead the patient or doctor to suspect acute appendicitis. The *pain* is often characteristic, starting in the epigastrium or generalized at first, but soon shifting to the region of McBurney's point, which in adults is 2 inches from the anterior superior spine of the ilium on a line drawn from this process to the umbilicus. The pain is only moderately severe but disabling, often inducing the patient to seek bed rest. Great variations occur, depending on many factors, including the location of the appendix, which may be retrocecal, extend over the brim of the pelvis, or upward toward the umbilicus. In gangrenous appendicitis, pain may be slight or absent. On the other hand, if the appendix lies along the ureter or near the base of the urinary bladder, the pain will radiate into the testicle or thigh and it may produce pain on urination. Such variations, though exceptional, will influence the severity, nature, and location of the pain. *Vomiting* is an important symptom and characteristically is *preceded by pain* and nausea. It may occur but once or twice, or be completely absent, particularly in the early stage of the disease, though nausea is usually present. Provoked pain, usually called tenderness (see below), localized to the acutely inflamed organ, is undoubtedly the most valuable single sign of acute appendicitis because it is the most frequent and least variable.

Abdominal tenderness may be observed by the patient because of the pressure exerted by his clothes. He frequently prefers to lie with his thighs and knees flexed because of relief of pain afforded by this position. Abdominal tenderness is most evident when the appendix is free in the peritoneal cavity. Careful, thorough examination will, in most cases, suggest the location of the inflamed appendix by finding the site of maximum tenderness. Palpation will also elicit *muscle spasm*, the degree of which varies roughly with the severity of the infection and becomes generalized only when the appendix has perforated and general peritonitis has started. It must be remembered that, at times, acute appendicitis may actually progress to perforation without muscle spasm, particularly if the appendix is surrounded by adhesions or other organs or is retrocecal. When the appendix is retrocecal, tenderness may be slight or elicited only on deep palpation, but tenderness posteriorly may be significant. At times, localized right lower quadrant tenderness will be elicited only with the patient in the prone position, the examiner's hands being placed underneath the abdomen. Rebound tenderness, i.e., on sudden release of palpation, should be noted when present, for it may be found in the absence of muscle spasm or ordinary tenderness. The pressure of palpation in the left lower quadrant often produces pain in the right lower quadrant (*Rovsing sign*). On many occasions, *rectal examination* will reveal definite tenderness when the appendix lies along the posterior wall or over the edge of the pelvis. Rectal examination is essential in every suspected case of appendicitis, for in some, right tenderness may be the only objective physical finding (Harold Neuhof).

Leukocytosis usually appears shortly after the onset and is often progressive (12,000 to 18,000 per cu. mm.). Even when the count is normal, a differential will usually show an abnormally high percentage of polymorphonuclear forms. Although the pulse rate and temperature will usually rise sooner or later in the course of acute appendicitis, the physician *should not wait for fever* before he makes a diagnosis of acute appendicitis. Constipation is usually present. Diarrhea is *not* a part of the usual clinical picture in acute appendicitis unless provoked by ill-advised catharsis. Diarrhea may accompany appendicitis when the appendix lies along the anterior rectal wall. In such a case, localized exquisite tenderness may be felt on careful rectal examination. Acute appendicitis may also occur during a siege of diarrhea as a complication of acute enteritis which, on rare instances, becomes an instigating factor in the production of acute appendiceal inflammation. The history of diarrhea *preceding* the pain of acute appendicitis is usually characteristic.

Acute appendicitis during pregnancy deserves special mention because of the high mortality which follows perforation in a pregnant woman. Operation is therefore more urgently indicated. Local tenderness is important and is often a guide to the site of incision, since the appendix is normally displaced upward by the enlarging uterus.

Later manifestations are due to the complications already mentioned, i.e., local or general peritonitis (see Ch. 32, and below). The pain was formerly thought to diminish after perforation, but in a review of 150 patients with gangrenous or ruptured appendices only six had such a decrease in pain, a proportion smaller than seen in those without perforation. Vomiting, however, recurs and persists as more peritoneal surface becomes involved, and local tenderness spreads. *Fever* is a delayed manifestation of infection, being significant only at the time of or following perforation (except in children in whom it occurs earlier); it is therefore *not* necessary in the establishment of an early diagnosis. It is unfortunately true that many practitioners wait for fever before making a definite diagnosis of appendicitis and therefore get these patients to the hospital only after local or general peritonitis is present.

Differential Diagnosis. Since early appendectomy is the universal treatment, the only problem in acute appendicitis is early diagnosis. Unfortunately, many diseases simulate acute appendicitis. In a few, operation is contraindicated and if performed may lead to a fatal outcome. Thus, the surgeon is often confronted by a Scylla and Charybdis, a dilemma which, in some cases, may tax the most experienced and careful observer. The type of pain is important in establishing a di-

agnosis of acute appendicitis; elimination of this disease, diagnostically, is often made difficult by exaggeration or inaccuracy in the patient's description of pain. Vomiting is likewise important, especially because in appendicitis it rarely occurs *except when preceded by pain. Local tenderness usually associated with muscle spasm* is undoubtedly the most valuable manifestation, particularly when elicited by careful and expert abdominal palpation, the importance of which cannot be overemphasized. In the following discussion, three groups of conditions will be described, each capable of simulating acute appendicitis, but differing, sometimes decisively, in the eventual outcome should a mistake in diagnosis and therapy be made.

1. Of the various specific diseases which *simulate acute appendicitis,* one may, to some extent, dismiss those for which *operation is indicated.* These include perforated ulcer, intestinal obstruction, twisted ovarian cyst, perforation of a viscus, as well as many other similar surgical conditions. Since abdominal exploration is necessary in all of them, an erroneous diagnosis will not jeopardize the patient unless the actual lesion is not recognized at operation.

2. Most important are the diseases in which *operation is contraindicated* because of the threat to life posed by the operation. In this group are lobar pneumonia, acute nephritis, idiopathic (primary) peritonitis, coronary disease, and amebic dysentery.

In *lobar pneumonia* the pain may be referred to the abdomen when the diaphragmatic pleura is involved. However, the abdominal signs are absent or confined to the upper abdomen; the patient has a rapid respiratory rate; there is dilatation of the nasal alae and sometimes slight cyanosis. Chest examination in early pneumonia may reveal few signs, and roentgenograms may prove negative. With care and observation for several hours, differentiation should not be difficult.

In *acute nephritis* there may be vomiting and abdominal tenderness with rigidity of diffuse character. The presence of abnormal urinary findings (albumin, casts, blood) and evidence of renal insufficiency (high blood urea and nonprotein nitrogen) are characteristic.

Idiopathic peritonitis produces diffuse abdominal signs and is described on page 806. However, with the preoperative and postoperative use of chemotherapy the mistake of operation in this disease is of little danger as compared to the hazard in the days before chemotherapy.

Coronary thrombosis and occlusion not infrequently produce abdominal pain which, however, is located in the epigastrium and ordinarily is confused with perforated ulcer, biliary colic, and acute pancreatitis. The presence of dyspnea, orthopnea, and cyanosis indicates cardiac rather than abdominal disease.

Amebic dysentery produces acute, diffuse, cramplike pain with mucus, pus, and blood in the stool, and diarrhea. Amebas can usually be found in the stool. Atypical cases simulate appendicitis and, if erroneously operated upon, are associated with a high mortality.

3. In the final group *operation is not indicated* but is, at least, associated with little risk. These conditions comprise the following: fecal stasis (constipation), spastic colitis, acute enteritis, gastric crises (tabes dorsalis), rupture of a Graafian follicle, acute pyelitis, acute right-sided salpingitis, intestinal allergy, acute epididymitis, ureteral stone (renal colic), and abdominal wall pain. Thorough physical and laboratory examination is usually all that is needed to make the diagnosis. Thus it will exclude *pyelitis* (pus cells and bacteria in the urine) and *gastric crises* (absent knee kicks, Argyll-Robertson pupils, and so forth).

In *fecal stasis* the pain is slight, there are no signs of peritoneal inflammation; rectal examination may reveal sphincter spasm and fecal impaction. An effectual enema usually affords relief.

In *spastic colitis* there may be a history of mucus in the stool associated with constipation, perhaps with occasional attacks of diarrhea. A spastic cecum may be palpated.

In *acute enteritis* the history of eating spoiled food or of a dietary indiscretion may or may not be obtained; diarrhea is always present and the pain is diffuse and cramplike in character and does not tend to localize.

In *acute mesenteric lymphadenitis* the abdominal signs are marked but not localized.

There may be rigidity and severe tenderness almost as great as that found in perforated ulcers, but the signs are diffuse and are usually equal on the two sides. The disease is present only in children and is usually associated with a red, inflamed throat, fever, leukocytosis, prostration, and vomiting (see also p. 799).

In *rupture of a Graafian follicle* the pain, while severe, is of short duration with only transient local tenderness; its occurrence during ovulation is suggestive.

Patients with *salpingitis* due to the gonococcus usually give a history of vaginal discharge and urethritis (frequency and pain on urination). The facial appearance of these patients, even when the pulse is high and temperature is elevated, is characteristic, because it lacks the pained, anxious expression, and they do not appear so ill as do patients with acute appendicitis. The local signs are lower in the abdomen and pelvic examination usually reveals the nature of the lesion.

The pain accompanying *intestinal allergy* may be severe, but local signs in the right lower quadrant are usually not present; the differential blood count may show an eosinophilia.

Acute epididymitis may simulate the local signs of acute appendicitis when the inflammation extends up into the vas and seminal vesicle, and pain is referred up into the abdomen; examination of the testicle, however, is all that is necessary to detect the origin of the symptoms.

In *renal colic*, differentiation may be difficult or impossible although the pain is usually much more severe and colicky in nature and ordinarily radiates along the ureter and down one thigh or into the perineum. Blood may be found in the urine, and an x-ray may reveal a stone. When the appendix lies along the right ureter, however, it may, when inflamed, produce the same pain as a stone and even lead to hematuria. The local signs and leukocytosis serve to differentiate it from stone.

Abdominal wall pain is nearly always aggravated by movement of the spine and is often associated with obvious evidence of acute sacroiliac or lumbosacral sprain. Palpation of the abdominal muscles between the fingers often enables the examiner to localize the tenderness to the muscles. Abdominal wall pain is frequent and often a source of confusion unless it is kept in mind (Carnet, 65).

There are many other diseases which, on rare occasions, offer difficulty in differential diagnosis, such as Meckel's diverticulitis, tuberculosis of the cecum, regional ileitis, carcinoma of the colon, cholecystitis, and acute interstitial pancreatitis, all of which are discussed elsewhere.

As in other diseases certainty is often impossible in the differential diagnosis of acute appendicitis. Therefore, the surgeon must recognize and face the possibility and consequences of a mistaken diagnosis. Two kinds of mistakes may be made: (1) the surgeon may operate and find no surgical lesion, or (2) he may fail to operate and find that the patient has developed a peritonitis from perforation of an acutely inflamed appendix which he has failed to diagnose. In weighing the relative seriousness of these two mistakes, he thinks of the following considerations. First, the mistake of operating when no surgical lesion is present is harmful only if the patient is actually suffering from one of the diseases mentioned in the second group just discussed, such as pneumonia, coronary disease, nephritis, and amebic dysentery. If they can be excluded, the mistake is less serious because recovery practically always occurs. Careful study has shown that in the best hands such a mistake is made in about 10 to 20 per cent of appendectomies performed for suspected acute appendicitis. On the other hand, to fail to operate on a patient with acute appendicitis is clearly a serious mistake for reasons already mentioned. It is largely of the danger of peritonitis that most surgeons, when confronted by a difficult problem in differential diagnosis, will obviously prefer to make the lesser of the two mistakes discussed above.

TREATMENT. As stated by William Osler in his textbook of medicine, first published in 1902: "There is no medical treatment for acute appendicitis." Unfortunately, errors are still common and are probably responsible for the still excessive and unnecessary mortality in this disease. Catharsis pyramids the risk, not by alteration of the disease process in the appendix but by inducing sufficient

intestinal activity to prevent "walling-off" of the inflammatory process by adhesions of bowel and omentum (Dennis, Buirge, Varco, and Wangensteen, 61). In many cases, such dangerous treatment is self-inflicted; sad to relate, physicians are sometimes guilty. Often a cathartic is prescribed over the telephone. A drug clerk frequently advises it in order to sell some medicine. It is fortunate, however, that nature remedies the error in many cases by inducing immediate vomiting with consequent ejection of the cathartic. Nevertheless, the mortality records of acute ruptured appendicitis are filled with instances of unnecessary sacrifices to the great American practice of purgation. Many observers have recorded such evidence; Keyes (66), for example, found that the mortality of acute appendicitis in patients receiving cathartics was eight times greater than in those not receiving such medication. The rule should be emphasized that *laxative drugs are contraindicated in the presence of abdominal pain.* If a bowel movement is desired, an enema or a glycerin suppository will achieve a result with little or no danger, even if acute appendicitis is present.

A second dangerous form of treatment is the *indiscriminate use of morphia* to allay abdominal pain. This is unfortunately practiced by many careless physicians who make no diagnosis and who do not perform an adequate abdominal examination. The changes leading to perforation and peritonitis go on while the patient is blissfully sleeping with the aid of the magic hypodermic. But on awakening he may no longer have acute appendicitis—he may have a severe general peritonitis. Such a rapid progress is especially apt to occur in children.

A third and recently increasing yet potentially harmful trend is for physicians to use *chemotherapy for undiagnosed abdominal pain.* This may be disastrous if the patient is suffering from acute appendicitis, for there is no way of being sure that perforation is completely avoided thereby. Indeed, the antibiotics often mask symptoms of inflammation and increase the difficulty of diagnosis until the peritonitis is too far advanced to help by appendectomy.

The *safest treatment* for acute appendicitis is, therefore, an immediate and properly performed appendectomy. The mortality following operation before perforation is practically nil. Spontaneous subsidence, as already mentioned, frequently occurs, but can seldom be predicted unless the patient is seen at a time when he is obviously recovering from the acute attack and is clearly improving as shown by the history and examination. Appendectomy in such cases may still be indicated, but only as a prophylactic measure, especially if there have been previous attacks. The diagnosis in such a case is *recurrent appendicitis* and the operation is called an interval appendectomy.

COMPLICATIONS OF ACUTE APPENDICITIS. The complications of acute appendicitis vary with the degree and type of peritoneal infection which follows perforation or gangrene. Although a general discussion of peritonitis is found in Chapter 32, the special features of appendiceal peritonitis are described as follows.

General peritonitis, when well developed, offers no difficulty in diagnosis and usually follows neglect or mistreatment. On the other hand, the early manifestations after perforation, beginning with the first invasion of the peritoneum, are slight and, indeed, may be accompanied by a transient diminution in pain and local signs. As the infection gains a foothold, however, it may localize and form an abscess, which is discussed separately. If the infection spreads, the abdominal and systemic manifestations gradually or rapidly increase. In the full-blown case the patient becomes extremely ill or prostrated, "toxic," dehydrated, and distended. The various gradations in the degree of invasion are often referred to as local, spreading, or general peritonitis, a classification which is, however, often difficult at the bedside and even at the time of operation. After removal of the perforated or gangrenous appendix, the infection subsides, although residual abscesses may form later (see below).

In the past, the mortality has been high in severe and well-developed general peritonitis of appendiceal origin. Because of this, surgical opinion and practice were divided. One group claimed that the mortality could be lowered by removing the cause of the peritonitis by prompt operation despite the risk of the procedure in a seriously ill patient.

The other group maintained that more patients would survive by not operating and relying upon spontaneous localization. This difference has tended to disappear since the advent of chemotherapy. In any case, all surgeons would agree on the use of gastric decompression and chemotherapy and the replacement of deficits by parenteral infusions. Most surgeons, however, would operate promptly, using such measures merely as preoperative preparation. The present authors approve of and practice this policy in contrast to the older one of adopting a nonoperative program based upon the belief or expectation that localization and eventual subsidence of the infection will occur.

Modern combined chemotherapy has actually strengthened the advantages of early operation because, by reducing the operative risk even in those with severe septicemia, it has supported the principle of removing perforated lesions as soon as possible after the diagnosis is made. This principle is based on the well-known ability of the peritoneal cavity to resist rather severe bacterial invasion provided the source of the contamination is removed. If the source is not removed, the repeated contamination may be more than the peritoneum can withstand. While it is true that localization around a perforated or gangrenous appendix frequently occurs, it is difficult to be sure that it is actually taking place. The danger of spreading the infection by operation has been greatly exaggerated and, in any case, much reduced or eliminated by effective combined chemotherapy. It should be emphasized, however, that chemotherapy should be started before the operation so that the tissues will be well saturated with the agents when the anesthesia is given. At the St. Louis Children's Hospital only one child has died following prompt operation for appendiceal peritonitis since the use of combined chemotherapy. In that case, death one week after appendectomy was due to a Friedlander's bacillus pneumonia; at autopsy the peritoneum was clear. Unfortunately, newer antibiotics effective against this organism, now available, were unknown at that time.

Drainage of the area of appendiceal infection or of an actual abscess without appendectomy is undesirable but occasionally is done because of an extreme degree of inflammation. In practice, too, it is the rare case, indeed, in which the cause of the infection cannot be found, the damaged or necrotic appendix removed, and the stump closed. Drainage will thus seldom be necessary except when an abscess wall is present or when the cecal wall is badly inflamed and might perforate.

Appendiceal abscess is suspected when a definite mass is found on admission with a history suggesting an attack of acute appendicitis. Such a history may date back for weeks or a month or more, the mass having been present for this length of time. Under such circumstances, a differential diagnosis between an abscess and a neoplasm may be difficult but may be aided by radiologic study with a barium meal. In most cases, however, the history is shorter and the local findings of acute inflammation indicate that the mass is actually of appendiceal origin.

Treatment should be based upon the fundamental principles of prompt operation, as mentioned above, although the urgency may not be as acute as that existing in the treatment of abscesses in general (67), because the mass may be produced by indurated omentum surrounding an unperforated appendix. Even though nonoperative therapy for many weeks may lead to disappearance of the abscess, permitting an interval appendectomy later, the delay involved usually means a much longer period of convalescence than would be the case with prompt operation.

Residual abscesses, since the advent of chemotherapy, are much less common, but are suspected in patients in whom fever fails to subside in a few days, or recurs after it has returned to normal, usually within the first week or ten days. The various sites of such residual abscesses are illustrated in Chapter 32, Figure 5. In most cases of appendiceal infection, however, the most frequent location is in the pelvis. Clinical detection is relatively easy if the surgeon will remember to do frequent rectal examinations. A bulging cul-de-sac into the anterior wall of the rectum, accompanied by localized tenderness and induration, is diagnostic. Such abscesses usually rupture spontaneously into the rectum with complete relief. If this does not occur promptly and the abscess by palpa-

intestinal activity to prevent walling-off of the inflammatory process by adhesions of bowel and omentum (Dennis, Buirge, Varco, and Wangensteen, 61). In many cases, such dangerous treatment is self-inflicted; sad to relate, physicians are sometimes guilty. Often a cathartic is prescribed over the telephone. A drug clerk frequently advises it in order to sell some medicine. It is fortunate, however, that nature remedies the error in many cases by inducing immediate vomiting with consequent ejection of the cathartic. Nevertheless, the mortality records of acute *ruptured appendicitis* are filled with instances of unnecessary sacrifices to the great American practice of purgation. Many observers have recorded such evidence; Keyes (66), for example, found that the mortality of acute appendicitis in patients receiving cathartics was eight times greater than in those not receiving such medication. The rule should be emphasized that *laxative drugs are contraindicated in the presence of abdominal pain.* If a bowel movement is desired, an enema or a glycerin suppository will achieve a result with little or no danger, even if acute appendicitis is present.

A second dangerous form of treatment is the *indiscriminate use of morphia* to allay abdominal pain. This is unfortunately practiced by many careless physicians who make no diagnosis and who do not perform an adequate abdominal examination. The changes leading to perforation and peritonitis go on while the patient is blissfully sleeping with the aid of the magic hypodermic. But on awakening he may no longer have acute appendicitis—he may have a severe general peritonitis. Such a rapid progress is especially apt to occur in children.

A third and recently increasing yet potentially harmful trend is for physicians to use *chemotherapy for undiagnosed abdominal pain.* This may be disastrous if the patient is suffering from acute appendicitis, for there is no way of being sure that perforation is completely avoided thereby. Indeed, the antibiotics often mask symptoms of inflammation and increase the difficulty of diagnosis until the peritonitis is too far advanced to help by appendectomy.

The *safest treatment* for acute appendicitis is, therefore, an immediate and properly performed appendectomy. The mortality following operation before perforation is practically nil. Spontaneous subsidence, as already mentioned, frequently occurs, but can seldom be predicted unless the patient is seen at a time when he is obviously recovering from the acute attack and is clearly improving as shown by the history and examination. Appendectomy in such cases may still be indicated, but only as a prophylactic measure, especially if there have been previous attacks. The diagnosis in such a case is *recurrent appendicitis* and the operation is called an interval appendectomy.

COMPLICATIONS OF ACUTE APPENDICITIS. The complications of acute appendicitis vary with the degree and type of peritoneal infection which follows perforation or gangrene. Although a general discussion of peritonitis is found in Chapter 32, the special features of appendiceal peritonitis are described as follows.

General peritonitis, when well developed, offers no difficulty in diagnosis and usually follows neglect or mistreatment. On the other hand, the early manifestations after perforation, beginning with the first invasion of the peritoneum, are slight and, indeed, may be accompanied by a transient diminution in pain and local signs. As the infection gains a foothold, however, it may localize and form an abscess, which is discussed separately. If the infection spreads, the abdominal and systemic manifestations gradually or rapidly increase. In the full-blown case the patient becomes extremely ill or prostrated, "toxic," dehydrated, and distended. The various gradations in the degree of invasion are often referred to as local, spreading, or general peritonitis, a classification which is, however, often difficult at the bedside and even at the time of operation. After removal of the perforated or gangrenous appendix, the infection subsides, although residual abscesses may form later (see below).

In the past, the mortality has been high in severe and well-developed general peritonitis of appendiceal origin. Because of this, surgical opinion and practice were divided. One group claimed that the mortality could be lowered by removing the cause of the peritonitis by prompt operation despite the risk of the procedure in a seriously ill patient.

Fig. 24. Chronic appendicitis. Note the bands of adhesions and the kink in the appendix, produced by inflammatory scar. These fibrous bands are not to be confused with congenital bands which are due to anomalies in the development of the appendix and cecum. In many instances the past history is the only method of differentiation. In this case there was a history of several severe attacks due definitely to acute appendicitis which subsided.

velops. The relief of symptoms after appendectomy is common in these cases. It is the best proof of the above-mentioned pathogenesis.

"Chronic" Appendicitis. Aside from recurrent appendicitis and appendiceal colic, there remain a few patients in whom a diagnosis of chronic appendicitis may be justified. This designation in the past has been common, often based, however, on insufficient clinical evidence and after appendectomy on little or no pathologic change in the organ, and with no relief of symptoms, often, indeed, by an exaggeration thereof.

The *pathology* of "chronic" appendicitis is ill-defined except for the presence of fecaliths and peritoneal adhesions. Manometric determination of the pressure required to push fluid through the appendix and into the cecum commonly, in these cases, shows the resistance to flow to be higher than the upper limit of normal (30 cm.) and may be diagnostic in the absence of microscopically observable inflammatory reaction (Dennis, 1941). The presence of inflammatory scar, usually called adhesions (Fig. 24), as well as local *obliteration of the lumen* from previous infection, is often definite and is probably contributory to the obstruction responsible for symptoms. Lymphoid hyperplasia has also been described. In these cases, the surgeon may occasionally discover small tumors in the appendix, as described on page 760. Pinworms (Oxyuris vermicularis) are sometimes found in the appendiceal lumen and may have been responsible for symptoms. In rare instances, small foreign bodies are found.

Clinical Manifestations. The usual *clinical picture described as chronic appendicitis* consists merely of a discomfort of a persistent sort located in the right lower quadrant. The pain is chronic in character and may vary in degree with a variety of circumstances. The surgeon should, if possible, examine the patient during an exacerbation of the pain with the idea of eliciting local tenderness which may be of aid in localizing the source of the pain. Otherwise, in most instances abdominal examination will be negative. In some patients, the manifestations will be similar to those produced by duodenal ulcer, including epigastric distress *with tenderness, sour eructations*, and relief of pain by food. Since radiologic study reveals no evidence of duodenal ulcer, pylorospasm may perhaps be the factor responsible for the clinical symptoms. In many cases, these patients are young women and girls who suffer from chronic fecal stasis (constipation), or spastic colitis, or pelvic disease. In others, the pain may be a manifestation of lumbosacral sprain or psychogenic. These

tion is soft and fluctuant, it may be opened by an incision. When the location of a residual abscess cannot be determined accurately and the general condition of the patient is not improving, exploration may be justified and should be carried out preferably through an abdominal approach. Prompt timing in association with well-selected chemotherapy is important.

Wound infection may occur after operation for perforated appendicitis, particularly if the abdominal incision has been closed without drainage. Careful toilet of the contaminated wound by isolation of the wound edges with heavy gauze pads and irrigation with saline will minimize this complication. Diagnosis and treatment are the same as other postoperative wound infections, as discussed in Chapter 14. *Subdiaphragmatic abscess* sometimes occurs but is usually late; it should be suspected whenever the patient's temperature has returned to normal but recurs. The detection and diagnosis are discussed in detail on page 803. *Fecal fistula* is rare and suspected only when the drainage following operation for perforated appendicitis is necessary because of involvement of the cecal wall in the infection. Healing usually occurs eventually, particularly if there is no obstruction, as shown by the presence of normal bowel movements.

Sinus formation may be produced by any one of several factors including a foreign body, usually a fecalith, in the depths of the wound, or the presence of an unsuspected disease, such as actinomycosis, regional ileitis, colloid carcinoma of the cecum, or tuberculosis. The sinus must, of course, be differentiated from fecal fistula. *Pylephlebitis* is now practically nonexistent since the advent of chemotherapy. It is suspected when the patient develops a chill and high fever early in the disease (as discussed elsewhere). *Intestinal obstruction* is discussed in detail in Chapter 33. *Paralytic ileus* is really a normal phenomenon after operation for perforated appendicitis, in the presence of general peritonitis. After removal of the perforated appendix, however, the symptoms usually disappear.

APPENDICEAL COLIC. The onset of appendiceal colic is the same as that of acute appendicitis inasmuch as the pain is due to

Fig. 23. Gross specimen of an appendix, bisected, showing numerous fecaliths, which produced appendiceal colic. The patient, a 16-year-old girl had had many attacks of right lower quadrant pain, short in duration but severe and becoming so frequent as to produce serious disability. Complete relief followed appendectomy.

appendicular obstruction, usually caused by a fecalith which occludes the lumen (Fig. 23) with a resultant distention and hyperperistalsis. Although the pain is severe, it is transient and is rarely accompanied by vomiting and only occasionally by nausea. Attacks are frequently characterized by severe pain of a duration of a minute or two followed by a few minutes' relief, the pain alternating between the right and left lower quadrants; this diagnostic observation has been confirmed experimentally by deliberate placement of bird shot in the lumen of an appendix made available by appendicostomy (Dennis, 1941). Repeated attacks lasting from a few minutes to a few hours, leaving as rapidly as they come, may eventually, however, cause disability in themselves. Moreover, they always create a threat that at any time a total obstruction will follow and lead to inflammation and acute appendicitis. Fecaliths may be demonstrable in the appendix by radiography after a barium meal or an enema, but there is no proof that they have etiological significance. Appendectomy in appendiceal colic is curative, provided the diagnosis is correct, but is not urgent unless evidence of acute appendicular obstruction followed by inflammation de-

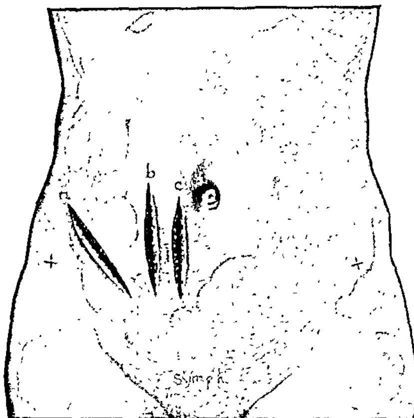

Fig. 25. Three types of incisions commonly used in operations for appendicitis. A, the McBurney, or gridiron (muscle splitting) incision. B, pararectus incision, the rectus muscle is split longitudinally instead of being retracted. C, paramedian incision, retracting the muscle laterally; this is used particularly when the diagnosis is uncertain, *since it affords better exposure than a McBurney incision.* (Schweich, after Brödel.)

of pelvic or upper abdominal structures through a McBurney incision, and it is difficult to locate an abnormally placed appendix in this way. The *perforated appendix should* be located and eliminated; this implies adequate exposure. Only rarely, if ever, will the exploration necessary to do so be too great to justify drainage alone. Careful exploration is also necessary to locate and remove fecaliths, which, if overlooked, may cause failure in healing of the abdominal wound. In no domain of surgery are gentleness and care more necessary than in the operative therapy of perforated appendicitis. *Abdominal packs* should be used with great care and gentleness because they traumatize intestinal loops and tend to spread infection, besides encroaching on the abdominal opening. Contamination is also minimized by removing pus as soon as encountered, with a suction apparatus if possible. Postoperative complications, particularly intestinal obstruction, may, in general, be minimized or completely avoided by an adequate incision and gentle *handling of the peritoneum and intraabdominal viscera.*

The question of drainage in operations for acute appendicitis must be decided at the time of operation. The principles upon which drainage is based was emphasized years ago by Yates. A drain is used, in general, because the surgeon wishes to create and maintain an open wound so that any excessive infection or source of contamination may reach the outside rather than become enclosed in the depths of the wound and thus lead to the danger of a local abscess or of a spreading peritonitis. *A drain is not needed* when the appendix is not ruptured. If a local peritonitis or an abscess is present some surgeons feel safer with the area exteriorized with drainage. In severe cases, drainage may

possible conditions should always be suspected as the cause of the abdominal symptoms.

TREATMENT. Careful clinical study has shown that relief of symptoms has been consistently achieved by appendectomy in those patients in whom the resistance to flow through the appendix into the cecum has been elevated. Relief has frequently not been achieved by appendectomy in this entire group of patients, including many in whom the disease process has not been so meticulously demonstrated to be genuinely in the appendix. In some of this latter group, the pain may even be magnified after the patient leaves the hospital. Careful selection of cases for appendectomy leads to relief of symptoms in three fourths of the cases and thus justifies the diagnosis of chronic appendicitis. The operation, however, should be carried out through a rectus incision, particularly if the patient is a female, so that an adequate abdominal exploration can be done at the same time to detect other possible lesions which may be of clinical significance.

Operations for Appendicitis. Until the part played by the inflamed appendix was discovered, operations for acute appendicitis were performed only for complications. Incision and drainage was carried out for what was clinically called "phlegmon of the abdominal wall" or "right iliac abscess." Because many physicians thought that the suppuration originated in the cecum, a frequent diagnosis was typhilitis or perityphilitis. In many instances, of course, general peritonitis occurred and the attending physician would note no localizing process in the right lower quadrant, and the death certificate in such patients usually carried the diagnosis of "acute indigestion." Needless to say, the mortality was exceedingly high, even when an abscess was opened and drained.

In 1886, a physician, Reginald Fitz (68), after a study of many autopsies, described his findings as "perforating inflammation of the vermiform appendix with special reference to early diagnosis and treatment." This report, along with others in other countries, played an important part in the development of the modern operation of appendectomy in acute appendicitis. Although many previous observers, notably Addison and Bright, as early as 1838, suggested the relation between appendicular infection and "iliac abscess" and general peritonitis, the teachings and observations of Fitz, who was primarily an internist and pathologist and not a surgeon, had a tremendous influence in clarifying the subject, in this country at least, and pointing to the importance of early appendectomy. Surgeons were quick to recognize the importance of these observations, and before the end of the century, many patients' lives were saved by adequate operation. Among others who have contributed to the knowledge of this disease, the names of Charles McBurney, Albert J. Ochsner, and J. B. Murphy should be especially mentioned. Nevertheless, it is true at the present time that failure to perform an appendectomy in acute appendicitis, especially before perforation has occurred, is still the most common yet avoidable cause of the considerable mortality in this disease.

Either of two types of incision is generally used in entering the abdomen for operation in appendicitis (Fig. 25). The McBurney incision is located over the McBurney point, is small and utilizes only the separation of the oblique and transversalis muscles in approaching the peritoneal cavity. Because the fibers of these muscle layers cross each other, this approach is often called the gridiron incision. It has the advantage of requiring less dissection of the abdominal wall, but the disadvantage of permitting only a limited exposure of or access to the peritoneal cavity. The greatest use of it is in the removal of the acutely inflamed appendix which is known to lie in normal position.

When the diagnosis is uncertain, preferably and widely employed is the low right rectus (low right median) incision, in which the right rectus muscle is split longitudinally (separated from its sheath medially) and retracted laterally. This incision may be extended as much as necessary and permits adequate exposure, thus requiring a minimum of intraperitoneal trauma. In "chronic" appendicitis, this incision is particularly indicated since it permits inspection and palpation of the other abdominal viscera. Exploration should be an essential part of the operation if there is even the slightest doubt as to the appendicular origin of the patient's pain. It is practically impossible to gain any information

bowel movements is usually important, especially if there has been a sudden change. In certain cases, delayed motility can be assumed if the patient notices increasing difficulty in passing stool, relieved only by the use of cathartics. Accurate measurements of colonic motility, however, can be made only by special methods, including the use of the x-ray.

Just as important as the motility of the colon is the character of the stool, the consistency, the color, the shape and particularly the appearance of gross blood. Many patients are entirely unaware of such changes because they do not or cannot inspect the stool after defecation. In such cases, negative statements are obviously of no value. On the other hand, accurate observation as to alterations in the appearance of the stool may, in many cases, prove of considerable diagnostic value. For example, tarry stools in the absence of medication, such as iron, may be an indication of bleeding high in the alimentary tract. Fresh blood obviously indicates an ulcerative lesion, benign or malignant, in the distal portion of the colon, although occasionally in the presence of extreme hypermotility such blood may originate from the duodenum. Many disturbances may produce melena, the differential diagnosis of which has been ably discussed by Gray and associates (70), based upon extensive clinical experiments of many types of cases. Acholic stools, particularly when the patient has not ingested a great deal of milk, is evidence of obstructive jaundice. Hard, marblelike feces, or narrow ribbonlike feces are usually associated with spasm of the colon, only rarely by a narrowing of the lumen. Frequent liquid stools, often referred to as diarrhea, may be due to extracolonic causes, but are often a manifestation of inflammatory, neoplastic, or functional disease in the colon. Mucus and pus are found in ulcerative disease, both inflammatory and neoplastic. Mucus alone may be present in purely functional disease, notably spastic colitis. Parasites of various types may be noted grossly, but microscopic search of the feces for their larvae will be a more accurate method. This is particularly true of amebiasis, proper facilities for the examination of which with a warm stage microscope should be available to all physicians. It is essential to this examination that the stool be freshly passed (one hour maximum).

Disease of the colon produces pain which is rarely specific in nature and occurs both in medical and in acute surgical diseases. The colon is well supplied with autonomic nerve fibers which may carry impulses of pain, of a poorly localized type. The pain may be referred to the anterior portion of the abdomen or to the back. The abundance of autonomic innervation may also explain the frequency of functional diseases which masquerade as organic lesions of the colon, and make the problem of diagnosis and treatment especially difficult.

Physical examination of the abdomen is obviously important in the diagnosis of diseases of the colon but is frequently of limited value. Although the transverse colon, cecum, and sigmoid are the most accessible to palpation and may reveal masses due to carcinoma, tenderness due to acute inflammation, or a hard tubular sensation characteristic of spastic colitis, very often the examination is entirely negative. It is because of inadequacies in the usual history and physical examination that special examinations are essential in the diagnosis of disease of the cecum and colon. The sigmoidoscope, which enables direct vision of the distal part of the colon, is described later in this chapter. It should be used routinely in the diagnostic study of gastrointestinal disease. More important, however, is the expert fluoroscopic and radiologic study of the cecum and colon after a barium meal ingested some hours before or with a barium enema. More recently, air contrast barium enemas have been added to the radiologic examination, and may reveal diseases not possible with the ordinary routine, particularly when carried out by experts. As mentioned above, laboratory examination of a fresh specimen of feces may be of great diagnostic value.

Chronic Constipation. Fecal stasis, or a delay in colonic motility is a more descriptive term than constipation and should be based upon other evidence than the mere statement of the patient himself. The frequency of bowel movements is, of course, the most important clinical evidence thereof, particularly if the patient has such difficulty

persist for two to three weeks. Occasionally, a fecal fistula follows operation for perforated appendicitis; in such instances, the fistula usually closes spontaneously unless an associated obstruction is present distal to the opening in the intestine.

Combined chemotherapy, though discussed elsewhere under the treatment of peritoneal infections, is mentioned here also because it has greatly reduced the indications for drainage. Unless there is a likelihood of fecal leakage or there is extensive irremovable necrotic tissue, most surgeons do not employ drainage, for it tends to increase the length of hospitalization. There is no evidence that the incidence of residual abscesses is reduced by drainage. As already mentioned, chemotherapy has also greatly reduced mortality and postoperative complications in patients with peritonitis. The use of a combination of bactericidal drugs, such as penicillin and streptomycin, gives a much greater antibacterial coverage than one alone, which is important because of the frequency of mixed infections in the severe cases. It is now a frequent experience for patients seriously ill with peritonitis from a perforated appendix to enjoy a relatively uneventful postoperative course following appendectomy.

Tumors of the Appendix. Tumors of the appendix are rare and are found usually at the time of operation carried out for chronic appendicitis or as an incidental appendectomy performed during the course of other abdominal operation, notably cholecystectomy. Carcinoid tumors of the appendix are apparent grossly as a slight to moderate enlargement of the organ which is firm in consistency. Carcinoid tumors may occur in all parts of the gastrointestinal tract, and may be malignant, although those located in the appendix are usually benign. A recent study contains many details and a review (49). Metastases in the malignant cases are usually referred to as carcinoidosis, and may be detected clinically by the appearance of diarrhea and periodic "flushing" of the skin, and by finding an increased output of serotonin (5-hydroxyindol acetic acid) in the urine (69). *Mucocele* is due to chronic low grade obstruction and is not a true neoplastic process; it is not infrequent and may be a rare cause of chronic appendiceal pain. Sympathetic *neuroma* in the appendix has been described in Chapter 27. True *carcinoma* of the appendix is likewise infrequent and may or may not produce specific clinical manifestations, dependent upon the rapidity of growth and involvement of the cecum. Either carcinoid or carcinoma, if located proximally in the appendix, may obstruct the lumen and lead thereby to acute appendicitis.

THE CECUM AND COLON

The large intestine is generally subdivided into two regional groups, the colon (including the cecum), which is discussed under the above heading and the rectum (including the anus), which is considered separately. The cecum and colon are the sites of a number of surgical diseases, the most serious of which is carcinoma. There are diseases which are best treated without operation and which simulate those requiring surgical intervention. Differential diagnosis is important and often difficult. Although abdominal pain is a frequent manifestation of colonic disease, it is often insufficiently characteristic to be of differential value. More frequent manifestations are due to alterations in the character and nature of the stool. This information, as well as knowledge of the character of the feces is an important part of the diagnostic data. Too often, in obtaining a routine history, this information is inaccurately or incompletely obtained or carelessly overlooked entirely.

Evidence of delay in colonic motility is of surgical importance in that changes in bowel habits from normal to constipation may be indicative of increasing obstruction. Such a delay is often unaccompanied by pain until the obstruction is complete. Even then the acute pain is seldom as severe as that encountered in obstruction of the small intestine. Details of intestinal obstruction in the colon are described in Chapter 33.

Changes in function of the large bowel are usually indicated by a change in the motility of the colon and are usually described rather poorly by the patient as either constipation or diarrhea, terms which may be misleading and really should not be used without a more exact and detailed description of what they mean. A statement as to the *frequency* of

In slightly more than half the cases diarrhea, usually of a very serious degree, develops almost simultaneously. The stools are voluminous and watery. Shock with a drop in blood pressure is common. Fever is present in most cases. Culture reveals a micrococcus pyogenesis in most cases, and frequently almost in pure culture. This floral change is presumably caused by a previous or current use of antibiotics. The chief pathologic feature is a pseudomembranous lesion associated with other evidence of severe bacterial inflammation. Sensitization tests should be made on the micrococcus and the indicated antibiotics given, although much more effective is the use of enemas of a suspension of fecal material.

Polyps. Most common in the sigmoid and rectum, these pedunculated tumors, really *adenomas*, are either single or multiple; when present in large numbers, the condition is referred to as polyposis. Polyps may give rise to bleeding, diarrhea, and abdominal pain. Diagnosis may be made by radiography following a barium enema, especially with the air contrast technic. If situated in the rectum or lower sigmoid, they may be directly visualized with a proctoscope or sigmoidoscope. Since they have a definite tendency to undergo malignant degeneration, excision and careful follow-up are necessary. Rectal polyps may be removed through a proctoscope, whereas those higher up will require an abdominal operation after adequate preparation of the colon. Segmental resection of the colon including the polyp is definitely indicated should the polyp show a broad base or gross evidence of malignancy. After removal of the polyp, the rest of the colon should be examined for other polyps. This will be aided by inspection of as much of the interior of the colon as possible with a sterile proctoscope.

Multiple polyposis may occur as an inherited disease which has a high incidence of malignant degeneration even early in life (Fig. 26). For this reason it is usually advisable to resect the colon as soon as the diagnosis is made in order to prevent the malignant transformation (78). In such cases, the rectum may be preserved providing all the polyps are removed through proctoscopy at the time and during subsequent repeated observations (79). Removal of the rectum, however, may be necessary when this is not possible, or when the polyps in the rectum are too numerous. Even then, anastomosis between the ileum and anus may be performed, and will preclude the need for a permanent ileostomy (75).

Carcinoma of the Colon. Carcinoma of the colon and rectum accounts for over one tenth of all deaths due to malignant disease. The neoplasm is usually an adenocarcinoma and may be either a bulky, fungating growth, filling the lumen of the bowel, or scirrhous in type, encircling the wall in the form of an annular stricture. Colloid carcinoma, though rare, also occurs, particularly in the cecum, and is prone to perforation and abscess formation. Metastases occur by way of the lymphatics to the mesenteric lymph nodes and by way of the portal vein to the liver or beyond the liver to the systemic circulation, involving lung, bones, brain, and other tissues. The tumor grows at any point in the colon, but increases in frequency as one proceeds from the cecum, being most common in the sigmoid and rectosigmoid portions.

Clinical manifestations will vary with the location of the tumor and the rapidity of growth. Right-side tumors tend to produce bleeding and anemia, weight loss, and a palpable mass. Pain often occurs and is sometimes mistaken for acute appendicitis, for which appendectomy is occasionally undertaken. In exploration for supposed appendicitis in which the appendix appears normal at operation, therefore, the surgeon must examine the colon for tumor in the course of his search for the cause of trouble. In the left colon, the diameter of the bowel is much smaller and the content is regularly more firm; cancer here is therefore more likely to lead to obstruction. Obstruction may be manifested by gradually increasing meteorism and difficulty at stool, or may appear abruptly and full-blown with few or no antecedent manifestations.

Early in the disease, symptoms may be limited to evidence of ulceration or low grade obstruction, which should always arouse a suspicion of cancer in an individual of middle or older age. Early evidence of ulceration is the appearance of blood and mucus in the stools, or of frequent liquid stools; early evidence of obstruction consists of increasing

as to require the use of cathartics. As mentioned above, this condition is of diagnostic significance in surgical diseases, at least when it appears suddenly without warning in an individual who has previously had normal bowel habits. It is such a common condition that the surgeon should acquaint himself with some of the features and the therapy.

Spasm or atony of the colon may be the cause of fecal stasis; the terms *spastic constipation* and *atonic constipation* are applied to these conditions. Spastic constipation must be recognized by the surgeon lest the associated pain lead him to the erroneous diagnosis of a surgical lesion.

Tuberculosis. About half of all intestinal tuberculosis is said to occur in the cecum. Over one third of all patients with pulmonary tuberculosis are believed to have demonstrable lesions in the alimentary tract. Most patients with tuberculosis of the colon also have an active lesion in the lung. Of great import surgically is tuberculous ulceration of the cecum, a lesion accompanied by annular ulceration and secondarily by fibrous thickening of the wall, producing symptoms and signs which may at first be indistinguishable from those provoked by carcinoma. Fortunately, tuberculosis of the gastrointestinal tract is becoming a rare condition, along with the gradual disappearance of other forms of tuberculosis.

Abdominal pain, diarrhea, and blood in the stool are the chief manifestations. In the early cases, pain is the only symptom, which may simulate mild appendicitis, and lead to an operation. The surgeon in such a case should be a good enough gross pathologist to recognize the true nature of the disease. In other untreated cases, stenosis will ensue, which may be sufficient to produce a partial obstruction.

Diagnosis is readily made roentgenologically with the aid of a barium meal and/or enema. The deformity noted by x-ray may be identical with that produced by carcinoma, but the extreme irritability of the cecum is often characteristic. Pulmonary tuberculosis should always be looked for. Operation for removal of the lesion may be indicated if severe symptoms are present. Medical therapy, especially with streptomycin and associated drugs, is preferable.

Ulcerative Colitis. This disease is a definite pathologic and clinical entity of unknown etiology. It may initially produce abdominal pain which simulates acute appendicitis, but later the history of chronicity, the presence of diarrhea, blood, and mucus in the stool should eliminate any difficulty in the differentiation. On the other hand, it may be confused with the manifestations of carcinoma. Very important in the differentiation is expert radiologic and proctoscopic study. Treatment is a medical problem, at least at the onset, and includes attention to dietary and psychogenic factors (71). Unfortunately, some cases do not respond to medical therapy and develop complications or recur so frequently that surgical intervention is indicated.

Surgical therapy is being used more and more because of the increase in the number of cases which do not respond to medical therapy, the danger of cancer, and the development of complications such as cirrhosis and arthritis (72), in the persistent cases, and especially because radical surgery has become safe, often lifesaving, and frequently yields dramatic restoration of the patient to relatively normal life even with a permanent ileostomy (73, 74). Complete proctectomy and colectomy is the safest and most effective procedure to employ and is often possible in one stage. An ileostomy may be avoided in some cases by a staged procedure ending with an anastomosis between the ileum and the anus (75), or the rectum may be preserved with anastomosis of ileum to it. Both these procedures carry a higher risk of death and of unsatisfactory functional result than proctocolectomy does. Total colectomy is usually an elective procedure, but may be urgently needed as an emergency in the face of acute perforation or of fulminating toxicity not responsive to medical means. Segmental ulcerative colitis, which may be related to regional enteritis, has also been described and may rarely respond to less extensive operation (76).

Pseudomembranous Colitis. This is an uncommon but serious disease of the colon occuring almost always after operations in the abdominal cavity. In almost half the cases (77) the operation has been performed for carcinoma of the colon. Cramping abdominal pain, nausea, vomiting, and distention are the most common early symptoms.

Fig. 27 Carcinoma of the colon. Note the characteristic filling defect adjacent to the hepatic flexure following a barium enema. The x-ray was particularly helpful in this case inasmuch as the history of abdominal symptoms was vague, consisting merely of anorexia, moderate loss of weight and slight upper abdominal tenderness. At operation the tumor was found and a resection of the colon performed (see Fig. 28) in two stages according to the Mikulicz technic. 10 years have elapsed since operation and the patient, now 67 years old, is well, asymptomatic and carries out her duties as housewife.

colostomy and to postpone resection and anastomosis for the second stage. During resection, care is necessary to avoid manual massage of the tumor, which has been shown (80) to dislodge malignant cells into the lumen of the bowel with possible implantation into the suture line, and into the portal stream to be carried to the liver. Wide excision with ligation of the vein and artery to the excised segment as the first step will ensure against leaving cancer cells. Further details, including the results of surgical therapy, will be found in several reports (81, 82, 83).

Diverticulitis. Diverticula in the colon are common after 45 years of age and are usually diagnosed during routine radiologic examination with barium as multiple rounded shadows (diverticulosis). Occasionally, they become inflamed and produce symptoms of diverticulitis (pain, cramps, diarrhea) which are usually mild and transient. Serious manifestations are due to perforation, obstruction, or bleeding. The clinical picture of acute diverticulitis may be that of acute appendicitis located in the left instead of the right lower quadrant because the diverticula are nearly always located in the sigmoid colon. The inflamed diverticula may perforate into the peritoneal cavity and produce a local peritonitis or abscess. Bleeding per rectum or signs of colonic obstruction and other manifestations will simulate carcinoma (84).

Treatment of acute diverticulitis depends upon the complications produced. If an acute perforation has occurred with signs of spreading peritonitis, operation will be necessary. The procedure to be followed is clo-

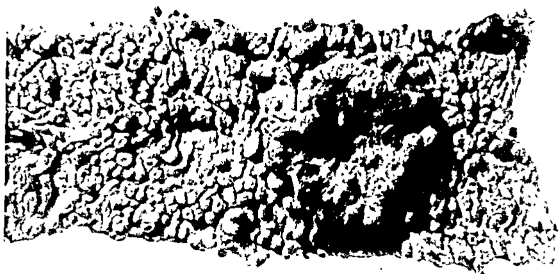

Fig. 26. Multiple polyposis of the colon. In this patient, a male aged 32, there was a history of frequent stools for many years; during the past six months they had been mixed with blood. Examination of the resected specimen reveals an ulcerating carcinoma which presumably started in one of the polyps.

difficulty in regular defacation and attacks of cramping abdominal pain. Frequently, periods of obstructive and ulcerative symptoms alternate. Such manifestations, unless explainable in some other way, call for *investigation of the colon* by radiologic means. Diagnosis in this way may frequently be achieved early in the disease (Figs. 27, 28). In tumors of the distal colon and rectum, direct visualization with a sigmoidoscope is usually possible, and a biopsy may be obtained for histologic verification.

Loss of weight, acute intestinal obstruction, and severe anemia sometimes, but not always, mean an advanced lesion and unfortunately are occasionally the first clinical indication of disease. Usually, however, a period of weeks or months of lesser symptoms precede them, and it is during the earlier period that diagnosis should be made in order to institute hopeful therapy. It cannot be emphasized too strongly that change, sudden or insidious, in the pattern of gastrointestinal behavior of a patient past 40 years of age should demand a careful study for cancer of the colon, rectum, or stomach.

Treatment is wide resection of the tumor, together with the adjacent mesenteric lymph nodes. This is most safely done after adequate preparation, which includes chemotherapy. If there is no obstruction, the tumor may be excised and a primary anastomosis performed at one stage. In the presence of obstruction in the right colon, aseptic operative decompression, primary resection of terminal ileum, cecum, and colon to the midportion or left portion of the transverse colon, together with all possible mesentery and omentum, is the procedure of choice. Primary end-to-end anastomosis is in order. In the presence of obstruction in the left colon it is safer to perform a preliminary

Wide excision with ligation of the vein and artery to the excised segment as the first step will ensure against leaving cancer cells. Further details, including the results of surgical therapy, will be found in several reports (81, 82, 83).

Diverticulitis. Diverticula in the colon are common after 45 years of age and are usually diagnosed during routine radiologic examination with barium as multiple rounded shadows (diverticulosis). Occasionally, they become inflamed and produce symptoms of diverticulitis (pain, cramps, diarrhea) which are usually mild and transient. Serious manifestations are due to perforation, obstruction, or bleeding. The clinical picture of acute diverticulitis may be that of acute appendicitis located in the left instead of the right lower quadrant because the diverticula are nearly always located in the sigmoid colon. The inflamed diverticula may perforate into the peritoneal cavity and produce a local peritonitis or abscess. Bleeding per rectum or signs of colonic obstruction and other manifestations will simulate carcinoma (84).

Treatment of acute diverticulitis depends upon the complications produced. If an acute perforation has occurred with signs of spreading peritonitis, operation will be necessary. The procedure to be followed is clo-

Fig. 28. Carcinoma of the colon. Gross and microscopic appearance of resected specimen in the case described in Fig. 27. The rectangular area at the edge of the ulcer represents a block of tissue which was removed for microscopic section; note how it includes normal as well as diseased tissue. The photomicrograph shows clearly the difference between the normal epithelium of the colon (at the top) and the malignant tissue, i.e., adenocarcinoma (below).

sure of the perforation with a "patch" of omentum, inasmuch as it is usually difficult to close it, aided by colostomy to relieve the obstruction in the colon which is usually associated with the inflammation at the site of perforation. A transverse colostomy is also indicated if operation is performed for acute obstruction without perforation or for the drainage of an abscess. In such a case, the differentiation from carcinoma will be difficult (84) but obviously important because of the difference in further therapy. The subsequent use of the x-ray following a barium enema will often be helpful. In most cases of diverticulitis the obstruction subsides; however, resection is indicated when carcinoma is suspected or when a fistula persists. Large abscesses resulting from perforation require drainage. Occasionally, perforation occurs slowly into adjacent organs and leads to a fistula into the bladder, cervix, or vagina. In such cases, too, resection preceded by colostomy will be the procedure of choice. The various surgical implications of diverticulitis have been well described by Allen (85).

The lesser and more chronic types of diverticulitis may produce pain and diarrhea and, in occasional cases, bleeding. The diagnosis is usually made after careful study by radiography and occasionally by sigmoidoscopy. In most cases medical care is sufficient, but resection may be required in the persistent cases. Welch's studies show that difficulty with diverticulitis before the age of 45 or 50

is followed by rapidly increasing troubles and that early elective resection is the prudent therapy.

Miscellaneous Diseases of the Colon. In the older literature, much attention was paid to the condition known as visceroptosis. The term refers really to an abnormal mobility due to a long mesentery. For this reason, when the patient stands, his viscera tend to drop toward the pelvis. It is doubtful whether this condition produces significant symptoms, although the redundant and mobile sigmoid may be responsible for the development of volvulus with signs of acute strangulation as discussed in Chapter 33. Operations for the correction of visceroptosis are no longer performed; the condition is generally considered to be normal for certain hyposthenic types of individuals.

Actinomycosis of the colon occurs really in the cecum and has a distinct propensity to produce symptoms similar to any of the ulcerative lesions already mentioned, including perforation. Actinomycosis, however, has a tendency to produce a chronic mass and multiple fistulous openings to other viscera or to the outside. The diagnosis is made by finding the ray fungus in a freshly opened abscess (see p. 109). In the past, treatment was unsatisfactory in the late stages, but now, if an early diagnosis is made, incision and drainage of the abscess, or excision of diseased tissue, combined with chemotherapy (e.g., sulfadiazine and *heavy* doses of penicillin), and radiotherapy, is usually effective.

Foreign bodies may become lodged in the colon after ingestion, although most of them will be passed in the stool. Should passage become arrested, which is most frequent in the hepatic or splenic flexures, symptoms of mild obstruction may follow. More commonly, if the object is sharp, a slow perforation may lead to the production of localized peritonitis, followed usually by an abscess. Occasionally, abscesses adjacent to and attached to the colon are encountered at operation when no primary source can be found. Preoperative diagnosis is usually appendiceal abscess or abscess due to diverticulitis. Should a foreign body be located at the time of operation, the cause is obvious. Drainage may be followed by a chronic sinus or intestinal fistula, which may require subsequent therapy. Although the swallowed foreign body is usually a toothpick or sharp bone, a history of swallowing it is seldom obtained.

Megacolon has been discussed on page 650.

Congenital anomalies are extremely rare and consist of stenosis or atresia. They are usually associated with similar lesions in the small intestine, as discussed in Chapter 33.

RECTUM AND ANUS

Carcinoma is the most serious disease of the terminal large bowel; hemorrhoids and inflammatory lesions, such as proctitis, cryptitis, ischiorectal abscess and fistula-in-ano, are the most frequent, and are important because they often cause serious disability.

Despite the frequency and seriousness of diseases of the anorectal region, they suffer more from neglect than any other group of lesions. Common inflammatory lesions are responsible for considerable loss of time at the office, the shop, and in the home. Carcinoma, which is so readily diagnosed, is frequently seen only in the late stages of the disease when hope of curative surgical therapy is greatly reduced. Many patients suffering from rectal diseases visit the pharmacist for relief. In no other field of disease has the charlatan and the purveyor of quack remedies so exploited the public.

The members of the medical profession themselves are almost entirely to blame for this situation, first because they have only recently accorded adequate attention in the medical curriculum to study and teaching of anorectal diseases. Moreover, the practitioner himself has been responsible because of his failure adequately and thoroughly to examine this part of the body either during the routine physical examination or even when the patient presents symptoms referable to this area. Although the rectal cavity is really just as accessible to inspection and palpation as the oral cavity or vagina, few physicians carry an anoscope in their bags or even maintain one in their offices, even though they are well supplied with vaginal specula, not to mention, of course, tongue depressors, auroscopes, stethoscopes, and even opthalmoscopes. The easiest and simplest method of making a diagnosis of rectal

cancer is with the palpating finger, yet rectal examination is often neglected even during an otherwise thorough physical examination.

Methods of Examination and Diagnosis. Inspection of the anus and rectal palpation with the gloved finger should be part of every routine physical examination. In addition, every patient complaining of anorectal symptoms should be given a more complete local examination, in addition, of course, to a complete history, which alone may lead to the diagnosis.

In the history of a patient suspected of anorectal disease, the following questions are especially important. 1. Is there, or has there been any change in bowel habit, such as a definitely increasing constipation or persistent tendency to diarrhea? 2. If the patient has inspected the stool, has he noted blood or blood-tinged mucus from the rectum, or has he noted blood on the toilet paper? 3. Has the patient had persistent pain in the perineum or in the anus either during or after defecation? 4. Has pus ever been noted on inspection of the stool? 5. Has the patient ever noted a protrusion or external swelling, and if so, is it permanent or does it reduce spontaneously, or can it be reduced after each bowel movement? The anorectal area should be suspected in pain referred to the posterior perineum and coccyx.

Simple inspection of the anus after gently spreading the buttocks apart will frequently reveal a fissure, an external thrombosed pile, or the opening of a fistula or a pointing ischiorectal abscess. Digital examination is next, but may be impossible or postponed if there is severe anal spasm or exquisite tenderness. No digital examination is made without a rubber glove for the protection of the physician himself. The finger cot is an inadequate safeguard in patients with syphilitic or other infectious anorectal diseases.

The best position for anal and rectal examination is with the patient lying on the left side, or still better, in the prone knee-chest position. Good illumination is essential. The well-lubricated gloved finger is gently pressed against the anal opening and painful points, if present, detected by palpation at regular intervals around the periphery of the anus. The posterior commissure is the most frequent site of painful lesions. The patient should be assured that the examination will be gentle, and that it will be terminated on the slightest indication of pain. By such reassurance and *extreme gentleness,* contraction of the anus can be readily overcome and the examining finger introduced without further difficulty. This is often aided by asking the patient to strain. The tone of the muscle is first noted. The healthy sphincter which relaxes under digital examination and fails to contract over the finger, tiring rapidly into a state of relaxation, suggests a diagnosis of tabes dorsalis, syphilis of the central nervous system, or tumor of the spinal cord. The prostate is next examined and the size and consistency noted. In the female, the firmness and movability of the cervix uteri and other pelvic organs may be observed. In virgins and in children, the rectal finger aided by the abdominal hand permits excellent bimanual pelvic examination. The coccyx too should be examined during a rectal examination, palpating it between the two index fingers, one in the rectum and one over the coccyx. The examining finger then measures the mobility of the rectal mucosa, the size of the rectal ampulla, and the possibility of stricture, polyps, growths, foreign bodies, and impaction, as well as the general consistency of the stool. It should be emphasized that fully half of all carcinomas involving the rectum can be diagnosed by the examining finger.

Anoscopy is an indispensable part of the examination in anorectal disease (Fig. 29). Although in some cases, bowel preparation is necessary, in most instances this is not needed. Should vision be obscured by feces, removal by enema or catharsis will be indicated. The anoscope is an instrument used for the examination of the lower part of the rectum and anal region. It is a hollow metal tube 1.5 to 3 inches long and 0.75 inch in diameter, carrying an obturator with a tapering end which renders introduction easier. The examination, if carried out gently, should cause only slight discomfort. Once introduced, the obturator is withdrawn and with the patient in the knee-chest position, the internal viscera have a tendency to drop forward so that the inrushing air dilates the rectum, allowing one to visualize the interior well up toward the upper limits of the rectal

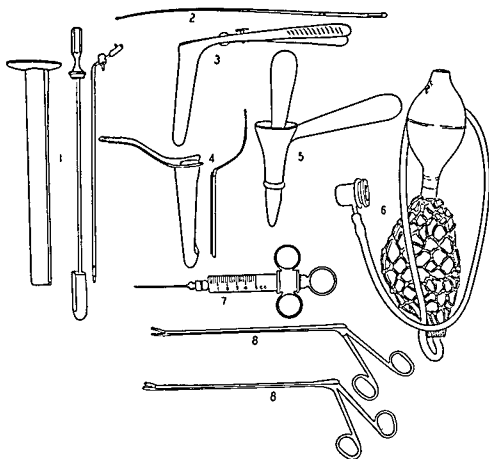

Fig. 29. Instruments ordinarily used in performing a complete anoscopic and proctoscopic examination. 1, proctoscope. 2, flexible probe. 3, bivalve dilating speculum. 4, speculum (Brinkerhoff). 5, anoscope. 6, air dilator and eyepiece for proctoscope; this apparatus is important in the introduction of the proctoscope (see text). 7, syringe and needle for injection of internal hemorrhoids; the needle should be of small caliber. 8, biopsy forceps for removal of tissue through the proctoscope.

ampulla. Carcinoma as well as benign polyps or other low-lying growths can in this way be seen and even biopsied. The lumen of a low rectal stricture can also be seen. Hemorrhoids cannot be seen until the anoscope is withdrawn to the anorectal line. With the sphincter thus dilated, aided by slight straining by the patient, internal piles quickly prolapse into the lumen of the anoscope and frequently drop outside the anal sphincter as the instrument is withdrawn. A careful inspection through the anoscope under direct light may reveal the internal opening of rectal fistulas and diseased rectal crypts, enlarged rectal papilla, and all the various conditions, including fissure, in the anorectal area. The anoscope should really be part of the instrumentarium of every physician. Failure to use it is the most important cause of errors in the diagnosis of anorectal lesions.

Visualization and inspection of the upper rectum and sigmoid requires a longer apparatus provided with a light. The proctosigmoidoscope is a hollow metal tube from 9 to 10 inches in length, provided with a tapering obturator to aid passage through the anal sphincter. It is provided with an air pressure device to dilate the rectum and sigmoid, which aids in the passage of the instrument under direct visualization and in the better observation of the interior of the bowel. The proctoscope is a safe instrument when properly used, but may be dangerous when carelessly used. Every physician should be trained in the use of this instrument and should learn certain simple rules to eliminate

any danger from the procedure. He should learn a definite routine to assure discovery of all lesions that might be found by proctoscopy. It is highly important to place the patient in the knee-chest position or on a modified table that permits the body to recline face down with the chest fairly dependent. The proctoscope should first be thoroughly lubricated, warmed to body temperature and introducted just past the sphincter muscle, at which point the obturator is withdrawn. Here, under direct illumination, the first observation is made. The lens or eyepiece is then applied and air is introduced until the ampulla is dilated. The instrument is now introduced further under direct vision. This method is safe and should be used in contrast to any blind introduction which carries a hazard of perforation. With wide-sweeping circles the instrument is swung around to examine the mucosa of the entire bowel upward as far as possible. Each rectal fold, of which there are several, called the valves of Houston, should be carefully flattened and examined. With experience, not only can the rectal mucosa be examined, but much of the sigmoid beyond the rectosigmoid junction as well.

The proctoscope permits direct vision in most cases of carcinoma involving the rectum and sigmoid up to 25 cm. from the anus. A biopsy can usually be taken of suspicious lesions containing a sufficient amount of tissue for microscopic diagnosis. In the case of rectal ulcers, the proctoscope permits direct vision and scrapings and swabbings which may lead to the diagnosis of amebic dysentery, even when the stool examination has proved negative, or to identified specific bacteria. Should no cause for blood or mucus noted in the ampulla of the rectum be found, the lesion responsible for this finding must be sought by radiologic examination.

Hemorrhoids. Hemorrhoids, usually called "piles," are probably the most common of all anal disease. Two types are recognized, each quite different in pathogenesis and clinical manifestations, although sometimes associated. External hemorrhoids consist of a bit of redundant skin usually covering a mass of veins not unlike a hemangioma. Internal hemorrhoids (Figs. 30, 31) are usually present in the internal anal canal and may not be evident except during defecation or after anoscopic examination. Internal hemorrhoids also consist of redundant mu-

Fig. 30.

Fig. 31.

Fig. 30. Uncomplicated internal hemorrhoids. The lesion was invisible to inspection until an anoscope was inserted. The hemorrhoids and redundant mucosa seen in the photograph appeared on withdrawal of the instrument. Symptoms consisted of the protrusion at each bowel movement, associated with pain and bleeding. Hemorrhoidectomy was performed with complete relief of symptoms.

Fig. 31. Prolapsed internal hemorrhoids. The hemorrhoids became prolapsed two days previously and could not be reduced. Note the ulceration, edema and inflammation. The pain was severe and required sedatives. The patient was 64 years old and previously had very little difficulty reducing the "piles." Operation was performed with excision of the redundant tissue.

cosa containing multiple dilated veins, but are found on the inner aspect rather than the outer aspect of the anal canal. The pathogenesis of hemorrhoids is not clear. Internal hemorrhoids, when they develop after childbirth, which they frequently do, are probably associated with venous obstruction and stasis. In other cases, they may be induced by excess straining at stool because of constipation and anal sphincter spasm. In many instances there is probably a congenital deficiency in the attachment of the rectal wall to the underlying fascia, thus permitting the redundant mucosa to be carried down into the anal canal during defecation. The pathogenesis of external hemorrhoids is not known.

Internal hemorrhoids may become evident to the patient early as a protrusion noticed particularly after defecation, and often associated with a mild degree of prolapse of the redundant mucosa. Usually the protrusion can be replaced manually by the patient or recedes spontaneously. During defecation there may also be *bleeding*, which is usually slight but may be persistent and sometimes severe enough to lead to secondary anemia. *Pain* is not characteristic and is usually absent except with strangulation outside the sphincter, infection, ulceration, or thrombosis. Pain is apt to be noted during and after defecation, which may leave a sense of soreness for many hours. In other cases, the pain may be persistent and continuous, particularly when severe acute inflammation develops. Constipation is often present because of the associated chronic inflammation, anal spasm, and fear of defecation. Internal hemorrhoids are visible on external examination only when they become prolapsed or protruded. Otherwise the diagnosis depends upon anoscopic examination, as mentioned above.

External hemorrhoids may produce annoyance in maintaining cleanliness, but rarely produce other symptoms unless acute inflammation develops, which usually occurs following thrombosis. *Thrombosis of an external hemorrhoid* is not infrequent; it produces localized pain, which may be so agonizing as to lead to complete disability. The diagnosis is obvious on inspection. Tenderness over the indurated mass may be excruciating.

Treatment depends upon the nature of the lesion and the disability produced. In mild cases, internal hemorrhoids require only a short period of rest, local application of heat, and a bland diet with mineral oil to produce a soft stool. If the patient presents a strangulated internal pile, the mass can often be reduced by gentle manipulation with the well-lubricated gloved fingers, with immediate relief to the patient. Obviously, a thrombosed external hemorrhoid should not be mistaken for a prolapsed strangulated internal hemorrhoid and treated in the same way. Operation for internal hemorrhoids consists of excision of the redundant mucosa and venous network and meticulous suture of the operative site to control hemorrhage and to produce adhesions to the underlying muscle during healing. The suture line of the excised tissue should extend in the longitudinal axis of the anus and rectum, ending as high up as possible and starting just above the mucocutaneous margin. Postoperative pain can usually be avoided if the distal end of the incision is left open, particularly when redundant skin has also been removed. The use of sclerosing solutions, such as phenol or sodium morrhuate, to obliterate small internal hemorrhoids, has been widely used and may be carried out as an office procedure. Should infection supervene, however, complications may be serious. Most surgeons, therefore, prefer to treat hemorrhoids by excision.

External hemorrhoids require treatment only when they become inflamed or thrombosed or bulky enough to preclude cleanliness. In the thrombosis, the acute pain located in an external tab can be completely, immediately, and dramatically relieved by a simple excision of the overlying skin and evacuation of the clot. This may require novocain anesthesia, but in most cases there is a sufficient area of skin deprived of blood supply and therefore insensitive enough through which the small incision can be made. Such an incision is not large enough to require a suture, and very rarely bleeds significantly. If the patient is seen 24 hours or more after the onset of the thrombosis, such a procedure cannot usually be performed, due to the organization of the clot.

Fig. 34. Ischiorectal abscess. The patient, a 40-year-old male, had had symptoms for four days. The local pain was so severe that defecation was impossible. After incision about 50 to 75 ml. of foul pus were evacuated. The cavity was adequately opened; it drained for four weeks and closed permanently. In a large majority of such cases a fistula-in-ano will develop. No communication between the abscess and rectum was apparent at operation. A, before operation; B, after being draped; C, after incision.

eral anesthetic is to be preferred. An adequate opening to expose all of the cavity is essential and is made in a radial direction from the anus. To prevent formation of a fistula-in-ano, the abscess cavity should be packed wide open so that healing can take place from below before the opening in the skin heals. Chemotherapy will be helpful in decreasing the possibility of fistula formation.

Fistula-in-Ano. An ischiorectal abscess nearly always precedes the formation of fistula-in-ano. The effective use of chemotherapy has undoubtedly reduced the incidence of this complication. Frequently there is a history of spontaneous healing followed by reformation of an abscess. Occasionally the infection may spread throughout the tissues of the perineum and produce numerous fistulous openings, which communicate with each other. Even when only one opening is observed, the tract may be long and tortuous. Some cases are associated with stricture of the rectum. The symptoms, aside from recurrent abscess formation, may consist of nothing more than a continuous discharge from the wound, which thus requires constant dressings. When the tract drains inadequately, pain and systemic evidence of infection may occur. A slight difficulty in moving the bowels is often present, sometimes accompanied by pain.

The fistulous tract may be simple or complex (Figs. 35, 36). Sometimes the communication with the rectum is absent or microscopic. When no internal opening is present, the term *blind fistula* is used. A *complete fistula* has two openings extending completely from mucosa to skin at any level. The relation of the fistula to the external and internal anal sphincters is important. Some are distal to the sphincters and thus entirely subcutaneous; others pass between the internal and external sphincters to enter the anal canal. *Internal fistula* is the result of an abscess which has broken into the rectum only. Variable, too, is the directness of the fistulous tract; nearly all are tortuous and burrow extensively, sometimes halfway around the circumference of the rectum, before they end. When more than one external opening is present, they lead to tracts which are continuous. The chronicity of the lesion and the failure to heal, in most cases, is due to the continuous exposure to infection from the rectum. In other cases, when the opening is blind, other factors, including especially insufficient drainage, may play a role; certain of them are tuberculous, and microscopic or cultural evidence thereof is obtainable, and when it is, most (75 per cent) of the patients are found to have demonstrable active or arrested pulmonary tuberculosis. A significant proportion of patients with pulmonary tuberculosis, moreover, suffer from anorectal infections.

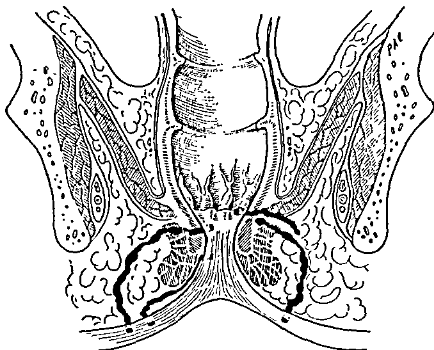

Fig. 35. Diagram showing four varieties of fistula-in-ano. The two on the left are complete and have two openings; one of the tracks opens above, and the other below the sphincter. The two on the right are "blind," in reality, therefore only sinuses, that one above an internal, the one below an external blind fistula. It is believed, however, in the case of the external blind fistula an internal opening does actually exist but is so small that it is not demonstrable.

Treatment requires operation, although well-selected chemotherapy is probably useful during the postoperative period. Excision is preferable to merely laying the tract open to allow granulation from below. If the tract passes deep to the external sphincter, this can be singly divided without significant loss of continence. If the tract passes deep to both the external and internal sphincters, division of both of these muscles is improper, as it will lead to incontinence. The recommended procedure in this circumstance is to open the tract widely with preservation only of the continuity of the internal sphincter, about which a loop of heavy suture material is loosely tied. At a second stage, two weeks later, the fibrosis induced by the presence of this seton will permit complete opening of the tract by division of the internal sphincter, without loss of continence. The wound in any case must be daily dressed and packed open to ensure healing from the bottom, without pocketing of suppurating foci (Gabriel, 88). The severe cases with multiple external openings, particularly when

Fig. 36. Fistula-in-ano. The patient was a 30-year-old woman who had had symptoms for two years following drainage of an ischiorectal abscess. The opening of the tract can be seen in the skin just below the anus. Injection of methylene blue into the external orifice of the fitsula failed to reveal an internal opening, nor was one demonstrated at operation several days later. The entire tract was excised; its deepest point was at least one centimeter from the rectal wall. Healing was complete.

stricture of the rectum is present and there is extensive perirectal infection, may require a permanent or temporary colostomy. Even if the lesion is tuberculous, cure may be achieved in a large percentage of cases provided careful, effective, and radical surgery is performed.

Stricture of the Rectum. Fairly common among Negro women, this lesion was considered of syphilitic origin, but most recent studies have shown that it is a manifestation of a venereal disease called lymphogranuloma venereum (see p. 111). The infection reaches the perirectal lymphatics through the venereal portal of entry and induces a mild type of proctitis which becomes evident by diarrhea, pain on defecation, and tenesmus. Ulceration may be seen at this stage. Slowly fibrous tissue is laid down, encircling the rectum and leading to a stenosis or stricture. Considerable infection above the stricture is usually present, and pus is passed with each stool, which is necessarily liquid in character. The infection may occasionally be responsible for the development of a perirectal (or ischiorectal) abscess which burrows through to the buttock and forms one or more fistulas which do not heal. Because of the many openings around the anus the term "watering-pot" is often applied. The condition of such a patient is distressing indeed; a colostomy above the sigmoid with the formation of a permanent artificial anus on the abdominal wall is often indicated. When the stricture alone is causing symptoms, progressive dilatation with the finger or rubber bougies of increasing caliber affords considerable relief, although a normal caliber cannot be regained. Radical excision of the involved area, backed by effective chemotherapy, is now feasible.

Polyps. These tumors occur in the rectum as well as in the colon and may be single or multiple. When in the distal colon or rectum, they may be seen through a proctoscope or sigmoidoscope. Polyps may also be detected in the rest of the colon, though with greater difficulty, by means of air contrast barium enema x-ray examination. Clinical manifestations are usually due to the tendency of a polyp to bleed. Polyps of the rectum are a common cause of rectal bleeding in early childhood. Young children may have a succession of polyps which slough off spontaneously in the feces after growing to a moderate size. A polyp near the anus may be mistaken for a prolapsed internal hemorrhoid. The greatest significance of polyps in adults, however, is due to the fact that they are definitely precancerous lesions, although the vast majority remain benign, as shown by the frequency of them in routine autopsies. Since it is impossible to determine clinically whether they are malignant or not, excision is the procedure of choice. When they have a long stalk, they may produce diarrhea and demand removal for symptomatic relief. The type of excision (local or radical) depends on whether they are judged to be benign or malignant.

Proctitis. This represents a medical rather than a surgical problem but produces symptoms which may be mistaken for other lesions. On proctoscopic examination, there are diffuse inflammatory changes in the rectal mucosa, including edema, multiple ulcerations, anemia, or hyperemia. Such changes are usually the visible portion of more extensive lesions higher up in the colon. X-ray after a barium enema will reveal the extent of the disease above the rectum. Proctitis in Negro women is frequently due to lymphogranuloma venereum (see p. 111).

Pruritus Ani. Itching about the anus is common, often annoying, sometimes disabling, leading in rare cases to uncontrollable torment. The etiology in most instances is obscure. In children, pin worms may be the cause of the itching. Careful proctoscopic examination of adults with pruritus ani will also lead to the discovery of these parasites in a few instances. On other occasions, food allergy appears to be the primary factor in the etiology. Fungus infection of the skin about the anus is common either as a primary cause or as a secondary invader. Troublesome itching may accompany fissure-in-ano or hemorrhoids, particularly the former. Treatment consists of removal of the cause if one is found. If the cause is obscure, it may be wise to try applying an efficient but not irritating fungicide or to advise meticulous cleanliness. At times the cause is relative to bacterial irritation; under such circumstances, changing the flora of the intestinal tract by taking large quantities of buttermilk

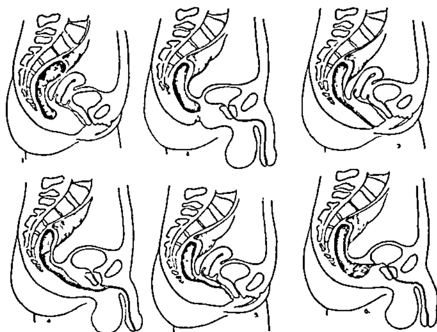

Fig. 37. Types of imperforate anus and the location of the various fistulous tracts formed. 1, absence of anus (proctodeum); 2, fibrous cord attaching rectal pouch and proctodeum; 3, perineal fistula; 4, urethral fistula; 5, rectovaginal fistula, and 6, rectovesical fistula. (From W. H. Cole. Arch. Surg.)

will yield spectacular results. In certain persistent cases, psychogenic factors may play a role (89).

Imperforate Anus. The various types of this congenital defect are illustrated in Figure 37. It is evident soon after birth when the nurse attempts to insert a rectal thermometer. Otherwise, it may not be noticed for a day or two until distention, vomiting, and abscence of bowel movements proclaim the existence of some difficulty, or the appearance of feces in the vagina or bladder is observed. The lower rectum may be blind or may communicate with the bladder (in males) or the vagina (in females). The rectum may end high in the pelvis or be separated from the outside by a single layer of skin and mucosa. X-ray with the infant upside down may show a bubble of gas at the termination of the rectum, and a film with a rectal thermometer placed in the anal dimple will provide valuable information preoperatively concerning the relative positions of these two structures (Wangensteen) (Fig. 38).

Some type of operation is indicated, depending on the kind of defect present. When the septum is thin, the skin at the anal sphincter is incised and, by inserting an instrument through the sphincter, the rectal pouch is located and opened. The rectal mucosa is pulled out and anchored to the skin by interrupted sutures. Dilatation at frequent intervals is usually necessary to prevent serious stenosis. If the rectal pouch is high in the pelvis, an immediate abdominoperineal repair has many advantages and is now relatively safe even in premature infants (90). The fistula, if present, is closed at the same time.

Foreign Bodies. On rare occasions, a sharp bone, toothpick, or other object lodges in the rectum after being swallowed and passed uneventfully through the stomach and intestines. A positive history is helpful if it can be obtained. Acute local pain is the usual complaint; if the object is sharp, it may lodge just proximal to the anus and produce an ulceration or abscess. Diagnosis depends on careful digital and proctoscopic examination. Treatment consists in removal of the foreign body and management of the local infection, if present. On rare occasions, a foreign body, such as a bottle, may be introduced into the rectum by the patient in a demented state. Acute rectal symptoms will be present, but the nature of the trouble will

stricture of the rectum is present and there is extensive perirectal infection, may require a permanent or temporary colostomy. Even if the lesion is tuberculous, cure may be achieved in a large percentage of cases provided careful, effective, and radical surgery is performed.

Stricture of the Rectum. Fairly common among Negro women, this lesion was considered of syphilitic origin, but most recent studies have shown that it is a manifestation of a venereal disease called lymphogranuloma venereum (see p. 111). Diagnosis depends on careful digital and proctoscopic examination. Treatment consists in removal of the foreign body and management of the local infection, if present. On rare occasions, a foreign body, such as a bottle, may be introduced into the rectum by the patient in a demented state. Acute rectal symptoms will be present, but the nature of the trouble will

Fig. 38. Imperforate anus. Roentgenogram of a 12-hour-infant while being held head down. Note the air in the rectum which outlines its terminal end. Fluid levels in the dilated colon can also be seen. An incision was made in the perineum, the rectal pouch located and brought through the sphincter after which the rectal pouch was opened and the edges sutured to the cut edges of the skin.

often be concealed by the patient. Rectal or proctoscopic examination makes the diagnosis. Removal of a large object usually requires a general anesthetic; when the object has been pushed up into the colon and is out of reach, laparotomy will be necessary.

Anal Incontinence. Incontinence of feces (involuntary defecation) may be neurogenic or myogenic. *Neurogenic factors* comprise organic lesions in the spinal cord, such as tabes dorsalis, injury, and neoplasm, and impaired cerebration, which, by releasing the inhibitory mechanism, may result in incontinence; functional as well as organic disease of the brain may be responsible. *Myogenic factors* are produced by injury or disease which has resulted in destruction of the integrity of the sphincters. Injury to the mother in childbirth, extensive inflammatory disease, repeated or radical operative trauma, or congenital absence of the sphincters may be responsible for anal incontinence of this type. It is important to emphasize that special precaution must be taken during operative procedures about the anus in order to prevent injury to the sphincter which may lead to incontinence. This is particularly applicable to operations for fistula-in-ano. The dangerous opinion has appeared in the literature that the internal sphincter may be divided at any one point without loss of continence. This is not the rule, as indicated above. The incontinence may be most prominent only when gas or liquid contents are present in the rectum.

Treatment depends on removal of neurogenic factors, if possible. Functional incontinence may disappear spontaneously or may respond to appropriate psychotherapy. The existence of extensive paralysis means a poor prognosis: careful nursing care is all that can be advised in such cases. When muscle is injured, operative repair by suture of the divided sphincter may be successful. When the sphincter is irremediably damaged or permanent neurogenic factors are responsible, a plastic operation may be advisable (91).

Carcinoma of the Rectum. Adenocarcinoma of the rectum is about as frequent as cancer of the rest of the colon combined. It

Fig. 39. Carcinoma of the rectum. The patient, a 54-year-old female, complained of bleeding from the rectum and pronounced weakness for one year. Rectal (digital) examination revealed a large tumor mass almost filling the rectum. A biopsy confirmed the clinical diagnosis of cancer and a colostomy followed by a perineal resection of the rectum was performed. The gross specimen is illustrated above; microscopic section of the highest lymph node revealed no evidence of metastasis. The two photomicrographs are from the biopsy specimen and show the malignant character of the epithelium. The growth takes a glandular form with irregular, large, deep-staining cells; there is no basement membrane and the growth has penetrated deeply through the wall of the rectum.

occurs anywhere between the rectosigmoid junction and the anus. Cancer at the anal opening is quite different from that of the rest of the rectum, being usually of the squamous type; it is described separately. Adenocarcinoma (Fig. 39), the commoner type of rectal cancer, grows from the surface of the rectum as a cauliflower growth, or penetrates into the wall. In either case, an ulcer forms which bleeds readily; in some instances the growth involves the entire circumference of the bowel, producing an annular tumor. Metastases occur by lymphatic spread posteriorly to the iliac nodes and into the colonic mesentery, or by blood vessels emptying into the portal vein to the liver, or by direct extension. The disease is twice as frequent in males as in females.

At the start, cancer of the rectum may be clinically silent, but in nearly all cases soon produces warning symptoms. *Bleeding* is common and is apt to be slight but persistent; it may be the first symptom noted. Blood passed at stool varies in color, depending

largely on the length of time it remains in the rectum. Though bleeding is most commonly due to benign lesion—that is, hemorrhoids or fissure—this assumption cannot be made without adequate examination, meaning rectal examination and proctoscopy. *Diarrhea* is also a prominent symptom, due presumably to irritation and infection of the ulcerated lesion, but more particularly because the stenosis created by the tumor promotes stasis and, secondarily, putrefaction and irritation of the bowel wall above the lesion. The stools in such instances may be frequent and may contain mucus and blood. *Obstructive symptoms* may be the first manifestations, especially when the tumor encroaches upon the lumen of the rectum, as a cauliflower growth. These symptoms start with increasing constipation or difficulty in moving the bowels, thereby necessitating catharsis. Pain, of a cramping character in the left lower quadrant, and increasing distention also occur. Total obstruction is almost never seen in carcinoma of the rectum proper; when such symptoms arise, the tumor is nearly always located at or above the rectosigmoid. *Change in bowel habits* in an individual past middle age, even if not marked, should be investigated. A sense of incomplete evacuation, looseness of the stool, the presence of blood or mucus, a more frequent desire for defecation, have all been noted by patients who later developed the more evident signs of cancer. However, there are so many other benign and functional or transient disturbances which produce such symptoms that the value of these symptoms lies only in provoking a thorough examination of the rectum. Biopsy should be done when a tumor is present to confirm the diagnosis by microscopic study. *Late symptoms,* such as pain in the region of the sacrum, cachexia, and loss of weight, are sometimes present even in operable cases; development of them therefore is not always a hopeless sign. Ordinarily, however, they signify a far-advanced lesion for which only palliative treatment is possible.

The *treatment* of carcinoma of the rectum is entirely surgical. The results of radiation treatment are not satisfactory. Palliative procedures relieve symptoms but will not prolong life; according to the extensive and excellent studies of Daland, Welch, and Nathanson (92), the average survival without excision of the tumor is about 12 to 18 months. In operable cases without obstruction, the procedure of choice is an abdominoperineal resection in one stage (Miles, 1906) after adequate preoperative preparation. With this procedure, a permanent colostomy is necessary. The results of adequate surgery in favorable cases of cancer of the rectum are gratifying, as shown by five-year survivals of 50 to 60 per cent.

Operation should include an extensive excision en bloc of the tumor, together with most of the high-lying regional lymph nodes. These nodes, as shown by Gilchrist and David (93) and others, are the site of metastases in over half of all cases and must obviously be removed if a cure is to be expected. A two-stage operation is indicated in the presence of obstruction, which is rare in carcinoma of the rectum except in advanced cases. In patients with large and seemingly inoperable tumors, surgeons have occasionally noted, after the colostomy has diverted the fecal stream for some time, that the tumor has become smaller and operable, due undoubtedly to subsidence of associated inflammation.

Carcinoma of the Anus. Malignant disease visible at and involving the anal orifice is rare; it originates outside the mucocutaneous margin and is therefore of the squamous cell type, similar in behavior to squamous cell carcinoma elsewhere. It is a painful lesion, leads to early ulceration, and metastasizes to the regional (inguinal) lymph nodes. Stenosis at the anal canal may occur. Treatment consists of surgical excision of the lesion by the abdominoperineal technic.

Colostomy. An artificial anus in the anterior abdominal wall, now widely accepted, formerly provoked horror in the minds of many patients and a few doctors. The operation, properly carried out with adequate indication, has been responsible for the prolongation of life in relative comfort and a minimum of disability. A colostomy may be placed in any of several sites. A most convenient colostomy is one located just below and to the left of the umbilicus; the bowel emerges through the retracted rectus muscle, which is thought by some to act somewhat as a sphincter. Many surgeons bring the colon

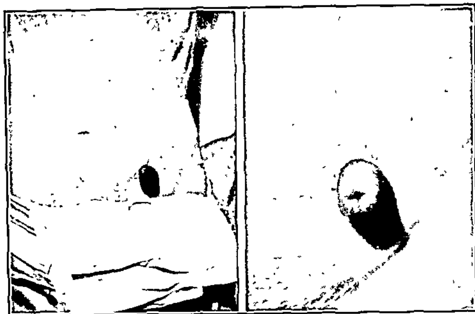

Fig. 40. Single barrel colostomy. A combined abdomino-perineal resection was performed for carcinoma of the rectum three years before. The patient, now 59 years old, works 12 hours a day without disability. In the left photograph above is shown the simple pad which is used to protect the colostomy; an elastic girdle is used to keep it in place. On the right is a close-up of the colostomy. This particular patient has a bowel movement every other day with the aid of small enema, and has complete control in the interval with no escape of gas or discharge.

out through a left lower quadrant (gridiron) incision, as illustrated in Figure 40. With adequate regulation of the diet, a properly performed colostomy will act, with the aid of irrigation, at a regular time every day or two and remain dry during the interval, thus interfering very little with a normal active life. Obviously some type of dressing with a belt must be worn; the old-fashioned colostomy bag is very inconvenient and not needed.

THE UMBILICUS

Because they are rare, diseases of the umbilicus will be considered only briefly. The most frequent lesion is umbilical hernia, which is considered on page 855.

Anomalies. During early embryonic life there is an opening between the primitive gut and the yolk sac which is called the vitelline (omphalomesenteric) duct. This communication is part of the primitive umbilical orifice, which gradually closes by approximation of the margins to form the umbilicus (navel) of extrauterine life. In addition to the vitelline duct, the urachus and the umbilical vessels also traverse the umbilicus.

In adult life, the urachus is represented as an obliterated cord connecting the umbilicus with the dome of the bladder. It arises embryologically from the cranial part of the urinogenital section of the cloaca. The cloaca, which is a part of the hind gut, ultimately separates into a dorsal portion, from which the rectum arises, and a ventral portion (urinogenital chamber), which divides into three parts: 1. the cranial part, which is converted into the urachus; 2. an intermediate part, giving rise to the bladder; and 3. a caudal part, which gives rise to the urethra and, in females, to part of the vagina.

PERSISTENT URACHUS. If the urachus does not become obliterated completely, it may give rise to a sinus which drains seromucoid material through the umbilicus (see below also); if it becomes obliterated at the ends only, a cyst may form. Such cysts rarely produce symptoms unless they become infected. An infected *urachal cyst* produces manifestations of a localized intraabdominal abscess which simulates an appendiceal abscess, except for location in the mid-line between the umbilicus and bladder (Fig. 41). If the infection is serious, drainage of the cavity will be the procedure of choice; however, a sinus

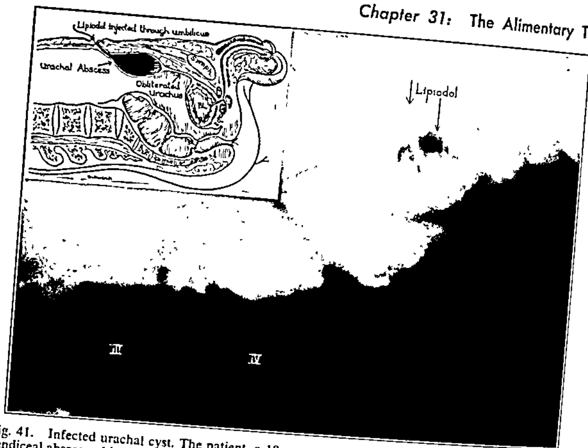

Fig. 41. Infected urachal cyst. The patient, a 19-year-old boy, entered the hospital with a diagnosis of appendiceal abscess which seemed entirely correct except for the fact that the tender area was in the midline below the umbilicus rather than in the right lower quadrant. Several hours later a large amount of pus escaped spontaneously from the umbilicus with complete relief of all clinical manifestations. The illustration above is a print from the lateral x-ray film, made several days later, after the opening in the umbilicus had been injected with lipiodol. Note the detailed diagram in the upper left corner. The patient had no further symptoms. The infection apparently produced a necrosis of the epithelial cells lining the urachus thus allowing healing to occur.

is apt to form which may have to be excised later.

VITELLINE (OMPHALOMESENTERIC) CYST. This anomaly is due to an incomplete obliteration of the terminal end of the vitelline duct, i.e., that part of the yolk sac at the umbilicus; such a defect is noted at birth as a cystic mass at the navel (Fig. 42). On some occasions, these defects may be of a polypoid or adenomatous character; the greater portion of the solid tissue usually consists of structures resembling intestinal wall, particularly mucosa. On extremely rare occasions, the entire length of the vitelline duct remains open, so that an actual communication with the intestine exists, producing a fecal fistula.

MECKEL'S DIVERTICULUM. This anomaly is probably frequent but remains unrecognized unless it produces symptoms (see p. 747). It is, in reality, a part of the vitelline duct but represents the proximal or deep end which enters the primitive gut and which fails to become obliterated completely, thus creating a permanent pouch or diverticulum in the distal portion of the ileum. Part of it may persist in the umbilicus, and, if it contains gastric mucosa, this mucosa will lead to a persistent discharge (see below).

Omphalocele or congenital umbilical hernia of the cord is described elsewhere.

Infections. The umbilicus may become infected after birth due to contamination and lack of cleanliness during delivery. More commonly the infections at the umbilicus occur in childhood or adult life as a type of *dermatitis*. The clinical manifestations include itching, slight pain, and discomfort, and particularly a chronic discharge of mucopurulent material. Inspection of the depths of the orifice will usually reveal a low grade type of superficial skin infection, often as-

Fig. 42. Vitelline cyst. The patient was an infant six weeks old. Methylene blue injected into the cyst emerged from the rectum a short time later. Note redundant tissue as well as the cyst. Treatment was conservative; however, the infant died later of a paratyphoid infection. (St. Louis City Hospital.)

sociated with tiny ulcers. Treatment is usually effective and in most cases leads to prompt healing; simple cleanliness and daily irrigation of the umbilicus with diluted hydrogen peroxide or boric acid solution, followed by careful drying of the invaginated skin, is all that is necessary. If such simple measures are not effective, the possibility of the presence of an anomaly should be considered. If a deep opening can be detected, x-ray examination following injection with lipiodol may reveal the existence of a urachal sinus.

On rare occasions, the discharge will be acid in reaction, as shown by the litmus paper test. This justifies a diagnosis of *aberrant gastric mucosa.* The umbilicus, if excised, then will, in fact, reveal a tiny stomach with well-developed mucosa.

Neoplasms. Primary squamous cell carcinoma has been observed at the umbilicus and presents the characteristics of the disease in general. Benign tumors are usually associated with anomalies, as already discussed.

32

THE PERITONEAL CAVITY

The peritoneum is the lining of the abdominal cavity. The visceral peritoneum covers the liver, intestines, and other organs, whereas the parietal peritoneum covers the interior of the abdominal wall. The peritoneal cavity is the potential space between these two layers; under abnormal circumstances it may be distended with fluid (ascites) or gas (pneumoperitoneum). The lesser peritoneal space is a small potential cavity (lesser omental sac) which lies behind the stomach and lesser omentum and normally communicates with the main peritoneal cavity by the foramen of Winslow. There are numerous compartments which become important in the presence of abscesses and other types of disease (Fig. 1). There are numerous spaces, such as the suprahepatic, infrahepatic, supracolic, infracolic, and pelvic.

PHYSIOLOGY OF THE PERITONEUM

The peritoneum is smooth and lubricated with a small amount of fluid, thereby allowing free motion of the intestines in their peristaltic function. The surface of the peritoneum is covered with endothelium. Beneath this, in the deeper layers of the peritoneum, is an unusually rich network of potential blood vessels which probably function only in times of stress (e.g., inflammation). Lymphatic spaces are likewise abundant. Under normal circumstances hypotonic and isotonic fluids, and even microscopical foreign bodies, are absorbed by means of the capillaries of the portal system and the lymphatics, chiefly the former. Which of the two networks is the more important in the protection mechanism cannot be established.

The peritoneum is highly resistant to infection, and bacteria coming in contact with it by operative contamination and so forth are rapidly destroyed. Phagocytosis by polymorphonuclear leukocytes is apparently the most important factor in this defense mechanism, as shown by the studies of Coller and Brinkman (1) and others. This resistance is so pronounced that historically it actually served as a stumbling block to the acceptance of Lister's teachings, e.g., Lawson Tait and others used the argument that abdominal operations were seldom followed by peritonitis, even though no attention was paid to Lister's principles. We now know that this is true because the resistance of the peritoneum is so much greater than that of other tissues that contamination during an abdominal operation may be severe enough to result in a serious wound infection, yet inflict no demonstrable harm within the peritoneal cavity. It must not be supposed from this statement that peritonitis is not feared; actually it is a most serious infection, because once it gets a foothold the mortality is high. Peritonitis occurs either because of continued contamination from a perforation or because an especially virulent organism is involved. Virulence may be lessened by an increase in the local immunity of the peritoneum. Immunity of the peritoneum to infection may be augmented appreciably by repeated or continued exposures of a mild character. This is exemplified clinically by the decreased tendency for peri-

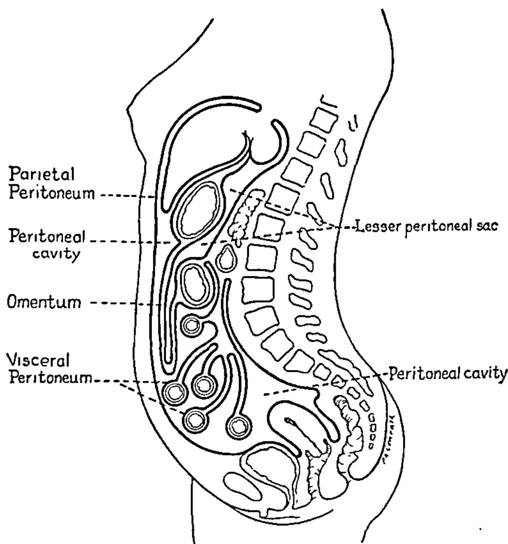

Fig. 1. Longitudinal section of the abdominal cavity in the anteroposterior direction to show the gross structures, and the relation of the visceral to the parietal peritoneum.

tonitis to develop even following serious operations upon the large bowel when there has been an antecedent colostomy or some other operation upon the intestine. As will be discussed in detail later, the healing power of the peritoneum may be augmented greatly by intestinal decompression with no oral intake except a small quantity of water to keep the tube open. Conversely, anything which will tend to increase intestinal movements (e.g., food, cathartics, or prostigmine) will interfere with the normal protective mechanism of the peritoneal cavity against infection.

The omentum, suspended from the greater curvature of the stomach and transverse colon, has often been spoken of as the "wandering policeman" of the abdomen because of its ability to locate and envelop foci of infection and prevent their spread. The omentum therefore plays a major part in the *defense mechanism* in the peritoneal cavity. It may even completely surround a perforation of the intestine and confine the process to a local area, thereby preventing a diffuse peritonitis.

Because of the peculiarities in the sensitivity of the peritoneum to painful and other stimuli, considerable confusion may be experienced clinically in localizing the source of the disease responsible for symptoms. The parietal peritoneum is sensitive to pain, but the visceral peritoneum is sensitive only to certain types of stimuli.

For example, pulling or tugging upon the mesentery of the intestine is painful, although the intestine itself may be cut completely

across with a knife or cautery without the production of any pain. Increased tension in hollow organs may likewise produce pain. The early work of Ross (1888) and Mackenzie (1920) demonstrated that visceral pain of this type is often referred to corresponding skin fields. This pain is frequently localized to areas not overlying the lesion producing the pain, because the localizing quality of the central sensory mechanism with which the visceral (autonomic) fibers make contact is poorly developed in comparison with localization by somatic nerve cells.

The mechanism of the production of the involuntary muscle spasm which appears early over an area of peritonitis is vaguely understood, but it is known to be an important protective mechanism. It may also be explained as a reflex phenomenon arising from the inflamed peritoneum by way of the spinal cord (see Fig. 13 in Chapter 27).

DIAGNOSTIC METHODS

The diagnosis of diseases of the peritoneum and peritoneal cavity is usually difficult and requires a good history and careful methods of examination. Besides inspection, palpation, percussion, and so forth, which are discussed later, certain technical methods may be of great value. For example, if there is ascites, aspiration of the peritoneal cavity will yield fluid. If the fluid is caused by metastases to the peritoneum, it may be blood tinged and when centrifuged, the sediment will show malignant cells. A flat x-ray film is sometimes of diagnostic value. Induced pneumoperitoneum has been advised as a preliminary to x-ray study but is not used widely. A special method of examination has been devised with an instrument called the peritoneoscope, which permits, under certain conditions, direct visualization of parts of the peritoneal cavity. On the other hand, most surgeons prefer a small exploratory incision under local anesthesia for such a diagnostic purpose because it often yields more information and has the advantage of permitting a safe biopsy of suspicious tissue. Under most conditions, however, the surgeon must rely upon the bedside examination of the patient's abdomen.

Experience is, of course, a very important factor in determining the amount of knowledge gained from the bedside examination, in the conduct of which certain habits or routines will be very helpful. Accuracy will be improved if the examiner will always conduct his examination from the same side, e.g., the right, if he is right-handed. Because this procedure of examining the abdomen is so important and requires such expert technic, a few of its essential details will be described.

Inspection. A great deal of information can be obtained by carefully inspecting the abdomen with the patient lying comfortably on his back, under good illumination. If the patient's neck is flexed slightly and the thighs flexed with the knees on a pillow, relaxation will be obtained and the abdominal examination be facilitated. The examiner must also be in a comfortable position in order to obtain the most information. Exposure not only of the abdomen but of the entire torso is necessary for completeness. First the examiner notes the degree of *distention.* Because of normal variations in the contour of the abdomen this may be difficult, although an estimate can be made from the patient's physique. A more accurate method would be to inquire from the patient whether any enlargement has occurred. Enlargement, when present, may be due either to tumor, to the accumulation of fluid in the peritoneal cavity, or to the accumulation of gas and fluid in the intestinal lumen. The examiner looks for *abdominal respiratory movements,* which are normally present, but disappear with the onset of any significant inflammation of the peritoneum. Asking the patient to breathe deeply will make the lag more notable. The patient is asked to cough, which may produce localized pain from peritoneal irritation. Other information may be obtained by noting any *asymmetry* in the abdomen. This may be due to the presence of an abdominal mass, to dilated bowel, herniations, and so forth. Intestinal patterns may be seen with or without peristaltic waves; the significance of these signs in intestinal obstruction has been discussed elsewhere. Discoloration of the skin and various types of skin lesions are of obvious importance and should be scrutinized

carefully, but they usually indicate nonsurgical disease.

Palpation. Palpation of the abdomen, particularly in patients with suspected acute peritoneal inflammation requires the utmost gentleness, yet meticulous thoroughness. It is an art which requires well-developed technic and complete cooperation of the patient. A number of important details may be suggested. Palpation must start from the part of the abdomen not involved so that the painful site will be approached gently without immediately producing pain. However, detection of pain by pressure, a sign which is called tenderness, is an important part of the examination. The patient should be so told, but assured that such pressure-provoked pain will be stopped immediately it is detected. It is important to start the examination with the entire flat surface of the hand in contact with the abdomen, later using the tips of the fingers for eliciting finer details. The main objectives of palpation in diseases of the peritoneum are the detection of (*a*) tenderness, (*b*) various degrees of muscle spasm, (*c*) masses, and (*d*) hyperesthesia of the skin. Tenderness and muscle spasm are often associated in most inflammatory lesions of the peritoneum and will be discussed together. The examiner must be confident, however, that these two signs are actually present and not due to fear or apprehension on the part of the patient. A rough examination may yield false evidence of tenderness and produce *voluntary* muscle spasm, which may lead to an erroneous diagnosis. Muscle spasm, to be of value, must be truly *involuntary*. It exists in various degrees, the least severe of which goes by the name of muscle guard or resistance, which is present in mild or early peritonitis. In the typical case, the muscles contract promptly under moderate pressure of the examining fingers. More severe degrees of muscle spasm go by the name of muscular rigidity, which in the most pronounced cases gives a sensation of boardlike hardness to the abdominal wall, even with the slightest palpatory pressure. Tenderness over the lower margin of the liver can sometimes be detected by having the patient take several deep breaths which results in downward movement of the liver against the examiner's fingers. *Rebound tenderness* is elicited by suddenly releasing the hand exerting the pressure, whereupon the patient complains of acute pain. It has no specific value except that it is sometimes present when direct tenderness is absent and may be an indication of early inflammation. Occasionally, pressure in the left lower quadrant may elicit pain in the right lower quadrant in patients with acute appendicitis (*Rovsing sign*). *Hyperesthesia of the skin* may sometimes be detected in the absence of other signs and will therefore be of value. For example, hyperesthesia is usually present in the right lower quadrant in acute appendicitis; frequently a similar area is found in the left hypochondrium in pancreatitis, and posteriorly behind the gallbladder in cholecystitis.

Palpation is also of value in detecting abdominal tumors. In examining for the existence of a mass, difficulty may arise in that a resistance is felt rather than a definite mass, particularly over inflammatory lesions. Nevertheless, an attempt should be made to locate the mass as exactly as possible, including all of its various characteristics, particularly size, shape, consistency, surface attachments, tenderness, and fluctuation. The examiner must bear in mind all of the possible causes and types of tumors but at the same time realize that the most common tumefaction in the lower abdomen is a distended bladder, particularly in patients with spinal cord disease, skeletal trauma, prostatic obstruction, and following many abdominal operations. The second most common tumefaction in the female is a pregnant uterus. Too often physicians have erroneously mistaken these two enlargements for cysts, neoplasms, or other abnormal masses.

During palpation it may be of some value to have the patient lift his head in order to detect a bulge at the site of a hernia, or to differentiate between abdominal wall and intraabdominal tenderness. Masses in the abdominal wall may also be detected more accurately by this procedure. With the patient lying prone (face down), abdominal palpation may detect differences in tenderness on the two sides which will be very helpful in locating the site of the peritoneal irritation, particularly when there is a question of acute appendicitis. No abdominal examination is

complete without examination of the back with the patient sitting up or lying on his side.

Percussion. Percussion has much less value than inspection and palpation, but should differentiate, as causes of abdominal enlargement, fluid or solid tissue which gives a flat percussion note in contrast to gas in the intestine, which yields a tympanitic note. However, such differences are often deceptive, but a flat x-ray film in these cases may be decisive. Detection of ascites by the demonstration of a fluid wave and shifting dullness is sometimes valuable, but often equivocal. However, dullness to percussion just over the symphysis is practically always present when a lower abdominal tumefaction is due to a distended bladder.

Auscultation. The use of a stethoscope over the abdominal cavity may yield valuable information. The presence of many sounds, such as gurgling and various metallic notes, is usually produced by active peristalsis, and this suggests that the abdominal distention is due to intestinal obstruction rather than to paralytic ileus, which is usually associated with a "silent" abdomen. The appearance or disappearance of abdominal sounds will likewise be of value in indicating changes in the progress of the intraabdominal lesion. For example, disappearance of peristaltic sounds while the patient is being observed is very suggestive of perforation into the peritoneal cavity.

Rectal and Vaginal Examination. No examination of an abdomen for the diagnosis of peritoneal disease can be complete without a *rectal examination* and, when possible in the female, a *vaginal examination.* This is particularly important in acute inflammatory lesions because it will often reveal a difference in tenderness on the two sides, which will aid greatly in the differential diagnosis. In women, an inflamed adnexa can be detected accurately upon vaginal examination by tenderness and induration of this region; if appendicitis is the cause of the inflammation, the adnexal region will be negative and the tenderness usually located higher up on the right side. Inspection of the cervix with a vaginal speculum may yield additional and important information; this is also true of proctoscopic examination.

ETIOLOGIC FACTORS IN PERITONITIS

Any inflammation of the peritoneum, whether caused by infection, trauma, or chemicals, may be classified as a peritonitis, but only that of bacterial origin is of much significance clinically, especially since the nonbacterial types heal so readily. If infection is spread diffusely throughout the peritoneal cavity, it is spoken of as general peritonitis in contrast to local peritonitis. It responds fairly well to antibiotics if there is no persistent source. If the source persists, as in a perforated appendicitis or perforated ulcer, antibiotics are of little avail; without *surgical treatment such lesions* are usually fatal. Even though general peritonitis responds favorably to antibiotics, local abscesses tend to form.

There are certain groups of organisms which are particularly virulent in the peritoneum, for example, *E. coli,* streptococcus, pneumococcus, tubercle bacillus, gonococcus, and staphylococcus. On many occasions, more than one organism will be present and may be demonstrable by culture. Such a mixed infection may or may not be true symbiosis. Many observers are of the opinion that various strains of gas bacilli are responsible for a great deal of the toxemia accompanying peritonitis caused, for example, by a perforated appendix.

There are numerous etiologic factors which may act in the production of peritonitis. These are described elsewhere in detail but are listed below to emphasize the variety and importance of the mechanisms:

1. *Appendicitis with perforation* is by far the most common cause of peritonitis and accounts for many deaths in the operated as well as nonoperated patients (Fig. 2). Early removal of the appendix lessens considerably the chance of a fatal outcome by eliminating the source of infection.

2. *Perforated peptic ulcer,* either duodenal or gastric, is an important and fairly frequent source of peritonitis, but the mechanism is quite different from that produced by a perforated appendix. Since the contents of the stomach and duodenum are practically sterile, the immediate bacterial contamination is usually insignificant. The gastric and duodenal contents are so damaging to the peri-

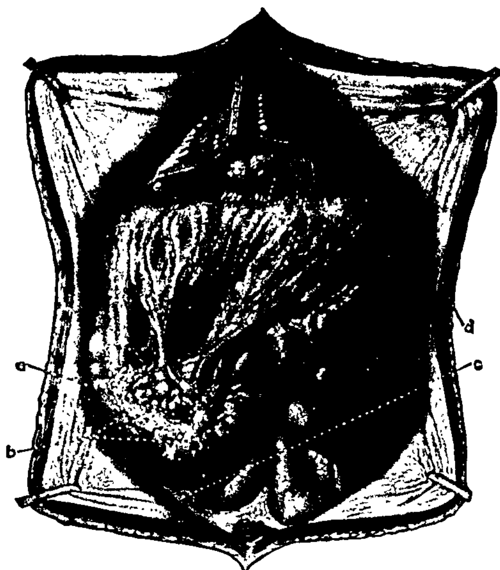

Fig. 2. Autopsy appearance of diffuse purulent peritonitis arising from a perforated (and therefore neglected) appendicitis. a, omentum adherent to appendix and adjacent coils of intestine; b, yellowish green protective plastic exudate; c, pus between coils of intestine; d, cloudy fluid found at a distance from the appendix. (From Babcock. Textbook of Surgery, W. B. Saunders.)

toneum, however, that even slight contamination (unless immediate repair is done) is sufficient to result in a serious bacterial peritonitis in 48 to 72 hours.

3. *Gonorrheal salpingitis* is a frequent source of peritonitis because of leakage of pus from the Fallopian tube, but the resultant infection usually remains localized and rarely produces the serious manifestations seen in appendiceal peritonitis.

4. *Peritonitis due to trauma* (caused by perforation of intestine, bladder, and so forth) is of special importance because of the difficulty in diagnosis created by the simultaneous presence of other injuries. Perforation of the intestine allows the direct contamination of the peritoneal cavity by fecal material including bacteria. The mechanism of the production of peritonitis due to contamination of urine is dependent upon chemical irritation with secondary infection.

5. *Peritonitis following celiotomy* is unfortunately an occasional complication of abdominal operations, much to be feared but usually avoidable. Among the factors producing peritonitis of this type should be mentioned: (*a*) leakage of an intestinal suture line, (*b*) contamination during operation, i.e., faulty technic, including particularly *virulent streptococci from the nose and throat*

of the operating room personnel, and (c) leakage of bile (bile peritonitis, see below).

6. *"Idiopathic" primary peritonitis* is a term frequently used to denote the fact that the pathogenesis of the peritonitis is obscure, although apparently blood-borne from a primary focus elsewhere. Streptococcus and pneumococcus peritonitis are types of peritoneal infection comprising this group.

7. *Tuberculosis* occasionally invades the peritoneal cavity but is usually secondary to an active lesion in the lungs, mesenteric lymph nodes, Fallopian tubes, and so forth.

8. There are numerous *miscellaneous lesions* capable of producing peritonitis which, when considered singly, are not of considerable importance because of their rarity. Diverticulitis with perforation (most commonly of the sigmoid) may produce a serious and fatal peritonitis unless operative repair or fecal diversion is performed soon after perforation. Meckel's diverticulitis may also give rise to peritonitis because of perforation through the wall of the diverticulum. Perforation of a typhoid ulcer of the ileum, and peritonitis secondary to puerperal sepsis were common several decades ago, but during recent years have practically disappeared.

A gallbladder may perforate because of acute cholecystitis, and the resultant leakage of bile into the peritoneal cavity may produce a serious type of peritonitis. Rarely, leakage of bile through traumatic rupture of the common duct, ulceration of the duct, and so forth, may result in *bile peritonitis*. The irritative action of bile on the peritoneum results in exudation of huge quantities of plasmalike fluid, frequently resulting in shock. The local protective properties are reduced, resulting occasionally in a severe inflammatory peritonitis, which usually becomes infected secondarily. Therefore, the seriousness of bile peritonitis is not related primarily to the bile itself but to the irritative quality of the bile, which may produce profound chemical alterations in the body or give rise to secondary infection in the inflamed area. The gangrenous tissue associated with a perforated gallbladder will no doubt also be an important factor in the development of infection and perhaps also in absorption of toxin from the necrotic tissue.

PERITONITIS DUE TO PERFORATION OF A VISCUS

Of the various types of peritonitis just enumerated, there are several whose pathology, manifestations, and treatment are similar. In this group should be mentioned appendicitis with perforation, perforated peptic ulcer, traumatic perforation of intestine, and postoperative peritonitis (Fig. 3). The predominating organism in peritonitis caused by such lesions is *E. coli,* with the streptococcus, staphyloccus, and proteus organisms occurring less commonly.

Pathology. The first evidence of peritonitis is a hyperemia and redness of the visceral as well as parietal peritoneum, which gradually loses its luster and assumes a grayish color. A clear fluid soon accumulates, but this exudate rapidly becomes cloudy and contains fibrin. On some occasions, fibrin appears to be deposited without the accumulation of free fluid. Within two or three days the fluid thickens and becomes true pus. In the meantime the fibrin and omentum attempt to mat various loops of intestine together so that the infection will remain localized and not be diffused everywhere throughout the peritoneal cavity. The success or failure of sealing of the perforated intestine or local lesion, with the development of a local abscess is dependent upon the rapidity of leakage and, to a less extent, upon the resistance of the patient and virulence of the organisms. If the leakage is slow, adhesions may form rapidly enough to form a local abscess and prevent diffusion of the intestinal contents of the various parts of the peritoneal cavity. Most of the fibrin is absorbed as the process heals, but if the damage has been great, permanent adhesions may result. The pathologic processes, such as local abscess, adhesions, and so forth, are discussed in more detail under Complications. In addition to the changes mentioned, if the peritonitis is diffuse, the entire bowel may become distended, paralyzed, and filled with gas and fluid, a condition known as *paralytic ileus* (see p. 823). The systemic effects of inflammation in general are usually pronounced. Because of vomiting and failure of absorption of fluid from the damaged intestine, marked dehydration may also be present. In general, there are cer-

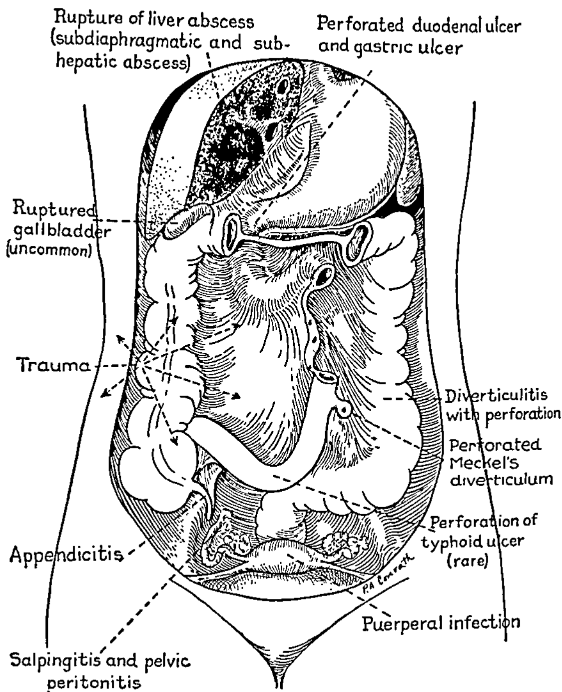

Fig. 3. Schematic drawing to illustrate the numerous lesions which may give rise to local or general peritonitis

tain pathways by way of which infective fluid from perforative lesions may spread to other parts of the peritoneal cavity. For example, purulent exudate produced by a perforated appendix may reach the subphrenic space by way of the right external paracolic groove. Fluid escaping from a perforated peptic ulcer may spread from the right subhepatic space by overflowing anteriorly across the colon into the right infracolic space, thence into the pelvis or across the ascending colon to the right external paracolic groove.

Clinical Manifestations. The clinical manifestations will depend largely on the stage of disease and the location, nature, and severity of the primary or causative lesion. The manifestations produced by the causative lesion itself should, if possible, be distinguished from those of peritonitis; they are usually elicited by a careful history. The term "peri-

toneal irritation" is used to describe an early inflammatory lesion which frequently precedes actual peritonitis. Obviously, any diffuse peritonitis starts as a local process, but the term "local peritonitis" implies the confinement of the infection to a local area by such barriers as omentum, adhesions, and adjacent organs. Whether a local or general infection is present will therefore depend not only on the lapse of time but also on the resistance of the patient.

LOCAL PERITONITIS. Pain is the first complaint and is usually so severe as to confine the patient to bed. Local tenderness is demonstrable early and is located over the lesion, in contrast to the referred pain which may be experienced during the onset. Anorexia and nausea are almost always present, but vomiting is variable. Muscle spasm is constant over the lesion, but is not present over the entire abdomen. Tachycardia occurs early, but fever is seldom encountered for 18 to 24 hours. After a few days, the above symptoms lessen in severity and, as the muscle spasm decreases, the local abscess may be palpable through the abdominal wall as a definite mass. Leukocytosis is rarely absent as long as pus remains undrained.

It is extremely important to discriminate between a true rigidity of the muscles of the anterior abdominal wall and voluntary muscle spasm which may be incited by rough palpation, cold examining hands, and so forth. True muscle rigidity, which is so pathognomonic of peritoneal irritation is of involuntary origin, may be elicited constantly and cannot be eliminated by distracting the patient. When examining a patient for muscle spasm and local tenderness, the examiner must assume a reassuring attitude and be gentle during the examination. If pain is inflicted, voluntary muscle spasm is incited and the information gained may be inaccurate. For this reason, it is usually wise not to palpate the area complained of until the rest of the abdomen has been examined.

DIFFUSE (GENERAL) PERITONITIS. Diffuse pain is one of the first symptoms to appear but is usually secondary to the primary lesion as is exemplified by the severe pain and prostration produced by a perforated peptic ulcer. On the other hand, there is little pain associated with peritonitis produced by a leaking suture line, except that produced by distention. A few hours after the onset of the diffuse infection, anorexia and nausea appear and are soon followed by vomiting. Localized muscle spasm, preceded by diffuse tenderness, is manifested early and after several hours may be sufficient to present a boardlike sensation to palpation. Usually, however, the muscle spasm and tenderness, while diffuse, are more marked over the site of the perforation. Leukocytosis (10,000 to 30,000) is manifested early and usually persists. Tachycardia develops early, but fever is encountered only after 18 to 24 hours. The pulse gradually becomes weak and poorly sustained, and is one of the most reliable means of estimating the severity of the infection and the physical condition of the patient relative to operability and prognosis. Distention (Fig. 4) due to paralysis of the intestine (paralytic ileus) may appear within 24 hours, but rarely becomes pronounced for two or three days. This cessation of peristalsis, obviously resulting in constipation, is one of Nature's methods of preventing the spread of the infection. The dullness of free fluid may be demonstrable in the flanks. As noted previously, the clear fluid which forms first *rapidly turns to pus, which at operation is ob*served to have a characteristically foul fecal odor if the infection is caused by *E. coli*, as is usually the case.

After a time the pain becomes less noticeable, but the vomiting (more often slight regurgitation) persists regardless of whether or not food or water is taken by mouth. Occasionally, the vomitus is fecal, indicative of regurgitation from paralyzed ileum. Restlessness is pronounced and unless adequate sedation is given, the patient will suffer physically from lack of sleep. After two or three days all the classical signs of peritonitis will be demonstrable. The Hippocratic facies, consisting of anxious expression, sunken and staring eyes, pinched nose, and dusky pallor is pathognomonic of a diffuse peritonitis, but is of little value therapeutically, since it is a late manifestation. The patient retains consciousness until a short time before death. Since the introduction of intestinal decompression, parenteral fluids, and chemotherapy in the treatment of peritonitis, many of the cardinal manifestations mentioned above are

Fig. 4. Distention is one of the most constant of the signs of peritonitis, but is slow in forming, usuall requiring two or three days for its maximum development. Part of the swelling is due to accumulatio of exudate but most of it is due to paralytic ileus which is produced by the peritoneal infection.

rarely seen. Under this therapy as described in detail later, the patient may pass safely through the peritonitis phase of the infection, but later may develop abscesses which usually require drainage (Fig. 5).

Postoperative peritonitis produces manifestations which may be much more insidious. The abdominal pain, tenderness, and muscle spasm are much less pronounced. Moreover, the pain produced by the peritonitis is apt to be mistaken for the abdominal discomfort incident to laparotomy. Vomiting and distention are quite constant. Frequently, tachycardia with a gradually weakening pulse, fever, distention, and occasional vomiting are the only demonstrable manifestations, but the diagnosis should not be difficult, especially if other complications (such as wound infection or pneumonia) capable of producing a similar clinical picture are excluded.

The severity of symptoms is dependent upon many factors, among which should be mentioned etiology, virulence of the organism, age of the patient, and type of treatment. In children, peritonitis develops rapidly, usually presenting all of the classical symptoms and signs, whereas in the aged, progression of the infection may be slow and atypical which is also true of postoperative peritonitis. For example, pain, muscle spasm, and even fever may be insignificant or absent. In the aged, even though few manifestations are exhibited, the prognosis is nevertheless poor and in fact worse than in children.

Differential Diagnosis. In no other group of disease is it so necessary to make an early accurate diagnosis as it is in the diseases leading to peritonitis, because early operation is often essential to the prevention of a fatal outcome. The number of diseases capable of simulating or producing peritonitis are innumerable and, at times, offer serious diagnostic difficulty. In reality, it is not necessary to establish accurately the cause of the peritoneal manifestations, but it is absolutely essential to make the correct decision as to whether or not an operation should be performed, since an error in this decision is serious and may lead to a fatality. In a consideration of differential diagnosis of the types of peritonitis it may therefore add to clarity to classify those diseases, which are discussed in detail later, into three groups: 1. diseases producing peritonitis for which operation is imperative; 2. diseases not associated with peritonitis, but for which operation is imperative or advisable; and 3. diseases not producing peritonitis and for which operation is contraindicated.

1. *Diseases Producing Peritonitis and for which Operation Is Imperative.* A patient with a general peritonitis caused by a *perforated appendix* may present such diffuse tenderness and muscle rigidity that the source of the infection will be undetermined. The diagnosis can perhaps best be made by careful consideration of the history, supported by the fact that the maximum tenderness and

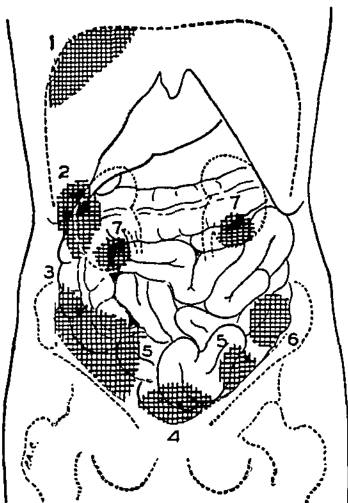

Fig. 5. Common sites for the location of intra-abdominal abscesses. 1, above and behind the liver (subdiaphragmatic), commonly secondary to suppurative appendicitis. 2, inferior surface of the liver (subhepatic) may follow suppurative appendicitis or acute cholecystitis with rupture of the gallbladder. 3, right lower quadrant, the common site for an abscess following suppurative appendicitis. 4, pelvis, may be secondary to appendicitis or acute pelvic inflammatory disease 5, tubo-ovarian region, secondary to salpingitis. 6, region of the sigmoid, secondary to ruptured diverticulitis. 7, about the lower pole of the kidneys (perinephric abscess).

muscle spasm will be located over the right lower quadrant. While the appendix is unperforated, the pain is not diffuse but usually located in the right lower quadrant. If the peritonitis is caused by a *perforation of a peptic ulcer* the point of maximum tenderness is more apt to be in the upper abdomen, but of more importance is the fact that the onset of pain, which is confined to the epigastrium, at least for a few hours, will be sudden and be of much greater severity than that produced by appendicitis. Moreover, the patient is invariably severely prostrated very soon after the perforation. An x-ray taken with the patient in a sitting posture will almost always reveal a collection of gas under the diaphragm, especially in the right side.

The symptoms of peritonitis caused by perforation of an *inflamed diverticulum* of the sigmoid differs from the other types of peritonitis in that the pain at the onset practically always is confined to the left lower quadrant unless the peritonitis becomes general. Palpation of the abdomen will likewise reveal the tenderness and muscle spasm located to the greater extent at least, in this area. Perforation of a diverticulum occurs more commonly in elderly people than in young adults.

An accurate diagnosis of an ulcerated or perforated *Meckel's diverticulum* may be difficult. About the only diagnostic feature, especially in its differentiation from peritonitis of appendiceal origin, is the location of maximum pain, local tenderness, and muscle spasm, which is usually demonstrable outside the right lower quadrant and frequently in the neighborhood of the umbilicus. Moreover, blood may at times be found in the stool.

Early diagnosis of a perforation of a *typhoid ulcer* may be difficult because of the existence already of considerable abdominal tenderness and pain and because of its rarity today. The perforation may not be accompanied by severe pain and muscle spasm, which are seen in patients with rupture of a peptic ulcer, but the presence of the symptoms and signs of typhoid fever should, of course, prevent confusion with such conditions, the other more common sources of peritonitis requiring operation. *Acute cholecystitis* is ushered in almost invariably with severe pain in the right upper quadrant, radiating frequently to the tip of the scapula and followed by fever, leukocytosis, and tachycardia with or without jaundice. There is local tenderness and muscle spasm. All signs increase sharply if the gallbladder perforates, especially if it occurs free into the peritoneal cavity. Perforation makes operation urgent. In the absence of perforation, surgeons differ as to whether or not operation is indicated for acute cholecystitis.

2. *Diseases Not Producing Peritonitis but for Which Operation Is Imperative or Advisable. Intestinal obstruction* because of distention may be difficult to differentiate from peritonitis, but an accurate consideration of the history, particularly as related to the onset and type of pain, will usually lead to the correct diagnosis. Fever, tachycardia, and leukocytosis are less common in intestinal obstruction. The pain of peritonitis is usually constant and confined to one area, whereas the pain associated with intestinal obstruction is intermittent and inconstant, coming on in cramping attacks, lasting a minute or two, and subsiding for an equal length of time. Visible peristalsis will be demonstrable through the anterior abdominal wall, except in obese patients, and in the late stage when the intestine is paralyzed. Likewise, auscultation will reveal an unusual amount of peristaltic gurgling except in the late cases, in contrast to the silent abdomen of peritonitis. If a loop of gangrenous gut is present (strangulation), the pulse will be rapid and the patient will appear unusually ill considering the duration of his illness. It is important to note that intestinal obstruction is usually secondary to a pre-existing lesion, such as hernia (strangulated hernia), tumor (e.g., carcinoma of the colon), and adhesions (produced by operation or inflammation). In infants and young children, especially the former, *intussusception* is commonly observed and will present many of the manifestations of peritonitis, including vomiting and prostration. However, fever is not present; mild abdominal tenderness is noted in contrast to the acute tenderness and muscle spasm which accompanies peritonitis. A mass in the region of the ascending, transverse, or descending colon is practically always demonstrable. If the intussusception has been present for many hours there is practically always a history of bloody diarrheal stools, or the passage of pure blood.

Acute mesenteric thrombosis is a rather uncommon condition frequently associated with, but not responsible for, peritoneal suppuration except, perhaps, in the terminal stage of the disease. It may occur in supposedly healthy persons without antecedent peritoneal symptoms or obvious disease. The onset is dramatic, with intense pain, and is associated within a few hours with the major manifestations of shock. If the colon is involved, the shock will be more intense than when the small intestine is affected. Examination will sometimes reveal a tender tubular mass which represents the loop of intestine, the vessels to which are thrombosed. A mild bloody diarrhea is not uncommon. Regardless of the presence or absence of diarrhea, blood-stained fecal matter will usually be found in the rectum. Muscle spasm is usually not so pronounced as it is in peritonitis with equally toxic manifestations. On many occasions, the intestine attached to the mesentery containing the involved vessels will become gangrenous, thereby making resection imperative. On the other hand, gangrene may not be produced by the thrombotic process; in that event, the

condition should obviously be classified in group 3, below.

3. *Diseases Not Producing Peritonitis and for Which Operation Is Contraindicated.* *Acute pancreatitis* is associated constantly with severe pain in the epigastrium and frequently with nausea and vomiting. Muscle spasm in the upper abdomen is fairly constant. Leukocytosis is usually present. The amylase content of the blood and urine is almost always elevated early in the disease, but this elevation may not persist longer than 12 to 18 hours. In acute pancreatic necrosis (much less common than acute interstitial pancreatitis) shock may develop with a rapid, weak pulse. If the diagnosis can be made, operation is contraindicated, but often indeed lesions (e.g., perforated ulcer) requiring emergency operation cannot be excluded.

Pyelitis is frequently confused with lesions (e.g., appendicitis) producing peritonitis, thereby leading to the performance of a needless laparotomy. Pyelitis occurs in patients of any age, but in children is most often confused with lesions demanding laparotomy. The disease is much more common in girls than in boys and may be ushered in insidiously with pain on one side of the abdomen, associated with abdominal tenderness, mild muscle rigidity, nausea, and vomiting. Chills are not uncommon. Careful examination will rarely fail to reveal the fact that the most tender area is located posteriorly over the kidney. The presence of pus cells in the urine should lead one to the correct diagnosis of pyelitis. Obviously, if the left kidney is affected, localization of the pain over the left side of the abdomen should help eliminate acute appendicitis in the differential diagnosis.

Acute enteritis due to "food poisoning," i.e., caused by organisms of the colon and proteus groups, may offer considerable diagnostic difficulty because of the presence of nausea, vomiting, and abdominal pain. The pain and tenderness, however, are usually poorly localized and are inclined to shift from one area to another. Moreover, nausea and vomiting are apt to precede pain, in contrast to the sequence in lesions leading to peritonitis. Muscle spasm of consequential degree is likewise rarely present. Leukocytosis usually does not occur. Frequently, a diarrhea is present, thereby issuing a warning that the diagnosis of early peritonitis must be quite definite before laparotomy is performed.

Acute salpingitis is frequently confused with lesions (particularly appendicitis) for which laparotomy is indicated. If the tenderness and pain are limited to the left side there will, of course, be no confusion with appendicitis. The history of frequency and burning on urination (urethritis), vaginal discharge, and positive findings on vaginal examination should lead to the correct diagnosis of salpingitis. In this disease, the severe manifestations of toxemia characteristic of peritonitis caused by *E. coli* are absent. Peritonitis, limited usually to the pelvis, frequently results from acute gonococcal salpingitis and, in that respect, does not fit literally into this group, but operation is distinctly contraindicated regardless of whether or not the infection extends beyond the pelvis.

In children, *acute mesenteric lymphadenitis* is rather commonly observed and usually presents a clinical picture which is differentiated from early peritonitis with extreme difficulty. Abdominal tenderness, pain, nausea, vomiting, leukocytosis, and even other signs of peritonitis may be present and develop acutely. About the only evidence which can be used to eliminate the diagnosis of peritonitis is found in the type of tenderness and pain. The pain and tenderness will usually not be localized to the right lower quadrant as it is in the most common disease (appendicitis) to be eliminated in differential diagnosis. The muscle spasm is apt to be diffuse and likewise located outside the limits of the anatomic location of the appendix.

There is still another group of patients, including both children and adults, which offers serious difficulties in differentiation from peritonitis; this syndrome consists of abdominal pain and mild muscle spasm, which is presumably a *peritoneal irritation secondary to upper respiratory infections*. Anorexia and nausea are common, but vomiting is rare. Leukocytosis is usually absent. The presence of fever is variable, though usually present, and tends to support the decision to refrain from a laparotomy, especially if the manifestations are suggestive of a localized peritonitis and not a general peritonitis. The performance of a laparotomy in these individuals

may, of course, be detrimental and damaging, and should be avoided if the diseases for which laparotomy is imperative can be reasonably excluded.

Ulcerative colitis (*"idiopathic" or amebic colitis*) may offer more difficulty in differentiation from the lesions necessitating operation. In the former instance there is practically always a history of pre-existing abdominal tenderness and pain. Vomiting is rarely present. Amebic dysentery of the acute type simulating peritonitis is usually accompanied by fever, diarrhea, and blood in the stool. Differential diagnosis is extremely important in amebic dysentery, since the erroneous performance of a laparotomy in this disease is very deleterious and often fatal. The pain in *spastic colitis* is usually mild and rarely localized. Nausea, vomiting, and leukocytosis are rarely present.

There are a few *miscellaneous diseases* which, on rare occasions, may produce pain and other peritoneal manifestations in the abdomen. Of this group, angina pectoris and pneumonia should be mentioned particularly. Although the pain of coronary thrombosis and occlusion (angina pectoris) may occasionally be referred to the epigastrium and be accompanied by muscle spasm, it will rarely be difficult to differentiate the disease from peritonitis, because of the history of pain in the left side of the chest and left arm, and the relative infrequency of vomiting and leukocytosis. It must be remembered, however, that vomiting may be present in acute coronary occlusion. When *pneumonia* occurs in a lower lobe there occasionally is sufficient diaphragmatic pleurisy to produce pain, tenderness, and muscle rigidity of referred character in the upper part of the abdomen. The presence of pulmonary signs, such as increased respiratory rate, respiratory grunt, sharp limitation of abdominal signs to the upper abdomen, will rarely fail to differentiate the disease from a peritonitis. Occasionally *acute nephritis*, particularly if bilateral, will present generalized pain, tenderness, and muscle rigidity over the abdomen, simulating peritonitis. Urinary findings should lead one to the correct diagnosis. The importance of establishing a correct diagnosis can be appreciated when one considers the fact that a laparotomy performed in any of the three diseases mentioned above (pneumonia, coronary occlusion, and acute nephritis) is apt to lead to a fatal outcome.

Treatment. Prophylactic therapy in reality is most important insofar as peritonitis is secondary to other lesions or to contamination which, if prevented or treated promptly, will eliminate infection of the peritoneal cavity. For example, when dealing with acute appendicitis, appendectomy should be done as soon as possible after the diagnosis is made, hoping to remove the diseased appendix before it perforates and contaminates the peritoneal cavity. Likewise, closure of a perforation of an intestine should be done as early as possible after injury, since the possibility of the development of a general peritonitis is dependent for the most part upon the length of time intervening between the injury and operative repair. The care with which the tissues are handled during the operation is also important. Rough handling may encourage the development of infection or even result in a tear or puncture of a loop of intestine, an accident which might lead to a fatal peritonitis unless repair is instituted.

Once a peritonitis is present, the question of operation is dependent almost entirely upon: 1. the source of the infection; and 2. the condition of the patient. Years ago, opinions differed as to whether or not immediate appendectomy should be performed in advanced peritonitis resulting from a *perforated appendix;* some surgeons considered it safer to treat the patient conservatively for a time. However, since the advent of penicillin and other antibiotics, operation can be performed much more safely in the face of a general peritonitis. Since a continuous leak in the peritoneal cavity is dangerous, it can now be said that immediate operation is preferable. About the only warning of danger lies in the axiom that no patient should be operated upon if he is so ill as to make it appear that operation is going to result in a fatality. Under such conditions nonoperative procedures should be instituted which may so improve the general condition as to make operation safer. Operative procedures are designed to remove the source of the infection if possible (e.g., appendectomy), to divert fecal stream, or to drain an abscess at the site of perfora-

tion in order to prevent further contamination from the peritoneal cavity.

To prevent spread of peritonitis the gastrointestinal tract is put at rest by allowing the patient *nothing by mouth,* and by insertion of a nasal tube to obtain Wangensteen drainage. Intestinal decompression alone will reduce the distention markedly, providing the tube is kept open. For the purpose indicated, passage of the tube into the ileum has no advantage over a gastric tube.

Sufficient fluid to correct water and electrolyte deficits must be administered, primarily by the intravenous and subcutaneous route. Glucose may be given by vein in 5 or 10 per cent solution but not faster than 300 to 500 ml. per hour. A 5 per cent solution may be given at a rate of 500 ml. per hour with utilization, and a 10 per cent solution at relatively the same speed with 95 per cent utilization. To prevent protein starvation, amino acids should be added on occasions to the glucose for nutritional purposes. Parenteral vitamins are also indicated. An amount of fluid equivalent to that lost by decompression must be added to the 2,500 or 3,000 ml. designated as the early requirement; half of this should contain physiologic saline because of the salt lost in the decompression fluid. In patients long on a potassium-free intake, potassium chloride (4 grams per liter) will be needed to correct or prevent a potassium deficiency, which is particularly likely following correction of dehydration with saline alone. The restoration of electrolyte balance can be more safely carried out over the course of two or three days than by attempting to correct the deficiency quickly. Clinical observations of the correction of dehydration are the best index for the continued administration of this electrolyte solution. After correction of the initial hypochloremia, the administration of more than 6 or 8 grams of sodium chloride (in addition to that lost by decompression, and the like) per day is very apt to lead to salt edema, especially if hypoproteinemia is severe; in such a case, urine output is small. Transfusions of whole blood or of plasma are nearly always indicated especially to correct hypoproteinemia which follows actual loss of plasma into the peritoneal exudate and wall of the intestine.

Since patients with peritonitis are restless, it is extremely essential that they be given adequate sedation, especially at night, to encourage sleep. It is not sufficient that the patient rest, *he must receive a required amount of sleep daily* if his general resistance is to be maintained. Elevation of the head of the bed one or two notches will add to the comfort of the patient. It is thought by some that elevation of the head of the bed (Fowler's position) prevents absorption from the upper part of the peritoneal cavity and thereby lessens the severity of the disease. However, this has never been proved; moreover, this position is harmful in that it tends to keep the patient immobilized and promotes venous stasis, thus encouraging thrombosis in veins of the leg and thigh.

Enemas may be given, but are seldom of any value. Peristaltic stimulants, such as pitresson and prostigmin, are *contraindicated* because the excessive peristalsis produced by them would tend to spread the infection.

The application of heat by a bake or an electric pad is usually a source of comfort to the patient and is to be preferred to cold applications. Bisgard (2) has shown that the application of heat over the abdomen decreases peristalis whereas cold increases it. This fact may be utilized in the treatment as discussed in the preceding paragraph. When distention is prominent, Fine and associates (3) have reported reduction by having the patient breathe 95 per cent oxygen.

Chemotherapy is of definite value in peritonitis. Although *E. coli* is perhaps the most important organism encountered clinically in peritonitis, it is well known that the infection is often indeed a mixed one; the streptococcus and staphylococcus are commonly found with *E. coli.* If possible, the causative organisms should be isolated and sensitivity tests performed to determine which antibiotics should be given. Although pencillin is slightly active against *E. coli,* Bloemers and Kempf (4) have shown that its effect against that organism has been greatly exaggerated. Those authors found streptomycin much more effective than penicillin. There is evidence that aureomycin, chloromycetin, and terramycin (Long and associates, 5) may be as effective against most gram-negative organisms of the enteric group as is streptomycin. Aureomycin and terramycin can be

given intravenously. Since a pyogenic (gram-positive) organism is often present along with *E. coli,* it is usually desirable to give penicillin along with one of the three agents just mentioned (see also Chap. 5).

For the prevention of peritonitis, chemotherapeutic agents have been recommended for oral use in reducing the bacterial count of the intestinal tract, although not all surgeons believe this procedure exerts a significant role in the reduction of peritonitis. Succinylsulfathiazole, in a dose of about 12 grams per day, and sulfathaladine, in a dose of 6 grams per day, for three or four days before operation is given orally by many surgeons when intestinal resection, particularly of the colon, is contemplated. Streptomycin given in a dose of 0.5 gram by mouth four times per day will eliminate the coliform bacteria from the feces more rapidly than the sulfonamides just mentioned, namely, in 48 hours (6), except that slightly longer may be required in the presence of an ulcerating lesion. Tetracycline (7) and neomycin are also rapidly effective (8), within 48 hours.

An enterostomy in general peritonitis is not only a useless but an unnecessarily deleterious procedure; it rarely relieves distention as long as the bowel is paralyzed, whereas as soon as intestinal movements are regained sufficiently to result in expulsion of gas through the enterostomy opening, it will not be needed. It should be emphasized that the procedure of drainage in operations in peritonitis is often misunderstood; the insertion of drains does not drain the general peritoneal cavity. As shown by Yates (1905), drainage of the peritoneum affects only a local area and not the entire infected surface. Drains should therefore be used only to aid in evacuation of a definite abscess, or in exteriorizing a possible site of contamination or infection (e.g., an insecure anastomosis); they should always be of soft material (e.g., gutta percha) lest the intestine or other organs be injured by constant pressure of the drain. The sump drain used by some surgeons in peritonitis may be effective for a few hours, but beyond that period *cannot possibly* drain any part of the peritoneal cavity other than the local area. It disregards facts established three or more decades ago.

Complications. *A certain percentage of* patients recovering from diffuse peritonitis develop complications of one type or another. Most of the complications are serious, although with good medical care, a lethal outcome can usually be avoided.

1. *Local abscess* may be single or multiple and is formed by the localization of areas of infection by omentum, adhesions, loops of intestines, and so forth. They frequently form at dependent sites, such as the pelvis and the concavities of the peritoneal cavity, *early in the infection before adhesions are* formed. Abscesses also develop between loops of intestine and their mesentery and *under the diaphragm.* The persistence or recurrence of fever after the severe toxic symptoms produced by the peritonitis have subsided is usually the first indication of the presence of an abscess. A mass may or may not be palpable, depending upon the size and location of the abscess. Consistent local tenderness over the abscess is usually present, but muscle spasm is absent in most instances. If the abscess is in the pelvis, rectal and vaginal examination will almost invariably yield positive information as to its presence. Such manifestations as fever, anorexia, failure to gain weight, weakness, and restlessness, usually accompany peritoneal abscess. Occasionally, after a variable length of time, an abscess will rupture into a loop of intestine and in this way discharge its content. This is to be suspected when the local signs suddenly subside, and the fever suddenly drops. Occasionally, the pus will be seen in the feces if looked for, especially in abscesses which have broken into the rectum. *Evacuation by this* means is usually as effective as incision, but unfortunately occurs only after the abscess has been present for many days or weeks. Incision and drainage are usually indicated but may be delayed if definite regression is revealed after a day or two of conservative treatment. Masses which consist primarily of inflamed omentum and adherent loops of bowel regress very satisfactorily following conservative treatment, but true abscesses will require drainage unless they rupture into the bowel. If incision is resorted to, drains should, of course, be left in the wound and, if the cavity is large, should not be removed for four or five days or longer. A Penrose *drain (tube of thin soft rubber),* a rolled strip

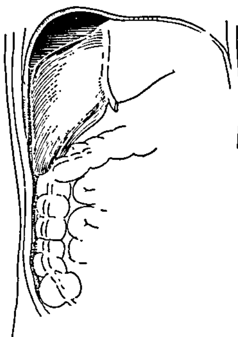

Fig. 6. Pathway of spread of infection into the subdiaphragmatic space with formation of an abscess. Cross-section to how the relationship to other organs. The shaded track along the ascending colon indicates the probable path of the infection in its migration to its present location. This pathway rapidly becomes sealed, however, with adhesions and scar tissue.

of rubber dam, or a cigarette drain (rubber dam around gauze) are drains most often used. In general, abscesses should not be drained across the free peritoneal cavity.

2. *Subdiaphragmatic* (*subphrenic*) *abscess* presents features which are so different from those of other intraperitoneal abscesses that it is considered separately. An abscess may develop under the diaphragm as a complication of almost any infection within the peritoneal cavity. Inflammatory lesions of the liver and biliary passages, stomach or duodenum, and appendix account for about 60 per cent of the cases (Hochberg, 9). At times it is difficult to understand how the infection travels upward above the liver from the numerous sources in the peritoneal cavity (Fig. 6). As would be expected, the majority of abscesses are on the right side. Dividing the right subphrenic space into posterior superior, anterior superior, and anterior inferior, Ochsner and associates (10) found the posterior superior space to be involved in 34 per cent of a large collected series. Next in frequency was the left anterior inferior space (20.5 per cent). Not all subphrenic infection proceeds to suppuration. Details of diagnosis may be found in the splendid article by Hochberg (9).

The existence of a subphrenic abscess should be suspected when the fever (produced by the initial lesion), which may have subsided somewhat, becomes more elevated and irregular. Systemic symptoms such as anorexia, weakness, sweating, malaise, nausea, and occasionally vomiting may be present. Pain is insignificant and is rarely of any aid in the localization of the abscess which is presumed to exist. However, palpation may reveal slight tenderness over the twelfth rib posteriorly, or along the costal margin anteriorly (depending on the location of the abscess). It may therefore be of some aid in determining the location of the abscess; otherwise abdominal examination is usually negative. The leukocyte count is usually markedly elevated. When a subdiaphragmatic abscess is suspected, the limits of hepatic dullness should be observed closely by percussion from day to day. However, the x-ray is of greater value and will be more accurate in determining the degree of elevation of the diaphragm. This observation is important since a subdiaphragmatic abscess rarely occurs without an elevation of the diaphragm on the affected side (Fig. 7). However, ele-

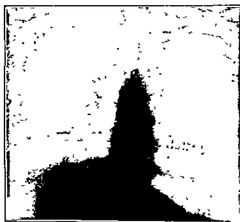

Fig. 7. Roentgenogram revealing elevated diaphragm (right) caused by subdiaphragmatic abscess resulting from perforated appendicitis. By far the majority of subdiaphragmatic abscesses occur on the right side.

Fig. 8. Anteroposterior and lateral view of subdiaphragmatic abscess containing gas. The right diaphragm is markedly elevated. Gas formation is unusual, but is pathognomonic of subdiaphragmatic abscess when found. Patient had a gastric resection performed several weeks prior to the time these x-rays were taken.

vation of the diaphragm is by no means pathognomonic of subphrenic abscess, since it may be elevated by numerous lesions in the absence of pus. Absence of respiratory excursions of the diaphragm, as noted fluoroscopically, is an additional manifestation of diagnostic value. A positive diagnosis can be made by x-ray if gas exists in the abscess cavity and is revealed on the film by the presence of a fluid level (Fig. 8). However, this situation will not be found in more than 20 per cent of cases. Aspiration should not be performed because of the danger of perforation of intestine, and hemorrhage. Pleurisy with sterile effusion on the affected side is the most common sequel and may be of diagnostic aid (Fig. 9). Other complications, such as rupture of the abscess into the pleural or free peritoneal cavity, are serious and are usually indicative of neglect.

As soon as the diagnosis is made, drainage should be instituted, provided the physical condition of the patient permits. Ochsner and associates (10) have emphasized the advisability of draining subphrenic abscesses extraserously, i.e., without entering the pleural or peritoneal cavity. Abscesses in the most common location, i.e., in the right posterior superior space (Ochsner), may best be drained

Fig. 9. Subdiaphragmatic abscess associated with pleural effusion. The dotted line represents the level of the right diaphragm. The shadow above the elevated diaphragm is caused by fluid in the pleural cavity—a common complication. This fluid usually remains sterile unless treatment is delayed or neglected; perforation through the diaphragm occurs under such conditions.

by excising the twelfth rib and incising into the subphrenic space at the level of the spinous process of the first lumbar vertebra. If the abscess is located anteriorly, it may be reached extraperitoneally by an incision along the costal margin, dissecting the peritoneum from the diaphragm upward until the abscess is reached. Only occasionally will it be necessary to drain through a lateral incision. Penicillin and other antibiotics should be given but are of little value in treatment of the abscess without surgery except that, no doubt, small abscesses will frequently be resolved. Likewise, as has been emphasized by Gerwig and Blades (11), antibiotics are surprisingly ineffective in preventing the formation of subdiaphragmatic abscesses.

3. *Intestinal obstruction* resulting from contractions of fibrous adhesions is not at all unusual and, if complete, may demand immediate release of the obstructed loop. Obstruction may be produced in this manner as early as three to four days following the onset of the peritonitis but usually occurs later (two to three weeks) and after the symptoms of the infection have become negligible. *Adhesions* which do not absorb are capable of producing obstruction, partial or complete, years after the attack of peritonitis. Except for intestinal obstruction, adhesions disclose little or no evidence of their presence. Details of intestinal obstruction are discussed in the following chapter. Fortunately, most of the obstructions occurring during the first few postoperative days can be relieved by intestinal decompression. Usually the relief achieved by decompression is only temporary, but in these early cases it is more often permanent, since the adhesions shrink or atrophy as the inflammation subsides.

4. *Pylephlebitis* or inflammation of the portal vein (accompanied usually by thrombosis) is an occasional and serious complication of peritonitis. The process may start in some of the extrahepatic tributaries of the portal vein and reach the major trunk by extension. One of the most reliable symptoms of pylephlebitis is the rather sudden occurrence of frequent chills along with an intermittent type of fever with sharp elevations and recessions. There may be few additional manifestations, perhaps icterus, tachycardia, slight abdominal tenderness, distention, signs of ascites, enlargement of the liver, and occasionally bleeding within the intestinal tract (see Ch. 31). Penicillin and one of the antibiotics active against gram-negative bacilli should be given as soon as the lesion is suspected. The disease, however, is extremely serious, and frequently results in death because of infection and portal obstruction.

5. *Pyogenic abscess* of the liver (see p. 667) may be encountered as a complication of peritonitis and, in most instances, is probably caused by an extension of the infection by way of the portal vein into the small intrahepatic tributaries. In many instances, the abscess formation will be multiple, in which case death almost always ensues. Suppurative cholangitis may likewise be responsible for multiple abscesses but is associated only with infections of the biliary tract. Multiple abscesses may coalesce into one large cavity, but when a single abscess is present it is usually caused by amebic infection. Operation is indicated as soon as the diagnosis of pyogenic abscess is made, in the hope that the abscess may be single and can be drained. Chemotherapy should be used as soon as the lesion is suspected. If the causative organism is a streptococcus or staphylococcus, good effects can be expected.

6. *Gastric dilatation* is a frequent complication of peritonitis as well as of abdominal operations in general; if untreated, it may produce damaging effects because of the mechanical pressure exerted upon the heart, lungs, and other viscera by the dilated stomach. The diagnosis should be suspected when there is persistent hiccup or frequent vomiting (or regurgitation) of small quantities of fluid. Gastric dilatation is in reality a part of the paralytic ileus which constantly accompanies peritonitis and, from a literal standpoint, perhaps should be considered as a manifestation and not a complication. Frequent gastric lavage or continuous "nasal suction" should be instituted.

7. There are numerous *miscellaneous complications* which may develop, many of which are extremely serious. Death from peritonitis is usually attributable to the systemic effects of the peritoneal infection with or without *septicemia.* As previously stated, *pneumonia* is a frequent complication of peritonitis, and commonly is a terminal feature.

Myocardial insufficiency, although secondary to other causes, is one of the main factors in the fatal termination.

OTHER VARIETIES OF PERITONITIS

Most of the clinical manifestations described in the previous pages of this chapter apply specifically to peritonitis secondary to perforation or contamination and largely caused by the colon bacillus. The following types of peritonitis are caused by different organisms and may present different clinical manifestations and therapeutic problems from the types of secondary peritonitis already considered. The infections produced by pneumococcus and streptococcus are the ones most frequently spoken of as *primary or idiopathic* peritonitis. In a study of 158 cases of primary peritonitis in children, Gross (12) found the hemolytic streptococcus to be the cause in 99, and the pneumococcus in 50.

1. **Pneumococcal Peritonitis.** This is a disease limited almost exclusively to children and occurs much more frequently in girls than boys. This latter feature has led some observers to conclude that the organism, on some occasions at least, gains access to the peritoneal cavity by way of the genital tract (vagina, uterus, and Fallopian tubes). This must be considered only one of the etiologic mechanisms, however, since pneumococcal peritonitis occurs as a complication of such diseases as upper respiratory infection, pneumonia, pleurisy, and nephritis, in which case it is blood borne. The length of time intervening between the onset of the original infection and the peritonitis varies from a day or two to many weeks, depending upon the severity and chronicity of the disease. Commonly, one of the first evidences of this intra-abdominal infection is the development of a diarrhea. The symptoms and signs are similar to those produced by the colon bacillus, except that the pain, even at the onset, is apt to be diffuse and poorly localized and examination reveals no local point of tenderness except in the late stage when an abscess may have formed. Vomiting is variable, at times being a prominent manifestation. The leukocyte count is markedly elevated. Palpation reveals diffuse tenderness with a doughy resistance but, in most instances, absence of boardlike rigidity. Occasionally, bulging is noted at the umbilicus (Fig. 10), representing nature's attempt to effect drainage. Blood culture may reveal the organism early in the disease. If much fluid is present in the abdomen, a carefully performed aspiration will be safe and will yield enough fluid from which smears and cultures will reveal the correct diagnosis. If aspiration is not feasible, or yields no fluid, it may be advisable to make a small exploratory incision under local anesthesia to obtain fluid for diagnostic purposes or to rule out appendicitis. Opinions differ as to the advisability of operation but Gross (12) favors a small incision for diagnosis and drainage. The character of the exudate in pneumococcal peritonitis varies but is usually thick, fibrinous, mucoid, greenish in color, and comparatively odorless. As soon as the diagnosis is made, chemotherapy is instituted with penicillin and antipneumococcus serum. Intestinal decompression with the nasal tube, administration of saline and glucose, and the like, as described previously in this chapter, may be indicated. Chemotherapy shortens the progress of the disease and minimizes the incidence of local abscesses.

2. ***Streptococcal Peritonitis.*** This type of peritonitis may occur as a postoperative complication; occasionally the streptococcus is the organism found in the pus produced by perforated appendicitis; however, it is more often encountered as an associated manifestation of respiratory diseases of some sort. Since streptococcal peritonitis is so commonly secondary to diseases treated effectively by chemotherapy, its incidence has decreased considerably in recent years. Occasionally no evidence of the original focus of infection can be found. The term "idiopathic or primary peritonitis" is therefore commonly applied to this type of infection as it is also to pneumococcal peritonitis, but perhaps correctly so only to the cases in which the portal of entry is not discernible and the infection is presumably blood borne. Except on occasions when streptococcal peritonitis is secondary to appendicitis or operative contamination, it is usually encountered only in children or infants (especially the latter). Regardless of the etiologic factor, the disease, before the days of chemotherapy, was

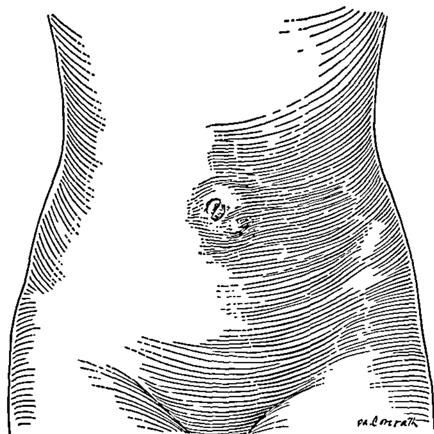

Fig. 10. Bulging at the umbilicus in pneumococcus peritonitis. This is nature's attempt to effect drainage; indeed, in neglected cases perforation occurs here with subsequent evacuation of an abscess cavity. This phenomenon occurs very uncommonly in any other type of peritonitis; it is usually a late manifestation, but in this particular instance occurred on about the third day of the peritonitis.

serious and associated with a high mortality. The manifestations are fulminating, and include practically all those encountered in peritonitis caused by *E. coli*. Because of the beneficial effect of chemotherapy, it is extremely important just as in pneumococcal peritonitis, that the diagnosis be made, resorting to a small exploratory incision for drainage and confirmation of diagnosis (12). An incision is often indicated because peritonitis due to appendicitis and other lesions requiring operation is difficult to exclude. In addition to chemotherapy, the various therapeutic measures, including parenteral fluids and gastric lavage, as described previously, should be instituted as indicated. The mortality rate in streptococcal peritonitis is in general higher than in the pneumococcal type, but should be low, if therapy is instituted early in the disease.

3. **Gonococcal Peritonitis.** This disease is confined entirely to females and is secondary to infection in the Fallopian tubes from which site the exudate containing the organisms (gonococci) breaks into the peritoneal cavity, but rarely ascends above the brim of the pelvis. There are always localizing signs in one or both of the adnexal regions, a manifestation which in itself should be sufficient to make a diagnosis, especially if a vaginal examination is made. Occasionally, however, if only the right Fallopian tube is involved the disease may be confused with perforated appendicitis. The peritonitis usually remains local and the patient does not appear as ill as in appendiceal peritonitis, even though there may be high fever and excruciating tenderness in the lower abdomen. The pulse rate is not as rapid and the face does not have the pinched, tired, and flushed appearance seen

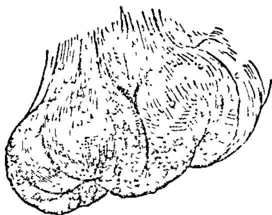

Fig. 11. Tubercles upon the peritoneum. (From Homans. Textbook of Surgery, Charles C Thomas.)

in patients with peritonitis caused by *E. coli*. Fatalities are rare. Occasionally, generalized abdominal rigidity, tenderness, and distention may be present which, however, subside spontaneously with the pelvic inflammation. The infection responds very well to penicillin, particularly if therapy is instituted early. Operations should not be performed in the acute stage; but months after the infection, it may be necessary to remove the Fallopian tubes, particularly in cases not receiving early penicillin therapy (see also Ch. 40).

4. **Tuberculous Peritonitis.** The invasion of the peritoneum by tuberculosis is usually secondary to local lesions in the lungs, mesenteric lymph nodes, cecum, appendix, or Fallopian tubes. Occasionally it is a manifestation of acute miliary disease. In many instances, it appears that organisms swallowed in sputum invade the intestinal wall (e.g., cecum), escape by way of the lymphatics of the mesenteric lymph nodes, and in this way give rise to a peritoneal infection.

Pathologically, the peritoneal lesions are quite variable. On some occasions numerous tubercles (0.5 to 1 mm. in diameter) are scattered about the peritoneum (Fig. 11), which is reddened, but otherwise unaffected. On other occasions, caseous masses are encountered and adhesions are present. Ascites is frequently noted, the fluid being clear and straw-colored, turbid, or even thick and purulent. The fluid invariably has a high specific gravity (about 1.015). There is no definite relation of the type of lesion to the duration of the disease, except that the type associated with tubercles and mild ascites without adhesions is frequently encountered early in the disease, and the caseous masses with adhesions late in the disease.

The *clinical manifestations* are extremely variable both as to type and severity. Occasionally, there is a rather acute onset with abdominal pain, nausea, and vomiting. This type is frequently confused with appendicitis and, at operation, will reveal tubercles scattered diffusely over a slightly reddened peritoneum associated, perhaps, with a small amount of clear, straw-colored fluid. However, usually the onset is insidious. Abdominal pain may or may not be complained of, but it is rarely severe. Gradually the abdomen becomes distended because of the ascites. Anorexia and nausea, but rarely vomiting, are complained of; there is a gradual loss of weight and an associated anemia, weakness, and malaise. Constipation or diarrhea may be present. Fever is extremely variable, but is usually moderately elevated in the afternoon and evening, receding to normal or subnormal by morning. The diagnosis is difficult and on most occasions is made only at operation. When found at operation, search should be made within the abdomen for the primary site.

Very important in *treatment* are streptomycin, isoniazid, and the other drugs found useful in tuberculosis; celiotomy does appear in many instances to have a mysterious curative effect regardless of whether or not a focus of the infection can be found and removed. For this reason alone, celiotomy appears justifiable in most cases, unless the presence of serious lesions elsewhere (e.g., lungs) contraindicates operation. In any case, diagnosis is thus made certain. However, patients with caseous areas and dense adhesions are rarely benefited by operation.

TRAUMA

Because of lawlessness, high speed automobiles, and the mechanization of industry, injuries to the abdomen which lead to peritonitis are becoming important surgically, especially since delay in treatment or a mistaken diagnosis may result in a fatal outcome. Civilian injuries of the type mentioned will be discussed here. War wounds of the abdomen are discussed in Chapter 42.

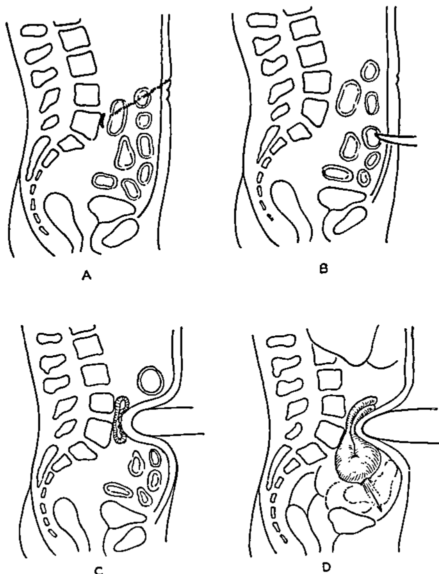

Fig. 12. Common mechanisms producing traumatic intestinal perforation. A, gunshot wound; B, stab wound; C, laceration of the intestinal wall by compression against the vertebral column by a blunt object; D, rupture of the intestinal wall by sudden compression of gas within the lumen.

1. **Rupture or Penetration of a Viscus.** Accidents resulting in perforation of an intra-abdominal organ, especially the intestine and bladder, may be sustained in one of three ways (Fig. 12): (*a*) A sharp object may penetrate the abdominal wall and perforate an intestine. Gunshot wounds of the abdomen are by far the most frequent example of this type of injury. Although the amount of bleeding resulting from a bullet wound of the abdomen is rarely sufficient to result in a fatal hemorrhage unless a major vessel is severed, in most instances a perforation of the intestine will be produced, which demands immediate repair because of the peritonitis which otherwise is bound to follow. (*b*) An intra-abdominal organ may be crushed and perforated, because of compression between two blunt objects or between a blunt object and the spinal column. In such a case there may be no external evidence of an intraabdominal injury or merely a slight contusion of the abdominal wall. (*c*) If a blow is sustained over the abdomen when the muscles are flaccid, there may be such a sudden and forceful expulsion of gas from one intestinal loop into another as to cause a rupture of the intestinal wall. A few instances of rupture of the colon

have been reported in which workmen have jokingly released compressed air near the anus of a fellow workman. The collapse resulting from a rupture of this type is profound in spite of the fact that little hemorrhage is produced, and most cases of this type are fatal, although operative therapy may be readily available and instituted. The serious effects are apparently due to the absorption of toxins (bacterial and otherwise) in the stool by the peritoneum.

The *clinical manifestations* of perforation or rupture of a hollow viscus, especially the intestine, are often overshadowed by the excitement of the occasion. However, severe *pain is experienced immediately unless the* patient is unconscious. A varying degree of shock, including such manifestations as tachycardia, weakness, and pallor, will be produced, dependent largely upon the amount of hemorrhage accompanying the intestinal injury. Local signs may be minimal at first, i.e., at a time when operation should be done. The most constant local signs are tenderness and muscle spasm which at first are confined to the injured area but soon spread to the rest of the abdomen. Unfortunately, as Musselman and associates (13) have emphasized, the early signs of rupture of the ileum and colon are less dramatic than those encountered in perforation of a duodenal ulcer. The surgeon must recognize the early minimal signs because waiting for frank signs of peritonitis before deciding to operate will usually result in so much delay that recovery will not take place. Tenderness is rather constant at the outset, but muscle rigidity may not be present for several hours. Nausea and vomiting will occur sooner or later, unless operative repair is instituted before vomiting takes place. An x-ray of the patient in the upright position may reveal gas under the diaphragm, a finding which is diagnostic of rupture of intestine or stomach. After a few hours, the leukocyte count becomes elevated, but fever is not present until the peritoneal contamination takes on the features of peritonitis (18 to 24 hours). Of the signs mentioned above, muscle rigidity, if present to a significant degree, is one of the strongest indications for operative intervention, so long as one can eliminate voluntary spasm, rigidity due to injury of the abdominal wall itself, and reflex spasticity from skeletal fracture, especially of spine or ribs. It should be emphasized, however, that for several hours after perforation of a viscus, particularly gunshot wounds of the stomach and small intestine, there may be an almost complete absence of gastrointestinal manifestations, including vomiting and muscle spasm; frequently, they are overshadowed by the evidence of prostration or primary shock. For this reason, the clinical manifestations are not nearly as important in deciding the question of operation as in the location of the wound, which is then the chief factor leading to the decision as to whether or not the *peritoneal cavity has been penetrated.*

Perforation or rupture of the bladder, ureter, or kidneys will present symptoms and signs similar to, but perhaps less severe than, those mentioned above. Diagnosis can usually be made readily by examining the urine for gross blood. The inflammation of the peritoneum produced by urine escaping into the peritoneal cavity may be conducive to the development of peritonitis and this complication may be the most important factor in the cases terminating fatally, especially those not treated by operative repair. On rare occasions, rupture of the base of the bladder or urethra may produce *extravasation of urine* into the subcutaneous tissues of the abdominal wall. This is a serious complication which may require expert judgement in its therapy; it is discussed in detail in Chapter 41.

The *treatment* of a ruptured viscus is, of course, surgical; the earlier the operation is performed (assuming the patient's physical condition permits it) the more likely is it to be followed by success. Indeed, when a penetration of the peritoneal cavity is produced (gunshot or stab wound), laparotomy is performed without regard to the presence or absence of the manifestations mentioned above. If shock is present and is not due to injuries elsewhere, it may be treated by transfusions or fluids while the operation is in progress as discussed under Intraperitoneal Hemorrhage. Occasionally, gunshot wounds of the abdomen are sustained without perforation of an intestine. The severity of the symptoms is much less pronounced in such instances, but the possibility of intestinal perforation is still

so great that the surgeon deems it unsafe not to perform a celiotomy; if the bullet has traversed any part of the peritoneal cavity in which a hollow viscus is normally present, an operation must be performed.

At operation, simple closure of perforations (whenever possible) is preferable to resection. Thorough search for puncture wounds and injury to viscera, including the retroperitoneal portions of the intestines, must be made. All free food or feces are removed gently by suction or with a moist sponge. If the large bowel is perforated or injured seriously, it is frequently safer to exteriorize the area than to close it by suture. If the bowel cannot be exteriorized, a colostomy will often be indicated. Drains are not indicated except occasionally down to the site of repair in the bowel. After operation, transfusions are given as indicated; intestinal decompression is maintained for 24 to 72 hours and adequate fluids are supplied. Oral intake of food is started slowly. Penicillin may be given prophylactically for two to four days in severe injuries.

The mortality rate in gunshot and other penetrating wounds of the peritoneal cavity is high and, in intestinal perforation particularly, is usually directly related to the length of time intervening between injury and operation. For example, in perforation of the small bowel, Musselman and associates (13) noted that when the interval was 6 hours or less the mortality rate was 15 per cent, between 6 and 12 hours it was 35 per cent, and between 12 and 24 hours it was 80 per cent. Peritonitis and hemorrhagic shock are the two most common complications causing death.

2. **Intraperitoneal Hemorrhage.** In most instances, intraperitoneal hemorrhage arises from rupture of an organ (e.g., the liver or spleen), but in penetrating injuries (such as gunshot and stab wounds), any large vessel may be the source of the bleeding. Crushing injuries or direct blows sustained over the abdomen may produce a laceration of the capsule of the organ and the parenchymatous tissue as well.

The *clinical manifestations* of hemorrhage of the type described above may be identical to shock produced by any severe hemorrhage (see Ch. 13). Pallor, tachycardia, weak and thready pulse, cold sweat, and mental dullness are some of the important manifestations observed. If the hemorrhage takes place rapidly "air hunger" may also be present. In addition, there are usually at least a few of the symptoms and signs of peritoneal irritation. A diffuse tenderness is present which, as a rule, is no more pronounced over the organ injured than in the rest of the abdomen. Muscle spasm is rarely as marked as it is when an intestine is perforated or ruptured. Likewise, nausea and vomiting are apt to be absent. Mild distention may develop and percussion may reveal a shifting dullness. If the abdominal findings are of such a trivial nature as to make the diagnosis of intraabdominal injury appear unlikely, important information may be gained by hourly observation of the erythrocyte count, and hematocrit and hemoglobin determinations. If the hemorrhage is significant, within a few hours there is usually (but by no means always) a sufficient drop in the above determinations to differentiate the condition from simple trauma and shock. Aspiration with a blunt needle may be very helpful in detecting intraperitoneal hemorrhage; however, if no blood is found, the presence of blood cannot be excluded. It might appear that accidental puncture of the intestine with subsequent leakage and peritonitis would take place; but in experienced hands, this is extremely rare.

If the hemorrhage is of sufficient magnitude to produce symptoms of shock which are not improved in an hour or two by two or three transfusions and other supportive measures, it is usally safe to assume that bleeding is still active. On such occasions, immediate operation is usually indicated, treating the shock with constant transfusion during the operation. On many occasions, the differentiation between hemorrhage and perforation of the intestine is so difficult that the latter possibility of itself will demand laparotomy. At operation any laceration of the liver or spleen should be repaired by suture, except that in lacerations of the spleen it is better to remove the organ than to attempt to repair the damage. If bleeding is severe, transfusions must be started early, continued throughout the operation, and repeated postoperatively as indicated.

Intraabdominal apoplexy is a term applied

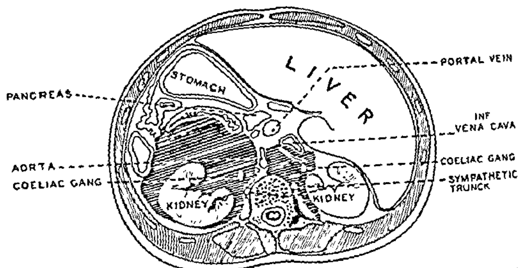

Fig. 13. Two common sources of retroperitoneal hemorrhage. On the left side is shown a blood clot arising from a lacerated kidney; on the right the hemorrhage is produced by a fracture involving the transverse process of the vertebra. In each case the clot infiltrates anteriorly. Note the close proximity of the blood clot to the numerous nerve trunks, ganglia and peritoneum of the posterior wall of the abdomen; this presumably accounts for the production of manifestations which are so similar to those produced by inflammation of the peritoneum.

to spontaneous hemorrhage from vessels in the peritoneal cavity. It is rather uncommon but may produce severe shock and require immediate operation. It occurs most commonly in men in the latter decades of life. Many of the patients will have hypertension or arteriosclerosis. Mild abdominal pain is complained of but, as in other intraabdominal hemorrhage, very little muscle spasm or tenderness will be found. The source of such hemorrhage is usually a mesenteric vessel, although it may occur in the retroperitoneal space and be manifested as a large mass (hematoma).

3. **Retroperitoneal Hemorrhage.** There are two common sources of hemorrhage of this type; 1. laceration of the kidney; and 2. fracture of, or severe injury to, the spine (Fig. 13). Occasionally, injury to the soft tissues in the back may be sufficient to produce a retroperitoneal hemorrhage. The similarity of the symptoms produced by retroperitoneal hemorrhage and early peritonitis was emphasized by one of us years ago (14). All the manifestations of peritonitis, including pain, muscle spasm, nausea, vomiting, and leukocytosis, may be produced by a hemorrhage of this type. Distention develops as in peritonitis, but muscle spasm is less marked, often being no more than a doughy resistance. It is difficult to explain the development of these symptoms in such an instance, but it seems apparent that the hematoma and the trauma located in this area may involve the nerves (sympathetic and somatic) which are important in the production of such symptoms. The surgeon may have ample evidence of damage to the kidney or spine (e.g., blood in the urine, x-ray of the spine showing fracture), but the symptoms may be so suggestive of intestinal injury that failure to perform an exploratory laparotomy is considered unsafe. However, in most instances, differentiation can be made on the basis of severity and number of manifestations; in general, vomiting and tachycardia are less pronounced in retroperitoneal hemorrhage. Moreover, the patient does not appear so ill in retroperitoneal hemorrhage; the expression is less apprehensive and the face less pinched. Conservative therapy is obviously indicated in the absence of injury to a viscus or large vessel, thus avoiding the damaging effects of a celiotomy.

MISCELLANEOUS DISEASES ASSOCIATED WITH THE PERITONEUM

One of the most important of these is *malignant disease*, because it may occur in almost any organ within the abdomen and may involve the peritoneum secondarily. The

invasion of the peritoneum by the tumor (e.g., carcinoma) is noted as one or many tiny, irregular, hard nodules which become attached to the deeper tissue as they enlarge and likewise attach themselves to adjacent organs by malignant tissue or adhesions. The peritoneum may likewise become involved by extension of the tumor toward the periphery of the organ. Invasion of the peritoneum by extension or metastasis is accompanied by the development of free fluid, which at first is clear but rapidly becomes bloody. With a relatively few exceptions the presence of bloody fluid in the peritoneal cavity is quite pathognomonic of the presence of malignant disease involving the peritoneum.

Ascites. This is encountered in many other conditions besides malignancy. It is associated, also, with such diseases as myocardial insufficiency, nephritis, and cirrhosis of the liver. In such instances, however, the fluid is practically always clear and, being a transudate, will have a low specific gravity. The presence of a large amount of ascitic fluid in the peritoneal cavity often produces a degree of distension which is occasionally differentiated with difficulty from the distention due to a tumor or even a slowly developing paralytic ileus. Ordinarily, however, palpation and percussion will reveal the true nature of the abdominal tumor. If the fluid is evacuated by a trocar (paracentesis abdominis) or by a laparotomy, much information may be gained by its physical characteristics. The most common lesions producing bloody ascites are carcinomatosis of the peritoneum, trauma, ruptured ectopic pregnancy, intestinal strangulation, volvulus, twisted pedicle of an ovarian cyst, and acute pancreatic necrosis. In doubtful cases, a small incision under local anesthesia will not only evacuate and reveal the nature of the ascites, if present, but will also provide a view of the peritoneum and omentum; often a biopsy of diseased tissue can be obtained, thereby establishing the correct diagnosis. This cannot be achieved by simple aspiration, a procedure, moreover, which is apt to be damaging if distended bowel rather than ascites is the cause of the swelling.

Hernias. With very few exceptions, hernias are associated with abnormalities of the peritoneum, are frequently secondary to congenital defects, and may be roughly divided into external and internal types (see Ch. 34).

Retroperitoneal Space. Diseases and injuries of the retroperitoneal space are important because of the confusion with similar conditions in the peritoneal cavity. Most important is the kidney. Fortunately, with the aid of pyelography (intravenous or cystoscopic), the kidney can be identified quite readily as the cause of disease. Neurocytomas, especially those arising in the adrenal are occasionally observed, particularly in children. Occasionally, serious tumors (lymphosarcoma) arise in the retroperitoneal lymph nodes. By the time they are discovered, they are rarely operable. Benign tumors, such as lipomas, have been reported. *Retroperitoneal abscesses* may develop (from the kidney, spine, and lymph nodes) and may present laterally or in the neighborhood of the inguinal ligament.

Diseases of the Mesentery. No doubt the most common lesion affecting the mesentery is *lymphadenitis* of the nodes within the mesentery. These may obviously be pyogenic (as described on p. 799) or tuberculous. In either case, suppuration may take place and lead to peritonitis, adhesions, and the like. Rarely, however, is the blood supply to the intestine jeopardized. *Cysts* of the mesentery are encountered occasionally. They are located near the junction of the mesentery and intestine and are frequently so intimately connected with the wall of the intestine that removal can be achieved only by resection of a segment of intestine. Occasionally, they compress the intestine so much that a partial obstruction is produced. When the cyst is so large and extends so far posteriorly that excision is not possible without injury to large vessels, marsupialization should be performed. *Cavernous lymphangiomas* have been encountered in the mesentery but are extremely rare. *Sarcomas* are likewise very rare and will be operable only when encountered at an early stage.

Diseases of the Omentum. Perhaps the most common lesion of the omentum is *inflammation*. Naturally, it may be affected secondarily when surrounding an inflamed appendix or other source of infection. Resolution without abscess formation in the omentum itself usually takes place. Occasionally,

inflammatory masses develop in the omentum without an obvious primary lesion; they may produce abdominal pain, tenderness, nausea, leukocytosis, and other symptoms of sufficient magnitude to lead the surgeon to a laparotomy. Resection is performed readily and relieves the condition. *Torsion of the omentum* is occasionally encountered as a complication of a hernia when the omentum is adherent to certain portions of the sac. More rarely it will be found within the peritoneal cavity, not associated with a hernia. In either case, abdominal pain and other mild symptoms may lead to laparotomy. Resection of the portion of omentum involved is indicated. *Tumors* of the omentum may be cystic or solid; each group is rare. Of the solid tumors, sarcoma (fibrosarcoma or lymphosarcoma) is most common. The only significant manifestation except in the terminal stage may be the presence of a mass. Resection may be possible. *Cysts* of the omentum, usually lymphatic in origin, are encountered but likewise are rare. Excision is simple and curative.

Chylous Ascites. This is a rare condition but is discussed here because of its surgical importance; up to 1954, Hoffman (15) found only 24 reported cases. In this group, the etiology was unknown in 10, due to trauma in four, due to demonstrable thoracic duct obstruction in three, and due to intestinal obstruction in three cases. In the majority of these cases the symptoms developed acutely, resembling those of acute appendicitis or perforated peptic ulcer. Nausea, vomiting, rebound tenderness, muscle spasm, and pain on palpation are common manifestations, although occasionally symptoms are minimal, consisting primarily of abdominal distention (with chyle). Leukocytosis is common (16). The disease is self limited; accordingly, no surgical treatment (such as ligation of the duct) is indicated, although the temporary drainage afforded by operation appears to improve the patient. All except one of the 24 patients reviewed by Hoffman recovered, and the one fatal case was a patient who had been acutely ill for four days and was almost moribund when he came into the hospital.

Talcum Powder Granuloma. Reference has already been made (Ch. 14) to the foreign body reaction resulting from talcum powder which is used as a lubricant on surgical gloves. When this granulomatous process develops in the peritoneal cavity, abdominal pain may become very troublesome. At operation, numerous adhesions are found associated with the granulomas which surround the talcum powder granules. Symptoms may persist almost indefinitely. To prevent this, almost all surgeons have abandoned talc in favor of some type of starch product for use in lubricating hands and surgical gloves. However, starch likewise causes granulomas occasionally; accordingly, it should be thoroughly washed off the gloves before the surgeon begins operating.

Porphyria. Although this disease is comparatively rare, it is described in slight detail here because so few physicians are familiar with it, and the condition is so important to the surgeon. Manifestations, including nausea, vomiting, abnormal tenderness, and muscle spasm, may present the same features as indicated in acute appendicitis, perforated ulcer, and so forth. It is a metabolic dysfunction of porphyrin metabolism. The porphyrins (17) are constituents and catabolic products of such substances as hemoglobin, myoglobin, and chlorophyll, all of which are concerned with cellular respiration. In porphyria there is an interruption in the process of synthesis, or breakdown of hemoglobin, resulting in the accumulation in the body and excretion in the urine of abnormal porphyrins. Watson (18) has divided the syndrome into three forms: 1. light sensitive; 2. acute intermittent, or acute idiopathic; and 3. mixed, with characteristics of Types 1 and 2. Types 1 and 2 are rare but may be present with hemolytic anemia. Type 2 may be encountered after infection, trauma, and drug therapy. Type 1 is usually found in infancy, Type 2 in adolescence, and Type 3 after adolescence. It is a familial disease. The most significant diagnostic manifestation is the passage of dark amber or dark red urine intermittently, although usually the color is not manifested until the urine has been standing exposed to sunlight.

"The diagnosis of acute intermittent porphyria is confirmed by the demonstration of porphobilinogen, uroporphyrin, or other abnormal porphyrins by one of the four following tests: 1. the Watson-Schwartz test for

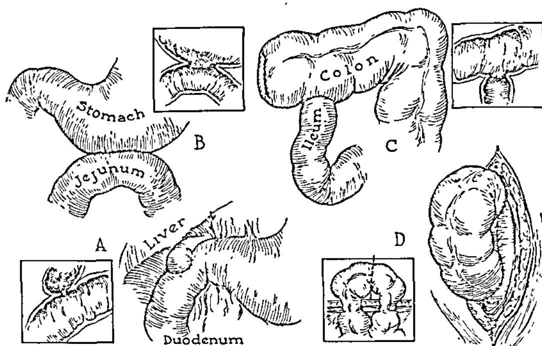

Fig. 14. Common types of intestinal fistula produced by operative means. A, cholecystoduodenostomy, performed usually for carcinoma of the pancreas or inoperable carcinoma of the ampulla of Vater; B, gastrojejunostomy, utilized in stenosis of the pylorus or duodenum; C, ileocolostomy, commonly performed in resection of the proximal colon for carcinoma; D, double-barreled colostomy, as performed to correct obstruction in inoperable carcinoma of the rectum. On the second or third day the sigmoid is cut across, as shown by the dotted line in the insert.

urinary porphobilinogen; 2. exposure of acid urine to sunlight; 3. spectroscopic examination of the urine (19); and 4. determination of melting point of urinary porphyrins," as indicated by Furste and Ayres (20). The latter authors have warned that pathologic conditions, such as acute appendicitis, may occur during an attack of acute intermittent porphyria. Accordingly, the surgeon must be aware of the possibility of these two conditions being present simultaneously. Melby and associates (21) have reported the effective use of chlorpromazine (25 mg. three or four times per day) in nine cases of acute intermittent porphyria.

Fistula. A fistula is an abnormal communication between epithelial or endothelial lined surfaces (usually hollow viscera) or a communication between a viscus and the exterior. They may be produced in several different ways.

1. Occasionally the communication may be *congenital*, that is, result from a defect in fetal development. Rectovaginal, rectovesical, and rectal fistulas are often associated with an imperforate anus.

2. *Postoperative fistulas* may be divided into two types. In the first group (*a*) the fistula is produced intentionally, connecting one viscus with another for functional reasons, e.g., cholecystogastrostomy, ileocolostomy, or gastroenterostomy (Fig. 14); (*b*) in a second group of cases, the fistula opens to the outside through accidental or intentional means, e.g., urinary fistula or biliary fistula. Pancreatic fistula and duodenal fistula likewise occur and develop most commonly following operation of the duodenum. A biliary fistula which persists is usually due to an obstruction distal to the opening. In a *fecal fistula,* the intestinal content is diverted to the outside; it is frequently performed intentionally, e.g., colostomy, preliminary to a resection of a carcinoma of the rectum. When a fecal fistula results accidentally it usually occurs because of a rupture of an intestinal suture line, which in most instances is caused by an obstruction distal to the operative site.

Fig. 15. Multiple sinuses and fistulas of the abdominal wall. Fecal material drains from only one of the openings. The lesions are of three years' duration and followed a pelvic operation. The patient was operated on and the involved areas resected. Recovery was uneventful. Ordinarily if a fecal fistula does not heal within six months, operation is advisable.

(Frequently, such a leak of intestinal contents produces a fatal peritonitis before a fecal fistula develops.) On most occasions, fistulas which develop in the absence of obstruction will close spontaneously; they may drain for months, however (Fig. 15). If the fistula is located high in the intestine, it will usually not heal spontaneously; furthermore, it may result in the digestion of the skin or the walls of the wound, causing severe pain unless treatment is instituted promptly. In addition to the methods of formation as described, a fecal fistula may also develop because of union of the skin with the intestinal mucosa. Treatment of fecal fistulas is considered below and elsewhere.

3. Fistulas caused by tissue destruction due to severe *infection* are extremely common, as clearly illustrated by the rectal fistula which forms as a complicating aftermath of a rectal abscess.

4. Fistulas may be of *mechanical origin*. A vesicovaginal communication may develop as the result of pressure necrosis during childbirth. A cholecystenterostomy may be formed by the passage of a gallstone from the gallbladder into the intestine.

5. Occasionally, a *malignant tumor* may be responsible for the development of a fistula. An intestinal operation performed through malignant tissue may produce a permanent fecal fistula leading to the exterior, if the patient does not first succumb to peritonitis caused by the leak in the suture line.

The *treatment* of fistula depends upon its location and cause. If the communication has followed some type of infectious process, excision of the fistulous track and closure of the opening in the viscus will usually effect a cure. A fistulous communication between two loops of intestines may be cured by dissection of the walls from each other, excision of inflammatory edges, and closure of the openings. Resection of the affected loops followed by an anastomosis may be necessary. The edges of the opening in the intestine must be inverted, since union will occur only when the peritoneal surfaces are approximated. A fistula produced by malignant tumors cannot be cured by closure with sutures but may be

eliminated if the growth can be completely excised and the resultant defect repaired with complete obliteration of dead space at the site of excision.

As already stated, most fecal fistulas, with the exception of those high in the intestinal tract, will heal spontaneously unless there is an obstruction distal to the fistula. If such an obstruction is present, it will obviously have to be corrected by operative means before the fistula will close. If the fistula persists because of attachment of the intestinal mucosa to the skin, an operation consisting of division of the union between mucosa and skin with inversion of the intestinal mucosa should result in a cure. Occasionally, such a repair will produce so much narrowing of the intestinal lumen that either obstruction or a recurrence of the fistula will result. On such occasions, resection of the defect, with an anastomosis between the two loops (proximal and distal) of intestine is indicated. When skin irritation develops, as it usually does in high small bowel fistulas, prompt and effective treatment will be indicated to prevent the severe pain and loss of morale which develops commonly. Many remedies have been recommended, but few are effective. Constant aspiration of the intestinal contents as they are extruded will relieve the irritation, particularly if powdered aluminum is sprinkled (twice a day) over the irritated skin, after it is thoroughly washed and dried.

As will be noted in the legend for Fig. 14, the suffix "*ostomy*" is commonly utilized to signify a fistulous communication between different organs of the body (especially intra-abdominal). The term implies the opening of an organ without closure, but establishment of communication with another organ or the exterior. The suffix "*otomy*," however, implies the opening of the organ or viscus and closure without establishment of a fistulous tract. When the suffix "*ectomy*" is used in connection with an organ or tissue, excision of that organ or tissue is implied.

INTESTINAL OBSTRUCTION

General Considerations
Specific Lesions Producing Intestinal Obstruction

In the continental United States about 5,000 deaths are reported annually as due to intestinal obstruction, in addition to an equal number attributed to hernia. The number has remained unchanged over the course of many years despite increasing knowledge and better diagnostic and therapeutic technics. The challenge for improvement in this field is therefore real. Before discussing specific lesions which produce intestinal obstruction, a few general considerations will first be considered.

GENERAL CONSIDERATIONS

Definitions. In the medical literature of the world the old designation generally applied to intestinal obstruction of all types is *ileus.* In this country at least, it is used to define a remarkable condition in which there is no actual organic obstruction but in which the intestinal contents are stagnant as if the lumen were occluded. Because this condition is produced by a cessation of intestinal peristalsis by one of several causes, usually general peritonitis, it is called and will be referred to in this text as "paralytic ileus." In contrast to paralytic ileus are the cases in which there is an actual organic obstruction. These comprise a great variety of lesions which may be divided into two general groups, the first of which will be called "simple mechanical obstruction." In this group, only the lumen of the intestine is primarily occluded. In the second group, called "intestinal strangulation," an occlusion of the mesenteric blood supply is of primary significance and indeed creates an acute surgical emergency, as discussed below. Anatomic causes, such as bands and adhesions, may produce either of these two latter types. Other anatomic causes, such as mesenteric thrombosis, intussusception, and volvulus, are defined and described separately later in the chapter. Other designations often used are high obstruction and low obstruction, indicating as a rule the level at which the obstruction has occurred. High obstruction usually indicates an occlusion at the pylorus, duodenum, or upper jejunum. Low intestinal obstruction is usually limited to the large bowel, so that a better designation is large bowel obstruction, as contrasted to small bowel obstruction. Acute is much more important surgically than chronic intestinal obstruction and most of the chapter will therefore be devoted thereto. Acute intestinal obstruction is produced by a sudden cessation in the passage of intestinal contents whereas chronic obstruction refers to partial or intermittent occlusion.

Classification. Acute intestinal obstruction is classified with difficulty as might be inferred from the many terms in common use. This difficulty is increased because a combination of elements is often present in each individual case, particularly when symptoms have been present several days. Nevertheless, for practical reasons, acute intestinal obstruction will be divided into three groups based on three distinct pathologic differences, at least in the beginning of the disease. In two of these three groups, an actual obstruction to the intestine is present; in one, the obstruction involves the lumen alone, in the other, the blood supply as well. In the third group, the intestine is not obstructed but merely unable to propel its contents. The terms used in these three groups are as follows:

1. Obstruction to the intestinal lumen from a band, tumor, stricture, or adhesion,

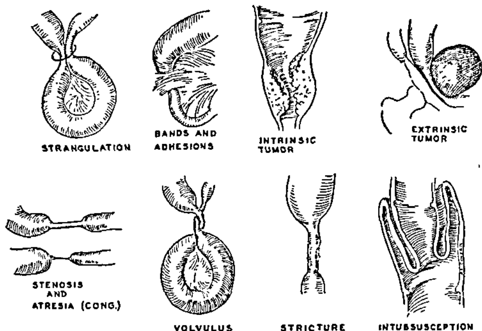

Fig. 1. Eight common causes of intestinal obstruction. Note the various mechanisms producing occlusion of the lumen as well as blood supply. Though not indicated strangulation includes volvulus and intussusception; bands and adhesions may also produce strangulation.

creating merely a simple mechanical obstruction.

2. Obstruction to the blood supply (intestinal strangulation) from a band, hernial sac, adhesion, or thrombosis, creating simultaneously intestinal obstruction.

3. Paralytic ileus, secondary to peritonitis, trauma, or other causes in which there is really no organic intestinal obstruction.

The three groups represent definite clinical types, but the classification is inexact anatomically for several reasons. Thus, the same obstructive agent may produce differences in the response of the intestine; there is more than one factor in the individual case; and, finally, the sequence of events varies after the onset of obstruction. Moreover, in any type of intestinal obstruction the status of the intestine and mesentery (of which the most significant are the patency of the lumen of the bowel, the activity of the intestinal musculature, and the integrity of the blood supply) is important, yet hard to evaluate clinically. Nevertheless, it is valuable to view each individual case in terms of such changes as well as of the three groups mentioned above.

Of the many anatomic causes, a few are represented in Figure 1. In the first group occluding the lumen only (proceeding from above downward) are esophageal stricture and cancer, gastric carcinoma, pyloric stenosis, small intestinal bands, adhesions, enteroliths, large bowel cancer, adhesions, and fecal impaction. Extrinsic agents, such as tumors or abscesses, may occlude the lumen at any level; the same is true of strictures of various kinds. In the group producing primarily intestinal strangulation are hernia, intussusception, volvulus, and mesenteric thrombosis. The third group or so-called paralytic ileus occurs in mild form after laparotomy and in a severe form in general peritonitis, presumably as a reflex phenomenon, after injury to the spine and other extensive skeletal trauma, or as a manifestation of potassium deficiency, or with serious extraabdominal disease, e.g., pneumonia, meningitis, nephritis.

Incidence. Three or four decades ago strangulated external hernia was by far the most common cause of obstruction, constituting as much as 40 to 45 per cent of the total number. This incidence has decreased sharply of recent years, partly because hernias are operated upon at an earlier date.

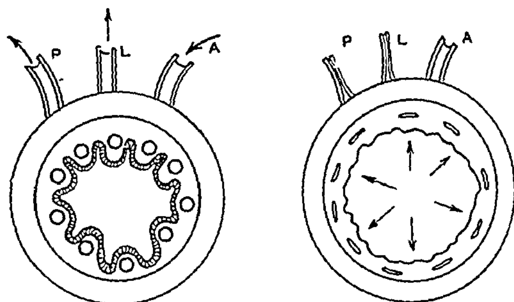

Fig. 2. Diagrammatic cross section of small intestine. Left, under normal conditions; right, under the influence of increased intraluminary pressure produced by a simple mechanical obstruction. Note that the vessels in the submucosa are flattened and that the mucosa is not represented because its viability has been destroyed by pressure. Although the arterial flow (A) is indicated as normal in contrast to the impaired portal (P) and lymphatic (L) flow, the arterial flow is impaired even before the venous flow. In any case, absorption can occur only through the serosal surface unless the intraluminary pressure falls enough to permit absorption into the blood stream. More important in producing sudden "toxic" absorption is a similar release of the vascular obstruction itself as in reduction of intussusception or volvulus, or on cutting the neck of the sac in a strangulated hernia.

Moreover, due to the increase in life span, carcinoma has increased, as has the obstruction due to adhesion because abdominal operations are increasing. Wangensteen (1) reports that in 1,262 cases of obstruction occurring between 1942 and 1953 at the University of Minnesota Hospital, 31 per cent were due to adhesions; in an additional 7 per cent, obstruction due to "operative complications" (presumably fresh adhesions) was recorded. Malignancy was the cause in 27 per cent and external hernias in only 12 per cent. Other clinics are reporting similar figures.

Pathology. Intestinal obstruction due to organic lesions produces pathologic changes which may be divided into those which are local and those which are systemic. The pathology of paralytic ileus is described separately for reasons already mentioned.

1. The local *changes* following intestinal obstruction are caused by two separate mechanisms, occlusion of the intestinal lumen and occlusion of the blood supply. Each of these mechanisms, however, is often involved to a varying degree in a particular case, as will be apparent from the following description.

(*a*) Occlusion of the intestinal lumen is one of the first effects of acute intestinal obstruction, whatever the cause may be. Although the occlusion may be partial at first, it soon becomes complete because of local changes brought about by the vigorous attempts on the part of the bowel to force intestinal contents past the barrier. Wave after wave of peristalsis (accentuated by the ingestion of food and especially of cathartics) beat against the narrowed lumen and succeed perhaps in forcing contents through for a time. Soon, however, the bowel above dilates (Fig. 2) and bacteria multiply in the stagnant contents. The bowel wall becomes edematous which may make the partial obstruction complete or the weight of the fluid above the obstruction may kink the bowel, completely obliterating the lumen.

In general, the subsequent changes are due to an increase in the accumulated obstructed bowel contents by swallowed air, intestinal secretions, and as the result of bacterial multiplication. The increased intraintestinal pressure thus produced distends the bowel more and more. The more regurgitation of bowel contents into the stomach leads to

Fig. 3. Strangulated, gangrenous small intestine due to an extensive volvulus. The lesion developed as a terminal manifestation in a patient with an extensive carcinoma of the lung. Nausea was present but no vomiting; severe prostration and circulatory failure developed shortly after the onset of abdominal pain. The photograph was made at the time of autopsy; note the striking difference in color between the normal viable gut, and the gut which is strangulated.

vomiting the less the bowel dilates. On the other hand, if the distention is unrelieved and becomes great enough, the blood flow through the bowel becomes occluded and loss of viability and even necrosis, first of the mucous membrane and then of the entire wall, may occur (2). This necrosis, though relatively uncommon, is similar to that in intestinal strangulation, which is described next, and thus explains how, even in simple mechanical obstruction of the lumen, the local effects in neglected cases may be the same as those produced by strangulation.

(*b*) *Occlusion of the blood vessels, or intestinal strangulation,* occurs frequently in intestinal obstruction, developing quite rapidly and coincidentally with the occlusion of the intestinal lumen in intussusception, volvulus, and strangulated hernia. Occlusion of the lumen may indeed precede by several hours occlusion of the blood supply. Conversely, as just described, simple occlusion of the intestinal lumen, if neglected and accompanied by severe distention, will impair blood supply and thereby produce the same, though perhaps less extensive and certainly slower, tissue changes as strangulation.

After a few hours, tissue injury in complete strangulation develops rapidly and is soon followed by necrosis and gangrene (Fig. 3). Since the bowel lumen contains many and virulent bacteria, infection rapidly sets in and the strangulated intestine then acts as any area of gangrene accompanied by a severe infection. The influence of bacterial growth has been convincingly shown by Cohn and Rives (3). Absorption of toxic material thus produced is most rapid when the gangrenous tissue is free in the peritoneal cavity, as in a case of complete volvulus. Rarely is direct absorption prevented by walling off by the omentum; in strangulation by hernia, the sac is usually so tight as to constitute an effective walling off of this sort. The gangrenous process may be so acute and rapid that the associated occlusion of the lumen, though nearly always present, is completely overshadowed by the effects of the strangulation.

2. The *systemic effects* of intestinal obstruction are also produced by two separate

mechanisms: (*a*) dehydration from loss of water, electrolyte and plasma protein, and (*b*) toxemia from absorption of infectious or other material present in strangulated bowel. Both of these mechanisms are sometimes so closely associated as to be indistinguishable clinically. Their pathogenesis, however, is so different that they will be discussed separately.

Distention in itself, it should be emphasized, regardless of the cause, may produce many of the systemic effects described below. Thus no systemic effects may follow a complete occlusion of the intestines provided distention is prevented in the absence of strangulation or of water and electrolyte deficits. Moreover, distention may result not only from occlusion of the intestinal lumen but also from inability of the musculature adequately to contract, as well as from other nervous and vascular factors, and still lead to the clinical picture of dehydration.

(*a*) *Dehydration* as mentioned before (see Chap. 9) is probably an inexact term to describe the systemic effects resulting from failure to replace the abnormal loss of gastrointestinal secretions which, of course, varies in content of electrolytes as well as water. The loss commonly takes place because of vomiting, which is a frequent symptom in intestinal obstruction. Distention in itself may result in vomiting from reflex action, whether the lumen is occluded or not; this has been experimentally demonstrated by abolition of vomiting through section of the nerves to the involved segment of the bowel. On the other hand, distention often follows because the obstructed contents are not vomited but, instead, accumulate in the dilated bowel. Moreover, distention sometimes aggravates the loss of water and electrolyte by stimulating secretion, thus increasing dehydration. It should be emphasized, therefore, that dehydration follows failure to replace the loss of fluid into obstructed bowel whether it is vomited or not; thus the actual amount of vomitus may not give a clear indication of the total amount of fluid lost into the obstructed stomach or intestine. Many liters have actually been measured in obstructed intestines.

To the loss of intestinal contents which contain only water and electrolyte, must be added the loss of fluid into the wall of obstructed bowel and into the peritoneum. This fluid differs from gastrointestinal secretions because it contains protein which approaches the concentration of that found in the plasma. Indeed, the term plasma dehydration may be used to describe this type of loss. Its mechanism is similar to that observed in peritonitis and burns, as described elsewhere.

The clinical picture of *dehydration* varies widely. The patient may be merely prostrated or, in the late neglected states, may be comatose. Surgical shock is found only when the loss of fluid has been extensive and rapid, especially if accompanied by extensive depletion of the plasma. The skin everywhere is dry and inelastic, the mouth is parched, the tongue is coated and furred, the lips dark red in color. Examination of the blood will reveal a hemoconcentration provided the red count was normal before; a red count of six or seven million per ml. is not uncommon and should obviously not be confused with a blood dyscrasia such as polycythemia. Blood chemical study may reveal pronounced changes, such as loss of chloride (hypochloremia), loss of sodium (hyponatremia), an elevation of the nonprotein nitrogen, a change in the CO_2 combining power of the blood (indicating either acidosis or alkalosis, depending on various factors), and alterations in the serum protein. If the dehydration has been due to loss of water and electrolyte alone, the plasma protein will show the same trend as the red count and hyperproteinemia may be found. However, if plasma has been lost in considerable amount, the plasma protein concentration will either be normal or below normal.

High intestinal obstruction because of the usual greater loss of fluid by vomiting is more likely to lead to dehydration and, if the obstruction is at the pylorus, is usually associated with alkalosis inasmuch as the gastric contents which are vomited are usually acid. Unless an associated strangulation is also present, the changes due to dehydration account for most if not all of the systemic manifestations in patients with high intestinal obstruction and often in those with obstruction lower in the gastrointestinal tract (4).

(*b*) The clinical picture of *toxemia* is often seen in intestinal obstruction whenever there is an associated impairment of the blood

supply to the bowel wall. The pathogenesis of these effects of strangulation is not always so clear as that just described in dehydration; nevertheless, it is undoubtedly true that they are due to the absorption of infectious material from the damaged bowel into the circulation. Such absorption is well known in the case of necrotic infected tissue elsewhere. Absorption from strangulated intestine is probably no exception.

Variations in the clinical picture of strangulation are great, dependent, no doubt, upon the degree and rapidity of the absorption. For example, the systemic effects may not be very clear-cut when absorption from the nonviable intestine is gradual; indeed, in such cases, the manifestations may often be scarcely differentiated from those due to dehydration. Much more definite are the systemic effects which follow sudden absorption as, for example, in volvulus of the sigmoid in which a loop of colon becomes completely strangulated, and the toxic transudate produced immediately absorbed through the peritoneum. Such patients are in shock severely prostrated, with a subnormal temperature, fast pulse, and low blood pressure. Although there is, in such cases, both occlusion of the lumen of the gut as well as of the blood supply, the latter occurs so suddenly that the symptoms of shock are produced before dehydration from persistent vomiting and distention have had time to develop.

In an individual case, therefore, the differences may be great due no doubt to variations in the local lesion and in the degree and rapidity of toxic absorption and of dehydration. Nevertheless, with the main outlines in mind it is remarkable how often the systemic effects can be evaluated in terms of pathogenesis.

3. In *paralytic ileus*, as already mentioned, there is no actual mechanical obstruction to the lumen. Although these patients may be distended and dehydrated, other factors, such as peritoneal infection, are responsible for the signs of toxicity often seen. In such cases, the bowel wall itself, in spite of distention, usually maintains a fairly good blood supply in absence of complicating lesions. Six general conditions nearly always precede paralytic ileus: 1. trauma during abdominal operations, which justifies the term postoperative ileus; 2. general peritonitis, usually from a gastrointestinal perforation; 3. skeletal injury, especially to ribs and spine, and retroperitoneal trauma; 4. extraperitoneal infections or toxemia, e.g., pneumonia, nephritis; 5. severe potassium deficiency which often remains uncorrected when water and electrolyte depletions are replaced by sodium chloride alone; and 6. drugs employed for reducing hypertension (such as ansolysin) may lead to abdominal distention of the paralytic type with all radiologic signs thereof. Pain may also be present, leading to a diagnosis of intestinal obstruction.

The fundamental derangement in paralytic ileus is undoubtedly an interference with the nervous mechanism initiating and maintaining peristalsis or a reduction in the capacity of the intestinal musculature to contract adequately. Another factor may be a partial interference in the blood supply following which the affected bowel becomes similarly paralyzed. Regardless of the mechanism, stasis of intestinal content with distention follows with loss of fluid and electrolyte, which is just as pronounced as if there were an actual mechanical barrier in the lumen arresting the passage of bowel contents. Once such stasis has supervened, distention ensues with its train of disturbances and blood chemical changes. The effects of distention in intestinal stasis due to peristaltic failure are just as severe as the distention from stasis produced from actual occlusion of the intestinal lumen.

The gradually developing changes in intestinal obstruction, whatever the cause, might be summarized as follows:

OCCLUSION OF INTESTINAL LUMEN AND/OR EMBARRASSMENT OF INTESTINAL CIRCULATION AND/OR FAILURE OF INTESTINAL PERISTALSIS	STASIS OF INTESTINAL CONTENT	DISTENTION OF INTESTINAL LUMEN	VOMITING DEHYDRATION BLOOD CHEMICAL CHANGES TOXIC ABSORPTION

Clinical Manifestations. The local or abdominal manifestations are described first, then the systemic or general signs and symptoms.

Soon after the intestinal lumen is occluded, regardless of the cause, many primary abdominal symptoms will develop, due to the mechanical occlusion per se. Strangulation often produces, in addition, severe signs and symptoms which are described separately. *Severe intermittent pain of a cramping type* is the most important; it occurs early, is generally located in the epigastrium or around the umbilicus, but may disappear as distention develops. There may be freedom of pain between attacks. Cramps may be especially aggravated by the ingestion of food or cathartics and are often accompanied by hyperperistalsis, audible with or without the stethoscope; this is a very important sign of intestinal obstruction (4). Obvious *distention* appears in a day or two and increases gradually. Distention is more prominent the lower the obstruction. The abdomen is tympanitic due to the presence of considerable gas (tympanites). Distention must be distinguished from ascites which produces shifting dullness, from a mass which reveals itself by careful palpation, and from a distended bladder which disappears after catheterization. Occasionally, the distended loops can be outlined as an intestinal pattern through the abdominal wall of thin individuals. On the other hand, it is often remarkable how much actual distension of the intestines may be present without much external evidence thereof, particularly in robust hyperesthetic individuals with thick abdominal muscles and in the obese. *Vomiting* is more common in high than in low obstruction. An early symptom, it is intermittent, usually follows eating or drinking and is practically or nearly *always preceded by pain*. The amount of vomiting varies greatly, and is usually inversely proportional to the degree of distention. Its character may indicate the site of the obstruction, e.g., clear fluid points to the pylorus; bile stained contents place the occlusion beyond this point; fecal-like vomitus usually originates from the ileum or below. Absence of bowel movements, while common in intestinal obstruction, is not necessarily pathognomonic thereof since it is possible to have bowel movements from retained feces below the obstruction or from a small amount of fecal material which has passed through a barrier not completely occluding the lumen. Another important sign is visible peristalsis which is especially observable in patients with thin abdominal walls, the waves being coincident with the cramping pain and with audible sounds apparent on auscultation. In infants with hypertrophic pyloric stenosis peristaltic waves crossing from left to right can often be seen in the upper abdomen. Palpation is usually negative unless a large tumor is causing the obstruction. In strangulation, a tender mass or localized tenderness may be present. Incarcerated external hernias can be felt except that a small part of the intestine may be strangulated in the femoral or inguinal ring without being apparent externally. Internal herniations are likewise not palpable externally but are rare. Abdominal tenderness is, in general, absent except for localized tenderness over strangulated bowel; there may be diffuse tenderness in the paralytic ileus of general peritonitis. Muscle spasm is rarely present except in the presence of peritonitis (from perforation) or occasionally in strangulation.

A *radiograph* of the abdomen (scout film) is of considerable importance in the diagnosis of intestinal obstruction. In the supine position, the film may reveal the position and contour of dilated loops of bowel. In this way it is usually possible to distinguish dilated small bowel by the characteristic herringbone or "accordion" pattern due to the valvulae conniventi from dilated large bowel which merely shows occasional haustrations. An upright film may reveal the so-called "step ladder" effect or multiple fluid levels. Positive x-ray findings may be seen quite early in small bowel obstruction. When there is an associated strangulation the gas shadows may not be easily found early; frequently the appearance of a small pocket of trapped gas suggests closed loop obstruction associated with volvulus and indicates the position of the obstructed loop. When the distention is due to ascites, x-ray will be valuable in excluding intestinal obstruction because no distended bowel will be seen. A barium enema is of considerable value in that it may reveal the site of or exclude obstruction of the large bowel. In high obstruction, barium by mouth

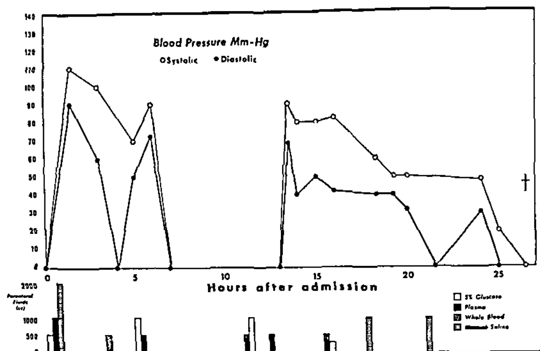

Fig. 4. Surgical shock in intestinal strangulation (volvulus). The patient was a 45-year-old female who died before a diagnosis could be made and who at autopsy showed a large loop of strangulated and gangrenous small intestine. Note the transient response of the blood pressure to intravenous injections. Inasmuch as the fluid lost in the intestine and peritoneum was adequately replaced, the fatal circulatory collapse was clearly due to "toxic" absorption from the damaged bowel. (From the Homer G. Phillips Hospital.)

may be advisable in order to reveal the mechanism or completeness of the occlusion, especially when it develops soon after a gastroenterostomy. However, barium as a routine *should not* be given by mouth in obstruction beyond the pylorus or in any case in which its removal is not assured, because of the danger of increasing the obstruction. This danger is due to the absorption of water from the barium suspension, leaving a hard, insoluble mass which acts as an enterolith. Occasionally, however, under the direct supervision and advice of a trained radiologist, a small barium meal may be so useful in diagnosis as to justify its hazard.

The *systemic manifestations* in intestinal obstruction have already been discussed in part, under pathology. In simple mechanical occlusion of two or three days' duration, such symptoms may be surprisingly absent. If vomiting is profuse, the picture of dehydration gradually develops as already described. Occasionally systemic effects may be absent even though the distended bowel has developed necrosis. This is due to the fact that absorption from the nonviable tissue is prevented by the poor blood flow accompanying the distention. In such a situation general symptoms and signs of a profound infection (fast, bounding pulse, restlessness, and high fever) may rapidly follow *sudden release of distention*. This remarkable occurrence is explained (Fig. 4) by the absorption of toxic material suddenly accelerated by the resumption of blood flow in the bowel wall due to the fall of intraintestinal pressure or release of the strangulating agent. This undoubtedly accounts for the occasional fall of blood pressure and tachycardia which is seen during operation when the neck of the sac in a strangulated hernia is cut, or in the postoperative fever which regularly follows reduction of intussusception.

Intestinal strangulation, when it develops gradually, often but not always produces much more severe local as well as systemic manifestations than does a simple occlusion. In general, *strangulation should be suspected*

when the patient becomes more prostrated, the pulse is rapid, the temperature subnormal, and evidence of circulatory shock is shown by a low blood pressure, cold extremities, and pale cyanotic skin. Pain is usually much more severe, and is more constant. Local tenderness is increased, usually over the site of strangulation. A mass may be palpable. A variable amount of muscle spasm develops. Extremely important in patients with simple mechanical obstruction is the fact that damage to the bowel wall may develop *at any time* during the course of the disease; indeed, occlusion of the lumen and of the blood supply may develop simultaneously. When these "toxic" symptoms develop in simple mechanical occlusion the cause, as already described, is probably the same as that occurring in cases of strangulation. Intestinal strangulation, when seen early as a primary disease, can often be differentiated from mechanical obstruction by the severity of the pain, which may be so intense as to induce complete prostration, though not necessarily shock. Prompt recognition of sudden strangulation is obviously important because of the need for early operation, as discussed below.

Laboratory study in any type of intestinal obstruction will show changes indicative of dehydration, but only when much fluid has been lost by vomiting or into distended bowel without adequate replacement. The urine will also be concentrated and scanty and is a fairly reliable clinical indication of the severity of the dehydration. The leukocyte count may be of differential value for it is usually normal in simple mechanical occlusion, whereas it may be elevated in the presence of strangulation even early in the process. A fall in plasma volume, due to loss of plasma into the affected bowel, has been observed in distention from intestinal obstruction. This change is not amenable to routine clinical measurement but its effect can be detected and, in fact, followed by observing progressive increases in the red cell count (hemoconcentration) and diminutions in the concentration of serum protein (hypoproteinemia).

Differential Diagnosis. The many diseases which simulate intestinal obstruction have been discussed previously and are important in the differential diagnosis of acute abdominal disease. As just mentioned, however, the surgeon must not only determine if intestinal obstruction is present but also must distinguish between functional and mechanical obstruction; of urgent importance is the decision as to whether or not the intestine is strangulated.

In the diagnosis of intestinal obstruction, the detection of an obvious cause is helpful. An incarcerated hernia, an abdominal scar from a previous operation, or an abdominal mass is obviously significant. *Cramping* intermittent pain followed by vomitus containing intestinal contents is especially significant. The x-ray is useful (Figs. 5, 6). Of greatest importance in diagnosis is the prompt detection of strangulation which demands immediate laparotomy.

In *paralytic ileus* the abdominal signs are distention, vomiting, and absence of bowel movements. Pain is frequently absent except in general peritonitis and postoperative ileus. In the latter case, the symptoms are usually transient and described as gas pains. It is important to emphasize that if pain is persistent or develops many days (a week or more) after operation, organic obstruction should be suspected. Tenderness is diffuse and more marked if peritonitis is present; rarely is muscle spasm encountered except in the presence of peritonitis or occasionally strangulation. The causes of paralytic ileus are usually obvious and nearly always permit the surgeon to make such a diagnosis or exclude it as a possible cause of the clinical manifestations.

Treatment of Acute Intestinal Obstruction. Treatment is primarily and *often urgently* surgical but depends first upon the type of disease present. To answer this question, the surgeon must first of all determine whether the clinical manifestations are due to paralytic ileus or to an actual organic occlusion and, if the lesion is organic, whether strangulation is present or not. Strangulation demands immediate operation. On the other hand, paralytic ileus seldom requires operation. In the case of mechanical obstruction, surgery is indicated, but evacuation of the stomach is first performed before the anesthetic is started, thus making anesthesia safer. Moreover, certain types of obstruction (primarily those due to adhesions) are cleared up temporarily by decompression of

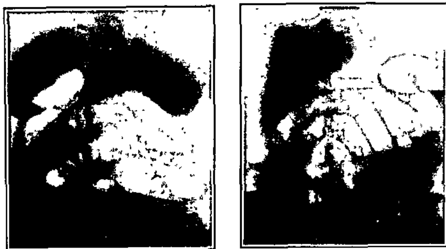

Fig. 5. Roentgenograms showing dilated small intestines. In both films the multiple transverse shadows across the dilated loops are clearly seen; they are called by such terms as herringbone or accordion pattern. The film on the right was taken in the upright position and shows multiple fluid levels as well. Note the similarity in the two pictures even though the lesions found at operation were entirely different. The one on the left was of a 26-year-old woman; distension was due to a simple mechanical obstruction of the terminal ileum from a fibrous band. The one on the right was from a 50-year-old man whose distension was due to a paralytic ileus from a general peritonitis following perforation of an acute appendicitis. In general peritonitis, dilatation of the large bowel (of which only the cecum and part of the ascending colon is visible in this case) constitutes the main roentgenological differentiation from simple mechanical small bowel obstruction.

the upper gastrointestinal tract (1, 5) as is discussed later in detail.

In the following discussion, treatment will be divided into three types, prophylactic, nonoperative, and operative.

1. *Prophylaxis.* An ounce of prevention is worth a pound of cure, which in intestinal obstruction concerns both the surgeon and the physician. For the surgeon, gentle and careful operative technic is essential to minimize the tendency toward postoperative adhesions which are a frequent cause of intestinal obstruction. A large percentage of cases follow gynecologic pelvic procedures; operations for perforated appendicitis are also prone to be followed by intestinal obstruction because of the excessive formation of adhesions which are commonly due to severe infection. The use of talcum powder in gloves undoubtedly led to talc granulomas which were responsible for many cases of postoperative intestinal obstruction. This hazard for the most part has now been removed by the use of soluble powders to aid in donning rubber gloves.

The physician can lower the incidence of intestinal obstruction by recommending herniotomy promptly in patients with reducible hernias, many of whom suffer the inconvenience of trusses for years. In infants and children too, hernia repair soon after the diagnosis is made will eliminate the possibility of strangulation and its high mortality.

Both surgeons and physicians can reduce the seriousness of intestinal obstruction by withholding and indeed condemning the use of catharsis and of morphine in patients with suspected intestinal obstruction. Nature often protects the patient when a cathartic is given when obstruction is present because usually the medicine is promptly vomited. If it is retained it whips up a bowel already working hard to force contents through the small opening and, by increasing peristalsis and distention, aggravates the edema which finally makes the obstruction complete. The tendency of physicians to prescribe a cathartic over the telephone except when the diagnosis is known is certainly a reprehensible one. Unfortunately, it is most often the corner drugstore attendant who is guilty of such well-meaning, but potentially dangerous, advice. The hypodermic of morphine does harm more certainly and insidiously when given

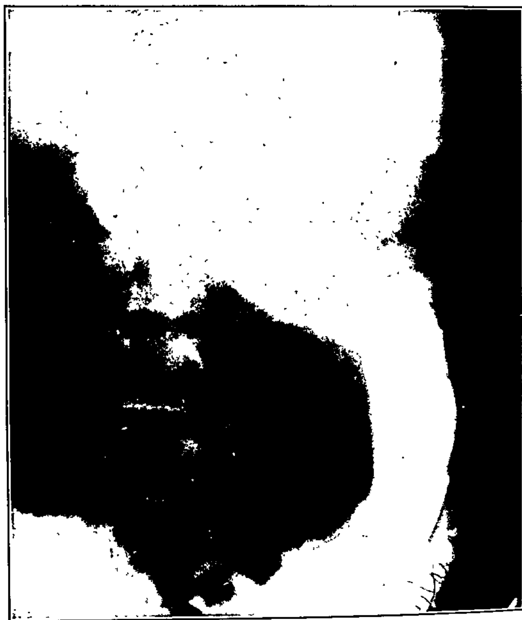

Fig. 6. Acute intestinal obstruction due to carcinoma of the colon. The patient, aged 45, had suffered vague abdominal distress for some months, but for 11 days had been unable to have a bowel movement. The roentgenogram following a barium enema is reproduced above, and shows a complete block at the splenic flexure. At operation a carcinoma was found at this site and was resected, including a portion of the mesentery and a primary anastomosis was carried out. Recovery was uneventful. The patient remained symptom-free for several years but died eventually of distant metastases.

merely to relieve pain. To be sure, it is occasionally useful early in strangulated hernia (i.e., within the first hour or two), because the relaxation induced may allow reduction of the hernia, especially in children; but the patient must be in the hospital and ready for immediate operation if reduction is not effected. The usual circumstance under which it does great harm is its use in the home, often after insufficient examination and certainly after incorrect diagnosis. The danger lies in the fact that the pathologic changes leading to necrosis go on under its apparent beneficent influence. The cramping pain is nature's warning call; the hypodermic stills this call effectively; the patient drops off to sleep and the family is grateful for the seemingly miraculous therapeutic result. But after a short time the patient's pain returns, less severe now, less insistent, but still calling for relief.

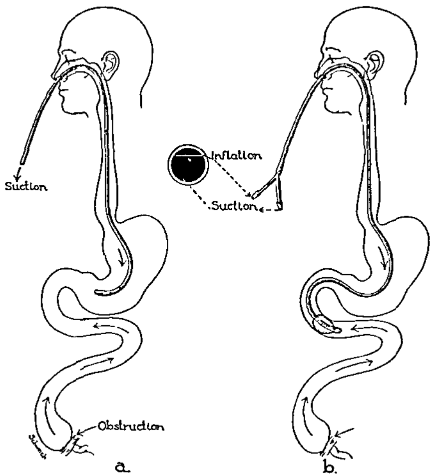

Fig. 7. Gastrointestinal decompression. a, a single lumen long catheter will decompress the stomach and occasionally the duodenum but will rarely enter the jejunum. Only when regurgitation is active can this technic achieve complete deflation; b, the double lumen Miller-Abbott tube, because of the inflatable balloon, once it is in the duodenum, can be carried down to the point of obstruction (provided peristalsis is adequate) and thus achieve complete decompression. In each case mild suction is employed, i.e., the equivalent of a column of water about six feet high. The apparatus must be constantly attended especially to remove plugs of food or mucus which tend to clog the lumen of the tube.

Distention now becomes more marked, dependent somewhat on the amount of fluid ingested and the amount vomited. By now the viability of the intestinal wall has become impaired, setting the stage for a fatal outcome because of absorption of toxic products of bacteria and cellular destruction.

2. *Nonoperative Treatment.* Although the treatment of intestinal obstruction is primarily surgical, a number of nonoperative procedures are important, particularly in preparing the patient for operation. These include the replacement of deficits with adequate parenteral fluids and the use of gastrointestinal decompression.

(*a*) In general, *gastrointestinal decompression* is quite effective in relieving the obstruction due to adhesive bands or paralytic ileus; the former may be completely relieved, especially those occurring within a relatively short time after the operation. On the other hand, in obstruction which develops late after operation, the band that is responsible has usually become fibrous and well developed, so that operation is advisable because of the likelihood of recurrence even though the obstruction is relieved temporarily. Under such circumstances, operation can be carried out with very little difficulty or risk. Continuous gastrointestinal decompression is, of course, strongly contraindicated in any patient in which the obstruc-

tion is due to a strangulated hernia, volvulus, or intussusception. However, even in such cases, decompression should be started along with the injection of fluids while the operating room is being prepared. Such patients will take a much smoother anesthetic with less danger of aspiration if the upper intestinal tract has been partly decompressed even during such a short period as a half hour.

When gastrointestinal suction is indicated, how long shall it be continued before operation must be performed? Too often, indeed, operation is delayed too long. In the consideration of choosing the time for operation certain criteria are important:

(i) The presence or development of intestinal strangulation obviously calls for immediate surgical intervention. This is, of course, immediately evident in a strangulated hernia or in volvulus. Indeed, operation is carried out as an emergency in such cases with no delay for conservative measures except for emptying the stomach and starting intravenous fluids. Much more insidious is the type of vascular obstruction with resulting strangulation which may develop in a patient starting off with a mechanical occlusion of the lumen of the intestine, distention of which may lead to nonviability of the bowel wall. Also insidious is strangulation which becomes superimposed upon a mechanical obstruction because of changes within the abdomen that permit bands to become tighter and occlude the vessels to a loop of intestine not previously involved. Careful study of the patient at frequent intervals usually enables the surgeon to detect even these instances of gradually developing strangulation. The following manifestations are indicative of strangulation: 1. increased pain and local tenderness; 2. increase in the pulse rate; 3. the appearance of either fever or subnormal temperature; 4. increasing leukocytosis; 5. the development of a palpable mass, especially with associated local muscle spasm; and 6. signs of even slight asthenia and prostration. It must be emphasized, however, that the dangers of strangulation are so great the surgeon should err on the side of operating early even if the presence of strangulation is merely suspected.

(ii) Gastrointestinal suction drainage must not be continued if decompression is inadequate and the patient appears to be losing ground. Adequate decompression is shown by the evacuation of considerable gas and fluid from the intestinal tract, cessation of pain, decrease in distention and abdominal tenderness, passage of gas and stool per rectum, and obvious improvement in the patient's general appearance. Several hours may be utilized in trying to achieve adequate decompression in patients who have none of the signs of strangulation as listed above. However, even though signs remain minimal, it is rarely justified to delay operation longer than 24 hours if by that time definite evidence of release (e.g., passage of gas or small amount of stool) has not occurred. If release of obstruction is obtained by decompression, it is very important that it be maintained for at least 48 hours beyond the time when the obstruction has been relieved; if the tube is removed and feedings begun before the lapse of that much time, the obstruction will usually return promptly. Even though decompression may relieve obstruction due to an adhesive band, it is usually advisable to operate later and sever the offending adhesion to prevent another attack, except in obstruction occurring in the immediate postoperative period which, with few exceptions, is relieved by decompression, and permanently. While decompression has been instrumental in saving lives and avoiding the need for operation in many cases, its use when not indicated (intestinal strangulation) or for too long a period has undoubtedly led to needless loss of life. The principle of successful gastrointestinal decompression depends on the fact that relief of distention, in the absence of strangulation, alleviates symptoms, corrects many of the local changes at the obstruction, and permits more adequate study of the patient. Decompression must be used intelligently and the tube must be kept open. The Miller-Abbott tube is designed to pass beyond the duodenum. It has two lumina, one for suction and the other to blow up the balloon on the end of the tube; this balloon acts as a bolus against which the intestine can contract, thus propelling the end of the catheter down the intestinal lumen. However, so much difficulty is experienced with the passage of this tube that it is no longer popular. Many other types of tubes have been devised for

passage into the small bowel. Mercury attached to the end of the tube moves primarily by virtue of its weight and will usually fall to the pylorus if the patient lies on the right side. By distending the stomach with air the same may be accomplished with the ordinary two-lumened tube without mercury. Many directors have been devised to aid in passage of the tube through the pylorus (Abbott, Devine, Smith). If intestinal decompression is to be used, it is best to pass the tube under fluoroscopic control, since otherwise there is loss of valuable time and lack of assurance that the tube is in the small bowel.

(iii) In large bowel obstruction, gastrointestinal decompression is not effective regardless of the cause. In such cases, cecostomy or colostomy is indicated as an emergency operation to relieve the distention and obstruction; if the obstruction is caused by an adhesive band (as it rarely is in large bowel obstruction), the band may be severed; but if a tumor is the cause, as will usually be the case, resection should be postponed for 14 to 18 days after the colostomy to permit adequate decompression and recovery from obstruction.

(*b*) *Parenteral fluids* to correct dehydration are used according to the various methods described in Chapter 9. Three important factors must be emphasized. First of all, the amount must be adequate. It is usually insufficient to give 500 or 1,000 ml. Ordinarily, at least 1,500 to 2,000 ml. must be given to bring the blood volume back to normal. In severely dehydrated patients, as much as 5,000 ml. may have to be given. In the absence of chemical analysis of the blood, one may gain a fair idea of the adequacy of the amount of fluid given by noting the bedside improvement in the patient's clinical picture and the secretion of a dilute urine, indicating that the fluid balance has been restored. Such a result may often be achieved within relatively few hours.

Second, sufficient electrolyte should be included inasmuch as this is an important constituent of the fluid lost by vomiting. Glucose is added because of its advantage as a source of calories, and amino acids as a means of supplying protein food. The correction of dehydration from vomiting with glucose and amino acid solutions alone without electrolyte do more harm than good. While present in the blood stream, the solution is effective in diluting the concentrated blood, but within a few hours the glucose and amino acids are metabolized or stored; the situation then becomes the same as if plain distilled water had been administered. In such a case the body fluids become hypotonic, as shown by a low plasma sodium level. This type of iatrogenic water intoxication calls for the injection of hypertonic (5 per cent) NaCl in amounts of 4 to 7 ml. per kg. of body weight. Dramatic clinical improvement and a good diuresis usually follow. Acute salt deficiency of this kind will not occur often if physiologic saline is used to correct the depletion due to loss of fluids by vomiting. To avoid potassium deficiency, the fluid given should also contain 1 or 2 grams of KCl per liter. To correct a potassium deficiency (as shown for example by persistent paralytic ileus) more must be added, although because of its irritating effect on the vein, one can use only 4 grams of KCl to each liter. In severe cases of potassium deficiency, several days may therefore be required before the intracellular and extracellular potassium levels are restored. Only the latter is revealed by the plasma concentration (see also Chapter 9).

Third, plasma transfusions may be added to replace that lost in obstructed bowel, and to prevent or correct hypoproteinemia especially if the patient has been chronically ill. Indeed, hypoproteinemia may of itself produce nutritional edema of the intestinal mucosa and give rise to signs of intestinal obstruction (Chapter 10). Obviously, if hypoproteinemia is present, the fluid injected intravenously must contain protein; plasma or whole blood transfusions are needed as much as saline and glucose. The existence of much distention should always call for plasma; if the red count is low rather than high, whole blood is preferable.

(*c*) Procedures designed to aid in the passage of obstructed contents from below are of value if successful. Enemas or a rectal tube are used for this purpose. It should be emphasized that the obstructed intestinal contents are nearly always liquid in character; the evacuation of intestinal contents from above the obstruction is indicated by the passage of gas and of liquid stool. This is of particular

importance after the institution of treatment in order to determine if progress is being made in the relief of the obstruction.

(*d*) Removal of fecal impaction, when producing obstruction, is an effective nonoperative treatment which is frequently overlooked, particularly when abdominal distention develops in older and debilitated patients or in children. A rectal examination will nearly always make the diagnosis; manipulation of the fecal mass with the finger aided by oil and small enemas will usually result in relief, particularly if performed in several sessions. Fecal impactions above the rectum probably occur but are difficult if not impossible to establish as a cause of significant obstructive symptoms.

(*e*) Oxygen inhalations are often useful in combating the serious manifestations of strangulation, i.e., "toxic" symptoms, circulatory impairment, and anoxia which may even persist after operative correction. Oxygen is also used to decrease distention.

(*f*) Combined chemotherapy, utilizing penicillin, streptomycin and aureomycin, or terramycin and neomycin, is of tremendous value as an adjunct to surgery, especially in strangulation (3).

3. *Operative Treatment.* Gastrointestinal decompression and other adjunctive procedures are important usually in preoperative preparation (Fig. 7). Even the elimination of gastric distention, which is part of intestinal obstruction, will be advantageous, particularly by minimizing aspiration if operation is done under general anesthesia. When the distention is so slight as not to interfere with surgical intervention, the safest procedure is early operation to correct the cause. Marked distention, on the other hand, always makes operation more hazardous and increases mortality because of the technical difficulties induced. Strangulation, when present, either primarily or as a complication, makes operation imperative as an emergency. However, even in such a case conservative measures, such as suction drainage and parenteral fluids, should be started while the patient is being prepared for operation, which, however, should not be delayed thereby.

Three general operative procedures are available for the relief of acute intestinal ob-

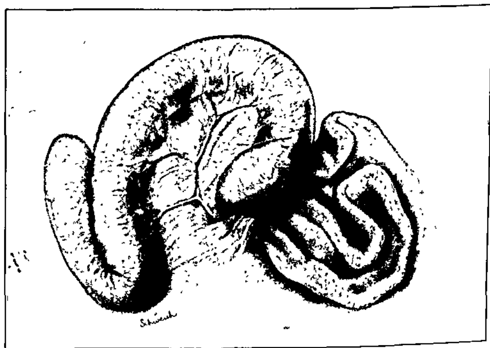

Fig. 8. Acute intestinal obstruction (mechanical occlusion of the lumen). Artist's drawing at time of operation; the dense adhesive band occluded the lumen completely. Note the marked distention of the proximal loop and collapsed distal loop; this obvious contrast was most useful at time of operation in locating the exact site of the occlusion which was corrected by cutting the band. The patient had had a hysterectomy two weeks previously; the pain, distention, vomiting, etc., were, at first, erroneously attributed to postoperative ileus. Recovery was complete.

structions, used either alone or in combination: 1. release of the obstruction; 2. enterostomy; and 3. resection and anastomosis. The details are to be found in works on operative surgery. When there is no evidence of damaged bowel or when relatively little distention is present, the site of the obstruction is located by finding the junction between collapsed and dilated bowel (Fig. 8). The band or bands are cut, or other causes eradicated. Deflation of the obstructed gut will follow correction of the cause. In the very ill patient in whom extensive exploration is unjustified or in whom the obstruction cannot be easily found, operation may be confined to an enterostomy performed under local anesthesia. If intestinal strangulation is present and the involved tissue is definitely nonviable, resection and anastomosis are indicated (Fig. 9). However, if the risk of primary resection and anastomosis is too great, the gangrenous loop may be exteriorized (Mikulicz procedure) before removal, and plastic repair made later. Whether the obstructed or strangulated bowel is viable or not is an obviously important question at the time of operation; the manifestations of viability in strangulation are described on page 845.

In paralytic ileus, operation is indicated only in general peritonitis for eradication of the source of the peritonitis, such as drainage of abscesses and closure of perforations. Although enterostomy has been advised and used in this condition, its efficacy is questionable even in relieving distention, for the drainage is ordinarily successful from only a short

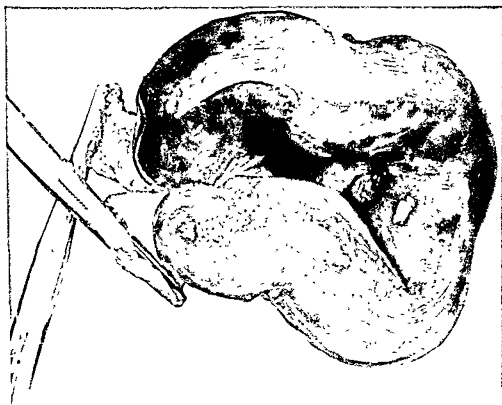

Fig. 9. Intestinal strangulation. Photo of specimen resected in a 35-year-old salesman. Note the gangrene sharply demarcated from normal bowel where the clamps are applied. The cause was a stout band producing this volvulus-type of strangulation The patient was admitted two hours after he was awakened from a sound sleep by agonizing cramping, abdominal pain, nausea, and vomiting. He had had an appendectomy two years before. Examination after admission was essentially negative. The abdomen was scaphoid and showed only slight diffuse tenderness, radiography was negative, laboratory tests all normal. Because of increasing pain he was operated on 10 hours later. A primary end-to-end anastomosis was followed by a relatively uneventful recovery. It is likely that had operation been carried out soon after admission, the band could have been cut and resection made unnecessary.

segment of bowel as long as peristalsis is absent. As soon as the gut becomes active, such drainage is unnecessary since, in absence of organic occlusion, the peristalsis carries intestinal content normally. The use of intestinal decompression is a direct approach to therapy in paralytic ileus, inasmuch as the decompression tube will aspirate back the swallowed air and prevent it from creating distention of the intestine. As the gut is decompressed, activity may be resumed wholly or in part. Ordinarily, however, as mentioned above, paralytic ileus responds to conservative treatment and to measures which correct the primary lesion.

Chronic or Partial Obstruction. Chronic obstruction may be produced by a variety of lesions, including carcinoma of the colon and regional ileitis. There is usually a history of transient attacks of acute obstruction which subside only to recur; occasionally, an erroneous diagnosis of acute appendicitis is made. Often, however, there may be only a progressive and insidiously developing abdominal distention with or without constipation. Besides the lesion causing the partial occlusion of the lumen, the intestine immediately above is thickened, dilated, and hypertrophied. Prompt vomiting and cramps, which follow acute distention of the normal bowel, occur late if at all. It is remarkable that a chronically obstructed small bowel can become so tremendously yet insidiously dilated. Early diagnosis is important not only because cancer may be present, but also because neglect of therapy will lead to progression of the intestinal changes. Radiography is of diagnostic value because the large, dilated, gas-filled loops of intestine show readily on the flat film. The use and danger of using a barium meal has already been mentioned. Treatment is, in general, surgical even if the lesion is benign. In chronic partial obstruction which on most occasions demands operative correction, the major issue will usually be the patient's operability, which will have decreased because of malnutrition, chronic infection, and so forth. If the patient is able to eat a small quantity of food (perhaps 1,000 calories per day), enough may be added intravenously (glucose, amino acids, and fat) and by tube feeding (nasal tube into the stomach) to get the caloric intake up as high as 2,500 or 3,000 calories; if this can be accomplished, it will be desirable to delay operation many days because, by so doing, the operative risk may be reduced from 15 or 20 per cent down to 1 or 2 per cent.

Chronic duodenal ileus represents a clinical syndrome consisting of anorexia, vomiting, and severe loss of weight. It is due to chronic, partial obstruction of the terminal duodenum by the superior mesenteric vessels at the ligament of Treitz as it crosses the bowel at this point. The diagnosis is usually made only by x-ray examination after a barium meal. If the presence of obstruction can be definitely established, surgical treatment is justified. Operation consists of an anastomosis around the occluding band, i.e., duodenojejunostomy.

SPECIFIC LESIONS PRODUCING INTESTINAL OBSTRUCTION

Strangulated Hernia. A common cause of intestinal obstruction is strangulation within a hernial sac; it is so frequent, in fact, that any patient with manifestations of intestinal obstruction should be examined for the possible presence of an inguinal or femoral hernia. The obstruction is nearly always complete. Any loop of intestine may be involved. Operation is, of course, imperative except when normal reduction is possible. A detailed discussion of strangulated hernia will be found on page 844.

Adhesions and Bands. With a few exceptions, adhesions capable of causing intestinal obstruction are produced by a previous abdominal operation, or inflammation, particularly of pelvic origin. Operations commonly producing such adhesions are gynecologic and those performed for perforated appendicitis. The obstruction may develop at almost any time following operation but is, perhaps, encountered most frequently within several months following operation. When true intestinal obstruction develops within the first two or three postoperative days, it is usually due to fresh adhesions associated with the recent operation. It may be difficult to differentiate this from partial rupture of the abdominal wound, with or without the presence of wound infection. Diagnosis may be difficult at this time because postoperative ileus

may produce similar manifestations, including abdominal pain, nausea, vomiting, and distention. Since the adhesions producing obstruction so early after operation are friable and not dense, nonoperative therapy, including decompression, primarily is almost always successful because it relieves edema, which is a prominent feature in the production of the obstruction. If decompression is not successful in yielding partial relief of the obstruction after passage of the tube, emergency operation may be indicated, especially if any of the signs of strangulation as previously discussed are present.

In intestinal obstruction occurring months or years after operation, the adhesive band is more apt to be tough and dense. The adhesion usually connects two peritoneal surfaces and, during the process of contraction, finally becomes tight enough to obstruct the lumen of the bowel, particularly when a secondary inflammation of the intestine and adjacent tissue with edema takes place. The adhesion may produce a necrosis of that portion of the intestinal wall in the area compressed by the band; an entire loop of intestine may be strangulated by a circular band. Obstruction is occasionally produced by attachment of a Meckel's diverticulum to an adjacent point with compression of the underlying loop. Even if the obstruction is relieved by nonoperative therapy, operation should be performed in order to cut the band and prevent the danger of recurrence or of chronic obstruction. The various procedures available for treatment of such patients have been discussed earlier in this chapter.

Neoplasms of the Intestine. With few exceptions, the neoplasms of the intestine capable of producing obstruction are located in the colon and are malignant. The small intestine may, however, become obstructed by attachment to cancer elsewhere or by metastases. Details of the clinical manifestations and treatment will be found where the specific lesions are discussed (Ch. 31).

Intussusception. Invagination of a portion of intestine into an adjacent distal loop (intussusception) is a fairly common type of obstruction; it is rare in adults, and occurs most frequently in infancy and less so with early childhood. This invagination occurs most commonly at the ileocecal valve, but may develop elsewhere in the small and large intestine, particularly in the terminal ileum and upper part of the descending colon (Fig. 10).

In most cases of intussusception, investigation at operation will disclose one or more anatomic features which undoubtedly play an important role in the invagination. An unusually long mesentery of the cecum and ileocecal region will be found most commonly as the only abnormality. In fact, it is doubtful if intussusception can progress far without the existence of this long mesentery. Occasionally, a small Meckel's diverticulum, or a polyp, or a bit of aberrant pancreas is the instigating factor. In any case, occlusion of the vessels of the intussuscepted loop occurs

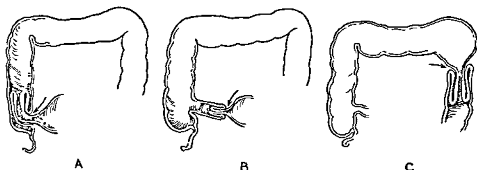

Fig. 10. Three sites for intussusception. The diagrams show only the initial step in the process. In most instances a far longer portion of the ileum or colon becomes involved by the time operation is performed. The arrows indicate the points at which the mesenteric vessels become obstructed by the intussusception. A, at the ileocecal valve; this is by far the most common location. B, at the terminal ileum; intussusception at this site is usually produced by a definite cause, such as an intestinal polyp, a Meckel's diverticulum, and so forth. C, in the descending colon which is exceedingly rare.

segment of bowel as long as peristalsis is absent. As soon as the gut becomes active, such drainage is unnecessary since, in absence of organic occlusion, the peristalsis carries intestinal content normally. The use of intestinal decompression is a direct approach to therapy in paralytic ileus, inasmuch as the decompression tube will aspirate back the swallowed air and prevent it from creating distention of the intestine. As the gut is decompressed, activity may be resumed wholly or in part. Ordinarily, however, as mentioned above, paralytic ileus responds to conservative treatment and to measures which correct the primary lesion.

Chronic or Partial Obstruction. Chronic obstruction may be produced by a variety of lesions, including carcinoma of the colon and *regional ileitis. There is usually a history of* transient attacks of acute obstruction which subside only to recur; occasionally, an erroneous *diagnosis of acute appendicitis* is made. Often, however, there may be only a progressive and insidiously developing abdominal distention with or without constipation. Besides the lesion causing the partial occlusion of the lumen, the intestine immediately above is thickened, dilated, and hypertrophied. Prompt vomiting and cramps, which follow acute distention of the normal bowel, occur late if at all. It is remarkable that a chronically obstructed small bowel can become so tremendously yet insidiously dilated. Early diagnosis is important not only because cancer may be present, but also because neglect of therapy will lead to progression of the intestinal changes. Radiography is of diagnostic value because the large, dilated, gas-filled *loops of intestine show readily on the flat* film. The use and danger of using a barium meal has already been mentioned. Treatment *is, in general, surgical even if the lesion is* benign. In chronic partial obstruction which on most occasions demands operative correc*tion, the major issue will usually be the patient's* operability, which will have decreased because of malnutrition, chronic infection, and so forth. *If the patient is able to eat a* small quantity of food (perhaps 1,000 calories per day), enough may be added intravenously (*glucose, amino acids, and fat*) and by tube feeding (nasal tube into the stomach) to get the caloric intake up as high as 2,500 or 3,000 calories; if this can be accomplished, it will be desirable to *delay operation many* days because, by so doing, the operative risk may be reduced from 15 or 20 per cent down *to 1 or 2 per cent.*

Operation consists of an anastomosis around the occluding band, i.e., duodenojejunostomy.

SPECIFIC LESIONS PRODUCING INTESTINAL OBSTRUCTION

Strangulated Hernia. A common cause of intestinal obstruction is strangulation within *a hernial sac; it is so frequent, in fact,* that any patient with manifestations of intestinal obstruction should be examined for the possible presence of an *inguinal or femoral hernia*. The obstruction is nearly always complete. Any loop of intestine may be involved. Operation is, of *course, imperative except* when normal reduction is possible. A detailed discussion of strangulated hernia will be *found on page 844.*

Adhesions and Bands. With a few excep*tions,* adhesions capable of causing intestinal obstruction are produced by a previous abdominal operation, or inflammation, particularly of pelvic origin. Operations commonly producing such adhesions are gynecologic and those performed for perforated appendicitis. The obstruction may develop at almost any time following operation but is, perhaps, encountered most frequently within several months following operation. When true intestinal obstruction develops within the first two or three postoperative days, it is usually due to fresh adhesions associated with the recent operation. It may be difficult to differentiate this from partial rupture of the ab*dominal wound, with* or without the presence of wound infection. Diagnosis may be difficult at this time because postoperative ileus

particularly because of their tendency to vomit. Parenteral feeding should be continued until there is evidence of a return of gastrointestinal function, as shown by the passage of stool and gas, and by auscultation of peristalsis. Starting with simple liquids, the diet is gradually increased.

The water and electrolyte requirements of infants are often exaggerated during periods of parenteral feeding, as pointed out by Gross (6). The basic water needs of the infant are closer to 75 ml. per kg. than to 150, as often stated. The latter figure is based on the normal oral feeding mixture but is excessive when applied to the sick infant requiring merely maintenance of water balance by parenteral fluids. Excessive salt is even more dangerous, as it is in adults and for the same reasons. To correct deficits, larger intakes are, of course, necessary.

Volvulus. Any free, usually redundant, loop of intestine may become twisted and fixed, thus producing a volvulus (or torsion). Fixation is maintained by adhesive bands but more commonly is due to structural abnormalities. When it occurs in the small intestine, adhesions are very apt to be the inciting factor, or at least the factor responsible for maintenance of the twist. When it occurs in the colon, the sigmoid is a common site for volvulus, apparently because of the long flexure, in which the limbs of the loop are approximated so closely, and because of the long mesentery which exists so frequently at this point. Volvulus of the cecum and ascending colon, though rare, occurs nearly always in children, as a complication of malrotation of intestine, as described later.

Volvulus produces a clinical picture similar to that already described for intestinal obstruction. If the blood supply at the mesentery is completely occluded, severe signs of intestinal strangulation will follow, which may be of dramatic suddenness and accompanied by shock. If the involved loop of intestine is in the colon, it becomes markedly distended with gas and fluid; this distended loop may be so prominent as to be palpable and thus lead to an accurate diagnosis. If strangulation exists, considerable blood-stained fluid may be found in the peritoneal cavity at operation.

On rare occasions, when the volvulus is of short duration and located in the sigmoid, the torsion may be relieved by a barium enema; occasionally, the torsion corrects itself spontaneously and a history of subsiding attacks may be obtained (recurrent volvulus). Occasionally, the obstruction can be relieved by inserting a sigmoidoscope and passing a large catheter up into the involved loop of sigmoid through the obstructed area created by the twist. However, most surgeons do not utilize this procedure; they prefer not to run the risk of failure that would obviously delay correction by operation, which is the only curative procedure. If strangulation is not present, untwisting the loop may be sufficient to entirely relieve the obstruction. Any adhesive bands present should be cut. Since the sigmoid is the area most subject to recurrence of a volvulus, excision of the involved loop may be indicated even if strangulation is not present. Resection with primary anastomosis is usually preferable when the torsion involves the small intestine: in the sigmoid, exteriorization after the Mikulicz procedure, followed by anastomosis later, is usually preferable, but a planned resection and primary anastomosis may be justified when the operation is carried out to prevent recurrent volvulus.

Malrotation of the Intestine. Anomalies of rotation of the intestine during embryonic life may be responsible for a number of different types of intestinal obstruction. Before the mechanisms of these types of obstruction can be understood, it is necessary to be familiar with the main features of intestinal rotation. Normally, the midgut recedes from its position in the yolk sac, through the umbilical orifice, into the abdominal cavity at about the tenth week of embryonic life. The cecum is the last portion of the intestine to enter the abdominal cavity and, from its position in the left posterior portion of the yolk sac, rotates 270 degrees on the axis of the superior mesenteric artery from the left upper quadrant in a counterclockwise direction to its permanent position in the right lower quadrant.

Incomplete rotation of the cecum is the most common anomaly. When this occurs, the cecum and part of the ascending colon with the terminal ileum are found in the upper left quadrant and the terminal ileum is attached to the jejunum with a broad band. This not only prevents return of the cecum

at a variable time after onset. As this vascular compression increases, gangrene of the involved intestine develops, which leads to a fatal outcome unless the necrotic segment is sloughed into the lumen; this occurs but is extremely rare. Adhesions may cause the intussusception and obstruction to persist.

The *clinical manifestations* are remarkably constant and dramatic. One of the first symptoms noted is pain, which is presumably severe, as expressed by irritability of the infant who screams and cries out frequently, holding its abdomen. Shortly after the onset of the pain, nausea and vomiting are noted. Within an hour or two, manifestations of shock, such as listlessness, weakness, prostration, and pallor, develop. The pulse rapidly becomes fast, weak, and thready. There are two features of this shock which appear to be of particular diagnostic significance, namely the dusky color associated with the pallor, and the extreme prostration which develops rapidly following onset. However, these features of shock may also be exhibited in infants with intestinal obstruction produced by other causes. Occasionally, shock of the type just described will be seen without pain (screaming and crying), the mother noting only listlessness, prostration, and pallor. It is not *uncommon for the infant to have a normal bowel movement* shortly after the onset of pain. Following this, other stools will be passed, which at first contain mucus, later mucus streaked with blood, and finally pure blood, the color of which depends upon the location of the intussusception. A mass is usually palpable, first in the right lower quadrant, but moves progressively upward toward the epigastrium and across to the left side of the abdomen with the lapse of time. Muscle spasm and tenderness are rarely severe, if present at all. Peristaltic waves may or may not be visible. *Distention usually occurs but is not* a prominent feature until after 24 hours. *Obstruction is usually complete* soon after onset; an enema yields chiefly mucus and blood. On rare occasions, the intussusception is relieved spontaneously or after an enema; this occurs only early in the disease and is apt to be followed by recurrence. Recurrent intussusception is probably the cause of certain obscure intestinal episodes in infancy. Fever may be present, but usually only in the late stage of the obstruction. Leukocytosis may or may not be present. Rectal examination will reveal bloody mucus in the rectum; the mass may be palpable by the examining finger.

Treatment is surgical and should be *delayed only long* enough to insert a catheter after cutting down on a leg vein for the injection of blood and fluids. This can be done in the operating room if necessary. Ether anesthesia will usually be indicated but very little if any is really needed if the child is in shock, at least in the beginning. Local anesthesia may be adequate. A right paramedian incision should be made if no mass is palpable. However, if a mass is demonstrable, the incision should be made over it. At operation, the intussuscepted loop is reduced most effectively by gentle compression from the distal end. Pulling on the proximal loop is comparatively ineffective when the intussusception has been present for more than a few hours and may produce a tear in the intestine. Reduction may be impossible, usually because of adhesions or gangrene. In this event, resection will be necessary and, in most cases, can be safely followed by primary anastomosis. Excision of the gangrenous mass will be followed by an immediate improvement in the general condition of the infant due to the *removal of the focus of* "toxic absorption." Should the mass be exteriorized for resection, thus creating a double-barreled enterostomy, repair should be carried out as soon as possible, usually in a few days. If manifestations of shock are at all pronounced or persist, a blood transfusion should be given during or immediately after the end of the operation. Oxygen inhalation will also be valuable in such cases. If the general condition is good, it may be advisable to do an appendectomy, which, by laying down scar tends to prevent recurrence. An intussusception, when seen *early and when the mass* is still small, can occasionally be reduced under the fluoroscope by means of a barium enema, which must be carefully given without too much pressure. However, this procedure has its limitations and, in any case, if used should not unduly delay operation which must be immediately carried out if the reduction by enema fails.

Proper postoperative feeding may be of extreme importance in the convalescence of these patients (most of whom are infants),

Fig. 11. Congenital hypertrophic stenosis of the pylorus. The infant was six weeks old. The two photographs were taken a few seconds apart. A, note the peristaltic wave beginning low in the left hypochondrium. In B, it has moved toward the patient's right and downward; the trough of a second wave is also seen approaching the pylorus, above and to the right of the umbilicus. Pyloromyotomy (Fredet-Ramstedt operation) was followed by an uneventful recovery.

of the impacted meconium. Should the obstruction persist, operation is indicated. Some of these cases, unfortunately, are associated with failure of a fibrocystic pancreas to produce adequate proteolytic ferment to dissolve the meconium. At operation, diagnosis is evident by the leathery, narrowed gut containing tough, sticky meconium. If it can be dissolved by the injection of solutions containing proteolytic ferments or hydrogen peroxide, continuity of the lumen may be achieved. Usually, however, it is necessary to resect the involved bowel. Gross (6) prefers resection by the Mikulicz exteriorization technic, closing the ileostomy two or three weeks later; there will be very little irritation of the skin because the intestinal fluids are deficient in enzymes.

Hypertrophic Pyloric Stenosis. This disease occurs in early infancy and is due to a pyloric obstruction produced by hypertrophy of the circular pyloric muscles, although there is probably some degree of associated spasm. The disease is much more common in males than in females. The symptoms first appear at the second or third week of life and consist primarily of vomiting. At first the vomiting may be manifested merely as a regurgitation but later becomes projectile. The child usually vomits after every feeding and frequently the entire feeding. The vomitus never contains bile since the obstruction is proximal to the ampulla of Vater. Unless the child is fed again after vomiting, dehydration and loss of weight may take place rapidly. In spite of refeeding and extreme care in choice of formulas and the use of muscle-relaxing drugs, gradual loss of weight is the rule. Constipation is obviously and always present. Shortly after the onset of the disease peristaltic waves will be observed, beginning characteristically at the left costal margin and passing to the right, particularly after ingesting fluid (Fig. 11). It may be necessary to examine the child several times before significant peristaltic waves are demonstrable. A palpable tumor in the right upper quadrant of the abdomen can often be felt; it is about the size of a small olive and represents the firm area of hypertrophied pyloric muscle. However, palpation of a tumor is not essential for diagnosis. A roentgenogram will reveal merely a large, dilated stomach. Fluoroscopy after a barium meal may be carried out

to its normal position in the right lower quadrant but leads to a twisting or volvulus of the entire small gut. *This obstruction may not* occur for several months or years after birth; manifestations are similar to those of obstruction and volvulus as already described. A history of intermittent attacks of intestinal obstruction may be obtained. Cure may be effected by cutting the band which has produced the obstruction and maintained the malrotated position. Occasionally, rotation takes place in the reversed direction (clockwise). In this case, the positions of the duodenum and colon with respect to the mesenteric artery will be reversed, i.e., the duodenum will be anterior to the superior mesenteric artery and the colon posterior to the artery.

The various features of malrotation of the intestine have been well described by Gross (6). *Even in the absence of volvulus, symp*toms of "chronic" intestinal obstruction may develop because of sharp angulations produced by anomalous attachments, particularly in the terminal portion of the duodenum. A correct diagnosis can seldom be made previous to operation even by means of fluoroscopic and x-ray study with the barium meal. At operation however, the diagnosis is usually evident, provided the entire gastrointestinal tract is eviscerated through a long incision and the true state of affairs accurately determined. Only then can the defect, of which there are many different and bizarre kinds, be detected and remedied.

Congenital Stenosis and Atresia. Complete or partial intestinal obstruction, when evident soon after birth, is usually due to congenital stenosis (narrowing of the lumen), and/or atresia (complete obliteration of the lumen). The former is due to the pressure of a congenital band, the latter to agenesis or undissolved meconium (see below). The various sites and varieties are shown in Fig. 1, p. 819. Atresias or stenoses are most common in the duodenum (third portion), next in the terminal ileum.

The symptoms produced will depend on the site and completeness of the obstruction. Duodenal obstruction will be associated with the vomiting of bile-stained material, unlike the vomitus of clear gastric contents in pyloric stenosis. The x-ray will usually be very helpful in establishing the diagnosis (7). If the obstruction is in the duodenum, the stomach and first part of the duodenum will show gaseous distention but no gas in the rest of the gastrointestinal tract. If the obstruction is located in the terminal ileum, the entire small bowel will be distended. When the obstruction is partial or intermittent, the infant may not be seen until later in life, since normal growth will occur between attacks.

Operation will be indicated immediately in the case of a complete atresia (8) and later in the case of partial or incomplete obstruction, which is serious enough to produce symptoms and/or to disturb the child's growth and nutrition. Newborn babies, even when premature, withstand operation surprisingly well (9) if the obstruction is relieved. Complete exposure is necessary. The introduction of a tiny plastic tube into the stomach, passed into the duodenum, and inflated or injected with fluid often helps in differentiation between atresia and stenosis, since congenital bands are sometimes present with atresia due to a diaphragm. Correction of the obstruction is, of course, a primary necessity and can usually be carried out in every instance, even if an anastomosis is needed. Fine arterial needles and silk are helpful. The most readily and easily corrected types are those caused by a congenital band, which is simply severed. Congenital lesions (e.g., multiple areas of stenosis) sometimes require resection of a considerable length of ileum or jejunum which are tolerated quite well by infants (10) —if they survive the immediate effects of the operation—but removal of long segments may be followed by gastrointestinal disturbances with limitations on growth. Imperforate anus, another type of atresia requiring operation, is discussed on page 777. For details of these and allied lesions of infancy and childhood see the texts by Gross (6) and Swenson (11).

Meconium Ileus. This is a rare but often serious condition occurring immediately or soon after birth. Inspissated undissolved meconium may remain in parts of the lumen of the terminal ileum and colon, producing all of the signs of intestinal obstruction with increasing abdominal distention, nausea, and vomiting. Fortunately, such symptoms are sometimes transient and cease on evacuation

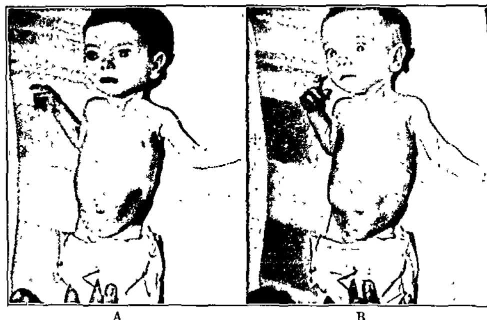

Fig. 11. Congenital hypertrophic stenosis of the pylorus. The infant was six weeks old. The two photographs were taken a few seconds apart. A, note the peristaltic wave beginning low in the left hypochondrium. In B, it has moved toward the patient's right and downward; the trough of a second wave is also seen approaching the pylorus, above and to the right of the umbilicus. Pyloromyotomy (Fredet-Ramstedt operation) was followed by an uneventful recovery.

of the impacted meconium. Should the obstruction persist, operation is indicated. Some of these cases, unfortunately, are associated with failure of a fibrocystic pancreas to produce adequate proteolytic ferment to dissolve the meconium. At operation, diagnosis is evident by the leathery, narrowed gut containing tough, sticky meconium. If it can be dissolved by the injection of solutions containing proteolytic ferments or hydrogen peroxide, continuity of the lumen may be achieved. Usually, however, it is necessary to resect the involved bowel. Gross (6) prefers resection by the Mikulicz exteriorization technic, closing the ileostomy two or three weeks later; there will be very little irritation of the skin because the intestinal fluids are deficient in enzymes.

Hypertrophic Pyloric Stenosis. This disease occurs in early infancy and is due to a pyloric obstruction produced by hypertrophy of the circular pyloric muscles, although there is probably some degree of associated spasm. The disease is much more common in males than in females. The symptoms first appear at the second or third week of life and consist primarily of vomiting. At first the vomiting may be manifested merely as a regurgitation but later becomes projectile. The child usually vomits after every feeding and frequently the entire feeding. The vomitus never contains bile since the obstruction is proximal to the ampulla of Vater. Unless the child is fed again after vomiting, dehydration and loss of weight may take place rapidly. In spite of refeeding and extreme care in choice of formulas and the use of muscle-relaxing drugs, gradual loss of weight is the rule. Constipation is obviously and always present. Shortly after the onset of the disease peristaltic waves will be observed, beginning characteristically at the left costal margin and passing to the right, particularly after ingesting fluid (Fig. 11). It may be necessary to examine the child several times before significant peristaltic waves are demonstrable. A palpable tumor in the right upper quadrant of the abdomen can often be felt; it is about the size of a small olive and represents the firm area of hypertrophied pyloric muscle. However, palpation of a tumor is not essential for diagnosis. A roentgenogram will reveal merely a large, dilated stomach. Fluoroscopy after a barium meal may be carried out

and will indicate the degree and completeness of the pyloric obstruction; however, if barium is given, the part remaining in the stomach must be evacuated by a nasal tube when the roentgen examination is completed.

The *treatment* is primarily surgical, but it is of extreme importance that operation be performed only after water, electrolyte, and other deficiencies are corrected; the parenteral route must be used and consists of hypodermoclysis of 200 to 250 ml. isotonic saline solution or Ringer's solution; intravenous administration of 20 ml. of 10 per cent glucose per kg. of body weight, once or twice daily, plus amino acids, may also be advisable. The alkalosis will nearly always be corrected by the giving of physiologic saline. In advanced cases, however, acidic (ammonium chloride) salts may have to be used. If potassium deficiency is associated, this salt should be added. Excessive parenteral fluid administration must be avoided, as already mentioned. If the infant is in especially poor condition a transfusion of 15 to 20 ml. of blood per kg. of body weight may be advisable. Because infants with pyloric stenosis are prone to acquire infections of various types, frequent examinations must be carried out to detect their existence, especially if fever is present. Such infections in themselves are apt to produce vomiting. Proper therapy, including chemotherapy, will be effective in the cessation or diminution of vomiting.

Pyloromyotomy, known as the Fredet-Ramstedt operation, first described in 1912, is curative if properly performed. It consists of division of the dense, firm, hypertrophied, circular muscle fibers at the most bloodless point on the pylorus. Separation is continued until all fibers are broken and the submucosa pouts out into the wound in the pylorus. Extreme care must be taken not to perforate the submucosa; if unrecognized or inadequately repaired, it will lead to a fatal peritonitis. This accident is most apt to occur at the duodenal end; if it occurs, the opening is repaired by one or two interrupted silk sutures taken in a diagonal longitudinal direction. Anchorage of a tag of omentum over the opening will also be of value. Local or general anesthesia may be used. The former should be supplemented with a preliminary sedative. Preoperative gastric lavage appears to increase the toleration for postoperative feeding.

Postoperative care should not be left to chance, especially in regard to feeding. The tendency to force feeding in too large quantities during the first few days is harmful because the stomach is frequently unable to fully empty itself because of gastric atony due to the previous and often long period of pyloric obstruction. Normal gastric peristalsis in such infants is regained only after 24 to 72 hours following pyloromyotomy. During this period, overdistention must be avoided. Half an ounce of water may be offered as early as two hours after operation, but it is probably better to wait 12 hours. Thereafter, the feedings should be dilute at first and limited to 15 ml. per feeding. A mixture of 30 ml. evaporated milk, 30 ml. of 10 per cent buffered solution, 30 ml. of water, and 4 grams of dextrimaltose is made up; this allows administration of six feedings of 15 ml. each. The individual feedings are gradually increased as tolerated. As a routine the amount may be increased 15 ml. each day so that the infant gets six feedings of 30 ml. on the second day, 45 ml. on the third day, and so on until a normal requirement of about 120 ml. is met. After several days the feeding should be concentrated slightly by prescribing a formula of two parts evaporated milk, two parts 1 per cent lactic acid, and one part water; sufficient dextrimaltose is added to make a 6 per cent solution. Before the child is discharged from the hospital, the feeding should be concentrated still more to that of a normal intake, i.e., equal parts of evaporated milk and water to which sufficient dextrimaltose syrup is added to make a 6 per cent solution.

If vomiting continues after operation it does not necessarily mean that the pyloromyotomy was inadequate and needs to be redone. Vomiting may sometimes be diminished or eradicated by sedation, such as one eighth grain phenobarbital every four hours, or, better still, by reducing the amount of feeding for reasons already mentioned. Gastric atony may also be combated by emptying the stomach once or twice every 24 hours for the first few days; favorable progress is indicated by the fact that the amount removed is progressively less than the amount ingested.

Electrolyte and especially potassium deficiency as well as protein depletion may play a part and demand correction. Occasionally, the vomiting is due to extraalimentary infection or other factors not connected with the operation, as mentioned above. A second operation is rarely necessary.

Miscellaneous Lesions Producing Obstruction. There are numerous miscellaneous lesions which are capable of producing either partial or complete obstruction; most of these are discussed in detail elsewhere. Not uncommonly, the amount of inflammation occurring with a *diverticulitis* of the colon will be sufficient to produce severe obstructive symptoms. *Stricture* formation (noncongenital) may occur in any part of the alimentary tract and may be sufficiently severe to produce a total obstruction. In the upper part of the digestive tract, it occurs most often in the esophagus and pylorus. Strangulation is rarely produced by this type of obstruction, although dehydration from loss of fluid through vomiting may produce severe systemic manifestations, particularly in pyloric obstruction. Detailed descriptions will be found elsewhere. Stricture of the rectum due to lymphogranuloma venereum rarely results in acute obstruction (see Chap. 7). Occasionally *benign ulceration* of the intestine, produced by amebiasis, tuberculosis, and so forth, will result in a stricture; these lesions are usually located in the colon. Confirmatory evidence of obstruction will be noted by x-ray, but a diagnosis of carcinoma will usually be made. Operative correction will obviously be indicated in

Fig. 12. Mesenteric thrombosis. Photomicrographs from a section of the excised intestine, showing obstructed vessels. A, is a thrombosed vessel in the intestinal wall and B, an occluded artery and vein in the mesentery. Note also the surrounding edema in A. The thrombosis in the mesenteric vein is obviously of longer duration than that in its accompanying artery. The patient was a 37-year-old housewife; two weeks previously she had been delivered of a normal infant and was enjoying a normal puerperium, when, two days before admission she was suddenly seized with generalized abdominal cramps which became severe and were accompanied by persistent vomiting; blood was noted in the stool Prostration became quite pronounced. At operation, two and one-half feet of nonviable intestine was resected and a primary anastomosis performed; followed by a lateral anastomosis; recovery was uneventful.

most instances. Two types of operative procedures are available: 1. an anastomosis around the stricture can be performed; or 2. the mass can be resected. However, as stated previously, resection of a colonic tumor (with primary anastomosis) is rarely performed in the presence of complete obstruction, because of the high mortality rate. Usually, the obstruction is relieved by a colostomy, and the resection done two weeks later. Regional ileitis often produces signs of intestinal obstruction and is described on page 745.

Mesenteric thrombosis produces nearly all the manifestations of a complete obstruction because of the paralysis of the peristaltic mechanism in the involved area (Fig. 12). More important is the effect of the thrombosis on the viability of the affected intestine, inasmuch as acute sudden manifestations, as described for intestinal strangulation, are produced thereby. The obliteration of the vessels may be due primarily to an embolus or thrombosis. The disease is encountered in patients afflicted with endocarditis, vascular disease, and the like, but frequently develops in supposedly healthy people in whom no etiologic factor can be found. The effects are similar, in general, to those produced by intestinal strangulation, which has already been described (p. 825). Pain is severe, diffuse, and constant; even large doses of morphine are often ineffective in relieving it. Nausea and vomiting are also present. Characteristic is the prostration and shock which rapidly develop; pallor, cyanosis, and low blood pressure with rapid, thready pulse may be noted.

Mesenteric thrombosis involving the colon may produce shock more rapidly but certainly not always. Examination of the abdomen reveals diffuse tenderness and muscle spasm. A tubular mass representing the involved intestine may be palpable. There is usually a marked leukocytosis. If a stool is passed, gross blood may be noted which is of considerable diagnostic importance. Often mesenteric thrombosis is first recognized at operation. If the bowel is gangrenous, resection or exteriorization is obviously indicated. If resection is necessary, prognosis may be more serious because more bacteria are present in the colon.

Intestinal obstruction due to *enteroliths* is rare but most commonly is produced by the ulceration of a large gallstone through the wall of the gallbladder into the duodenum with lodgment in the ileum (gallstone ileus), where it may be discernible in an x-ray film. Usually the diagnosis is first made at operation, during which the stone is removed and the opening in the intestine closed. Fecal impaction occurs frequently but only rarely produces manifestations of acute obstruction.

HERNIA

General Considerations
Specific Types of Hernia

GENERAL CONSIDERATIONS

Definitions. Any protrusion of tissue through an abnormal opening in the wall of a body cavity, particularly the abdomen (including an abnormal hiatus in omentum or mesentery) may be called a *hernia*. Through this opening, such organs as intestine, omentum, and so forth, may pass. Most hernias are *reducible;* their contents can be replaced by manipulation into the cavity of origin or may recede spontaneously when the patient lies down. When the mass cannot be reduced, the hernia is spoken of as *irreducible*. There is a time factor in the term irreducible, for many hernias are irreducible at times and reducible at others. When the hernia becomes permanently irreducible, the term *incarcerated* is used (despite some difference of opinion). An *obstructed hernia* is one containing intestine whose lumen becomes blocked by adhesions, angulation, volvulus, fecal impaction, and the like. Some authorities consider incarceration synonymous with irreducibility, whereas others use the term synonymously with obstructed hernia. Occasionally, only a portion of the intestinal wall is caught in a small hernial opening without obstructing the lumen of the intestine, thereby constituting what is called *Richter's hernia*. This type of hernia occurs most frequently in femoral and inguinal hernias. A *strangulated hernia* is one containing viscera whose blood supply is partially or completely blocked. In such an instance, gangrene obviously follows, unless the block is relieved within a few hours. The terms *true* and *false hernia* are sometimes used to differentiate between hernias having sacs (true hernias) and those not having sacs (false hernias).

Entirely apart from the above terms which really apply to the degree of herniation, hernias are ordinarily classified according to their anatomic location. The most common types are those in the inguinal and femoral region. These and others are described in detail later in the chapter.

Etiologic Factors. The development of most hernias is probably based on the presence of a congenital defect, such as a structural weakness of the supporting structures at the point of herniation, to an unobliterated embryologic channel or process. Despite a definite history of sudden pain in the groin associated with the appearance of a hernial mass immediately following severe strain, such as lifting, it seems probable that the strain was merely the precipitating factor. However, it should be stated that compensation boards usually consider trauma as being capable of producing hernias and rarely fail to return a verdict in favor of the workman who merely states that the hernia appeared during work.

Hernia may first appear at any time during life, but an analysis by Watson (1) indicates that 15 per cent occur during the first year. Obesity, pregnancy, and other conditions which predispose to relaxation and disuse of certain muscles are important secondary causes. In elderly men with prostatic obstruction, the straining incident to difficulty with urination is at times an apparent factor in the development of inguinal hernias, particularly the direct type. A more detailed discussion will be found in the book by Iason (2).

General Clinical Manifestations. A hernia is usually noticed because of the appearance

of a protrusion or mass and is nearly always accompanied by a moderate amount of pain during the first few days. It may or may not be preceded by a history of physical exertion. The pain decreases so that after two or three weeks the symptoms complained of consist of nothing more than a mild feeling of discomfort. There is a tendency for the protruding mass to increase in size. Most hernias are reducible, especially when they are of recent origin. The recumbent position facilitates reduction. After reduction of the mass one can usually feel the defect through which the hernia has protruded. Many hernias become irreducible, especially when the patient has been wearing an ineffective truss or other appliance, because of the adhesions produced between the sac and its contents. The mass is soft, semifluctuant, and usually not tender. In contrast to hydrocele (see p. 1152), it rarely transmits light. The surface is usually not so smooth or regular as that of hydrocele. If intestine is included in the contents of the hernia, percussion will usually reveal a tympanitic note. One of the most reliable diagnostic features of hernia is the impulse transmitted to and enlargement of the mass when the patient coughs. If a hernia is present but no mass presents, coughing will result in a protrusion which can be palpated by the finger placed in the hernial opening or inguinal canal.

Frequently a patient presents himself with the history of having been examined by an industrial doctor who has found a dilated external ring with an impulse on coughing and has advised surgical treatment before employment will be recommended. Though an actual protrusion is not always demonstrable in these cases, operation may be indicated. On many such occasions a small empty sac will be found. Such an empty sac can sometimes be felt along the cord by exerting slight traction on the testicle.

Pronounced and serious symptoms of hernia are produced when the contents become obstructed and strangulated. This, in itself, is such a serious complication that it is considered first.

Obstructed Hernia. Years ago, obstruction in a hernia constituted the most common type of intestinal obstruction. However, the increasing incidence of intraabdominal operations (with resultant obstruction due to adhesions) and the increasing incidence of cancer of the gastrointestinal tract have reduced the percentage due to hernias. In a study of 1,252 cases of intestinal obstruction, Smith and associates (3) found that hernia was the cause in 10.2 per cent, ranking third. However, in their series, hernia was the most common cause of strangulation.

The manifestations of obstruction due to hernia are similar to those of other types, consisting primarily of cramping pain, nausea, vomiting, and obstipation (see Ch. 33). It must be emphasized, however, that the local findings may be so minimal in about half the cases as to confuse the clinician. The presence of an irreducible mass (hernia), cramping pain, nausea, and vomiting, constitute indications for operation until proved otherwise. The over-all operative mortality rate in 130 patients with obstruction due to hernia treated by Smith and associates (4) was 6.9 per cent.

Strangulated Hernia. The term strangulated hernia is frequently applied erroneously to obstructed hernias. With few exceptions, strangulation does not develop until several hours after the hernia becomes obstructed (Fig. 1). Only in Richter's hernia does strangulation occur in the absence of obstruction. Obstruction, and particularly strangulation, are most prone to develop when the ring (e.g., external inguinal) through which the hernia protrudes, is small. The mechanism of strangulation consists first of compression of the veins, followed by edema, later by arterial compression, and gangrene.

When strangulation develops, symptoms are more acute (see Ch. 33). Tension within the mass increases, and there is less tendency to reducibility. Nausea and vomiting become more pronounced. The pain increases and is so persistent that the patient seeks medical attention early. This pain at first is poorly localized, but soon becomes most prominent in the mass, radiating frequently into the depth of the abdomen. The temperature is normal or subnormal, but later becomes elevated. Tachycardia develops early. Occasionally, the patient exhibits mild collapse with a cold, pale, and moist skin, especially if a large amount of intestine is involved in the strangulation. This may be caused in part by

Fig. 1. Gangrenous loop of small intestine removed from a strangulated hernia. The hernia had been present *almost asymptomatically for a great many years. About 12 hours before admission the patient*, aged 45, suddenly experienced severe abdominal pain, nausea and vomiting, and found that the hernia was irreducible. Marked prostration developed. At operation the entire loop of intestine constricted by the hernial sac was gangrenous; it was resected and a lateral anastomosis performed. The arrows indicate the points of constriction.

the large amount of blood and plasma which may become trapped in the obstructed area. Another explanation of shock is the absorption, usually transperitoneally, of toxic substances from the gangrenous intestine. Other manifestations of intestinal obstruction alone, including distention and tympanites, gradually develop (see Chap. 33). Enemas are ineffectual. The mass itself, if palpable, is usually *moderately tense and tender*. By percussion and transillumination of light, it may be possible to demonstrate the presence of both fluid and gas in the sac. The skin itself may become discolored but usually only after the strangulation and gangrene have been present for a long time. Spasm of abdominal muscles will be present if the hernia is intraabdominal; if the hernia is scrotal, moderate spasm with pain may be noted in the lower abdomen. It must be emphasized, however, that in certain cases, manifestations are so mild that it is difficult to differentiate a strangulated from a nonstrangulated (obstructed) hernia.

On rare occasions, strangulation may occur in an internal hernia and there will obviously be no demonstrable external herniation to account for the symptoms. In such instances, the patient is usually operated on for intestinal obstruction, and the actual strangulation is not discovered until the time of operation. When the strangulated tissue consists solely of omentum, the pain is usually much less severe and vomiting frequently absent. The degree of tachycardia and prostration are likewise less prominent. Although strangulation of omentum is obviously followed by gangrene, this condition is not as serious as strangulated intestine. Occasionally, the necrotic omentum becomes infected, which may eventually form an abscess and burrow through the skin.

The *treatment* of strangulation is emergency operation. If the acute incarceration is *recent* (i.e., of only two or three hours' duration), gentle efforts at reduction may be attempted after giving a narcotic or placing the patient in a hot bath. However, such manipulation must be *gentle* and performed with

judgment, lest strangulated bowel be injured or reduced en masse; if perforation results under such circumstances, it can only be because all the principles learned in medicine about gentleness in handling of tissues has been disregarded. If possible, operation should be performed under local anesthesia because these patients do not tolerate general anesthesia well. When the hernial sac is opened, a moderate amount of blood-stained fluid will usually be found within it, regardless of whether or not the contents consist of intestine or omentum. If the intestine is involved in the strangulation, color changes will be noted. In the early cases, the intestine may be merely reddened or slightly cyanosed and the glistening luster of the serosa will be unchanged. In later cases, the luster of the serosa will be lost, and the cyanosis will have progressed to a black color indicating that the intestine is no longer viable, and resection is necessary. The viability of the intestines is determined to a great extent by the presence or absence of the glistening appearance of the serosa. If this is lost and is not regained after release of the obstruction, and application of warm wet packs for five minutes, it is usually considered unsafe to replace the affected portion of intestine. Resection of this gangrenous loop may be performed in one of several ways. With few exceptions, resection with primary anastomosis is indicated.

SPECIFIC TYPES OF HERNIA

Inguinal Hernia. Hernias of this type may be either direct or indirect, but they can be more clearly discussed if the *anatomic* features of the *inguinal canal* are understood. This canal is an oblique passage about 4 cm. long in the male, passing downward and medially from the abdominal (internal) to the subcutaneous (external) ring and is situated parallel to, and above, Poupart's ligament. In the male, it transmits the spermatic cord and vessels, the ilioinguinal nerve and a branch of the genitocrural nerve; in the female, the round ligament and the two nerves just mentioned. The roof of the canal consists primarily of the aponeurosis of the external oblique, and at the upper third, the fibers of the internal oblique. The posterior wall consists largely of the transversalis fascia. Poupart's ligament forms the lateral wall, and the arched fibers of the internal oblique and transversalis muscle form the medial wall. The conjoined tendon is an important structure, particularly because its aponeurotic structure is useful in repair. It is a broad fascial band consisting of the union of the internal oblique, transversalis fascia and the anterior rectus sheath; it is attached to the tubercle of the symphysis pubis. The subcutaneous ring lies between the terminal portions of the conjoined tendon and Poupart's ligament; it varies normally in size from a slit barely large enough to admit the tip of the finger to a circular opening into which one or two fingers can be inserted. The abdominal ring cannot be palpated but can be occluded by pressure over it. The deep epigastric artery passes from its point of origin from the external iliac artery in the floor of the pelvis upward and inward toward the umbilicus from a point midway between the anterior superior spine and symphysis pubis. It lies between the peritoneum and abdominal muscles and is a landmark which determines (at operation) whether a hernia is direct or indirect; if the artery is lateral to the neck of the sac, the hernia is direct; if medial to the neck, the hernia is indirect.

INDIRECT (OBLIQUE) INGUINAL HERNIA. Hernias of this type in particular are due to a congenital patency of the upper end of the processus vaginalis, into which the indirect hernia makes its entrance into the inguinal canal (Fig. 2). This may be clarified by briefly reviewing the mechanism of the descent of the testicle. As the testicle descends from its embryonic retroperitoneal position, it carries peritoneum along with it through the inguinal canal and into the scrotum. This potential sac is called the *processus vaginalis* and some time before birth becomes obliterated through its entire extent, except the part which surrounds the testicle. This portion is normally not obliterated and remains as a closed potential cavity known as the *tunica vaginalis*. The part of the processus vaginalis which extends along the cord is called the funicular process. Normally, the funicular process closes throughout its extent, but if this mechanism fails to take place before birth, there will be a direct communication from the peritoneal cavity down to the testicle.

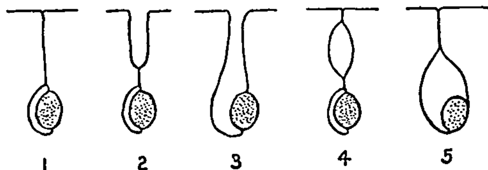

Fig. 2. Relation of the processus vaginalis to the more common types of hydrocele and hernias. 1, normal obliteration of the funicular process; the distal end of the vaginal process remains at the tunica vaginalis. 2, funicular hernia caused by the patency of the proximal portion of the process. 3, complete patency of the process, resulting in the formation of a testicular hernia. 4, hydrocele of the cord produced by patency of the central portion (and accumulation of fluid therein). 5, hydrocele produced by the accumulation of fluid in the tunica vaginalis and lower portion of the funicular process; this is spoken of as a testicular hydrocele.

allowing the abdominal viscera to descend into the scrotum. This is called a *testicular* or *congenital hernia* and is usually manifested within the first year or two of life. The spermatic cord and vessels are imbedded in the wall of the sac but can be separated from it if necessary. If the funicular process becomes obliterated only in its distal part, the portion persisting at the proximal end gives rise to a *funicular hernia*, which is perhaps the most common type. The term *infantile hernia* is used to describe a hernia whose sac for some reason forms close to, but not into, the funicular process. It is likewise common but is differentiated with difficulty from the funicular type, even at operation. If the funicular process is obliterated at its proximal, but not at the distal, end, fluid may accumulate in the latter portion of it and in the tunica vaginalis, thereby forming a hydrocele (Fig. 2). Occasionally, the process will be obliterated at each end but will be open at some intervening portion; accumulation of fluid in such a sac is known as hydrocele of the cord. The *canal of Nuck* in the female corresponds to the processus vaginalis in the male and may be the source of herniation of the oblique (indirect) type of hernia. If the canal becomes obliterated everywhere except at one area near its midpoint, as it may do on rare occasions, a hydrocele of the canal of Nuck is formed.

Indirect hernias occur in young people, enter the abdominal (internal) ring, and descend by way of the inguinal canal (Fig. 3). There is a tendency for them to increase in size and progress in their descent, regardless of the type of congenital defect originally present. When the hernia descends past the subcutaneous (external) ring it is called *complete*. When it reaches the scrotum it is spoken of as *scrotal* (Fig. 4). In the female, the hernia may descend so far as to enter the labia majora, the homologues of the scrotum, and is called a pudendal hernia. The symptoms produced have already been amply described and consist chiefly of the appearance of a mass and a moderate amount of pain at the onset which gradually diminishes, but is supplanted by a feeling of heaviness and discomfort. The classical way to detect an inguinal hernia is to invaginate the skin of the scrotum up into the external ring of the canal with the index finger, and have the patient cough. If a hernia is present, a protrusion is felt with the finger tip when the patient coughs.

Hernias are occasionally associated with undescended testicle. Conversely, most undescended testicles are associated with a hernia. Hernia is also nearly always present with a hydrocele.

Direct Inguinal Hernia. These hernias are spoken of as acquired since there is no congenital preformed sac present. On the other hand, they depend upon the presence of a weakened transversalis fascia and oblique muscles. They almost always make their exit

Fig. 3. Left inguinal hernia in a boy six years of age. Frequently more of the mass would descend into the scrotum than is shown in the photograph; however, aside from the mere presence of the hernia, very few symptoms were experienced.

from the abdominal cavity at the "weak spot" in Hesselbach's triangle. This weak spot is located behind the lower fifth of the inguinal canal between the deep epigastric artery and the outer edge of the rectus muscle. As the herniation progresses anteriorly it practically always breaks into the inguinal canal, since this direction offers the least resistance. The sac presents through the external ring, is usually small and globular, and possesses a wide neck. It is, therefore, rarely the site of strangulation. Rarely does it descend into the scrotum (Fig. 5). Direct hernia occurs practically only in men and, as a rule, occurs later in life than does an indirect hernia; it is frequently bilateral. Aside from the protrusion and perhaps mild dull pain, it produces few symptoms.

Fig. 4. Scrotal hernia (indirect). This man aged
had a hernia for 12 years; it has never been ir-
ducible, but for the past six years it has descended
times into the scrotum.

Differential Diagnosis of Inguinal Hernia. In the consideration of differentiation between inguinal hernia and other lesions in the inguinal region, the history of the development of the mass will frequently point to the correct diagnosis. For example, the history of reducibility is practically always present in the early stages of hernias, although adhesions may form later and result in irreducibility. When a hernia mass is present, an impulse will be detected over it when the patient coughs; when no mass is present, coughing usually results in a protrusion which can be detected by the examining finger. This characteristic is almost pathognomonic of hernia. However, when a hernia becomes in-

Fig. 5. Bilateral direct hernia in a 55-year-old man. The hernia on the right is not visible, but a definite protrusion is palpable upon coughing. Direct hernias are usually no larger than that observed on the left side; they strangulate infrequently and practically never descend into the scrotum.

flamed or strangulated, it may be impossible to detect an impulse, although a mass can be felt and there will, of course, be a history of rather sudden onset of pain accompanying the inflammation or strangulation. Occasionally, it may be difficult to distinguish between an inguinal and a femoral hernia, but an inguinal hernia always presents above Poupart's ligament, whereas a femoral hernia presents below the ligament, although the mass may extend upward and overlie it. Hydrocele may simulate inguinal scrotal hernia, but careful examination will rarely fail to make the correct diagnosis. When the mass is a hydrocele there will rarely be a history of reducibility, but there may be a gradual increase in size. An important feature is the shape. The hydrocele is pear-shaped, whereas the scrotal hernia is more cylindrical or globular. The percussion note over a hernia will be tympanitic, and peristaltic gurgling can frequently be heard by auscultation. On the other hand, the percussion note over a hydrocele is flat and no auscultatory sounds will be heard. If the hydrocele is small, it will be possible to demonstrate that the external inguinal ring is empty. There is, of course, no impulse over the hydrocele upon coughing, unless there is an associated hernia, which, however, frequently occurs. Light is transilluminated through a hydrocele but rarely through a hernia. In a chylous hydrocele (containing cholesterol), light will not be transmitted.

Enlargement of the inguinal lymph nodes may occasionally be confused with a hernia of the irreducible type. A lipoma over or in the inguinal canal presents a similar difficulty. Again, it is important to review the history of the development of the mass since reducibility is so constantly present some time or other in the course of a hernia. Acute inguinal lymphadenitis will usually be associated with pain and other inflammatory signs which, however, may also be demonstrable over a strangulated hernia. The sudden development of symptoms accompanying strangulated hernia is usually sufficient to establish a correct diagnosis (see Chap. 33). Occasionally, a psoas abscess may present in the inguinal region and produce a bulging mass which resembles a hernia. In such a case, the spine should be examined for the presence of Pott's disease.

Differentiation between direct and indirect hernia is of great importance at operation insofar as more meticulous care is required in repair of a direct hernia. As previously mentioned, the most important anatomic feature in the differentiation is the relation of the neck of the sac to the deep epigastric artery (Fig. 6). An indirect hernia passes through the internal ring into the inguinal canal lateral to the deep epigastric artery, whereas a direct hernia passes into the lower portion of the inguinal canal medial to the deep epigastric artery. Unfortunately, this important feature can rarely be made out by external examination. At operation, however, this relationship of the sac to the artery is easily demonstrable. Moreover, in direct hernia the spermatic cord usually lies in front of and external to the sac, whereas in indirect hernia the cord usually lies behind and internal to the sac. As stated previously, direct hernia occurs more frequently in older people than does the indirect hernia; it rarely descends into the scrotum, whereas the indirect

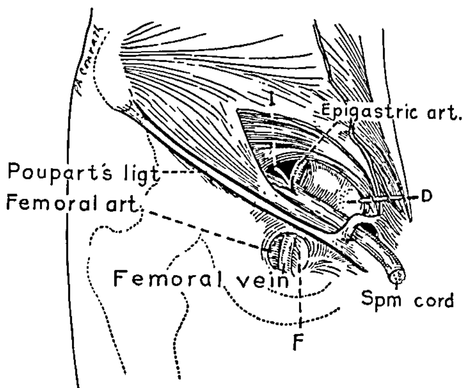

Fig. 6. Diagram to illustrate the sites of herniation of the three common hernias occurring in the inguinal region. I, indirect; D, direct; F, femoral.

hernia frequently does. The shape of the sac of the direct hernia is significant since it is usually globular (not elongated); the defect in the abdominal wall is large, considering the small size of the hernia.

TREATMENT OF INGUINAL HERNIA. Inguinal hernia can be cured only by operation which, in general, should be carried out as soon as the diagnosis is made unless there is a good contraindication. Inguinal hernia in infants can occasionally be cured by reducing the hernia and applying a yarn truss which, however, must be worn constantly for several months and must be tight enough to maintain reduction yet carefully kept in place. To most mothers this is difficult and imposes upon them too great a responsibility. Since the operation in infancy is so simple and safe, and requires hospitalization for but a day or two, the use of the yarn truss is becoming more and more of historical interest. Moreover, after the age of one year, hernias in infants are rarely curable by this conservative treatment. In elderly people, the question of operability presents itself. If the patient is no longer required to work, and the presence of a hernia produces only moderate symptoms, operation may not be indicated, particularly if the hernia is of the direct type. As a routine method of treatment, the use of a truss is to be condemned; in only a few instances will a properly fitted truss be a justified form of treatment.

One of the strongest reasons for advising operation is the tendency for a hernia to become irreducible if it is not already so, with the inevitable likelihood of strangulation and its threat to life. Operation is particularly indicated if manifestations of obstruction or strangulation were ever present while the hernia was irreducible. A hernia in which the neck of the sac is small is more apt to strangulate than is a hernia with a large sac; this factor also affects the decision to operate. This is particularly true of indirect inguinal hernia; direct inguinal hernia rarely strangulates.

The modern *operation* for the cure of inguinal hernia has many variations but its essential steps are: first, opening the inguinal canal; second, careful dissection of and high ligation of the sac; third, closure of the canal. These features were first described independently by Halsted and by Bassini over

50 years ago. The variations in the operation are mainly concerned with the third step, i.e., the method of closure of the canal after the sac has been eliminated. Ferguson did not transplant the cord; Bassini transplanted it *external to the approximation* of the internal oblique and conjoined tendon, with the shelving portion of Poupart's ligament; Halsted transplanted the cord external to the external oblique. It is important to notice however that Halsted later described an operation in which the cord was not transplanted. Indeed, of the three surgeons usually stated as originators of the modern operation (i.e., Halsted, Bassini, and Ferguson), Halsted is the only one who continued, after his original publication, to write about his experiences during which he made additional contributions to the subject. Thus it may be stated that he probably did more toward the gradual perfection of inguinal herniotomy than any other surgeon.

It is impossible to state just which type of hernia repair is the best, partly because many are equally good, but especialy because one may be superior with a certain hernia defect and not so good with another. The Ferguson operation, not transplanting the cord, is a simple procedure and entirely adequate for children. In infancy and young children under three or four years of age, an even simpler procedure consisting of ligation of the sac without a plastic repair is adequate. However, when hernias occur in adult life most surgeons now feel that the Ferguson operation will be followed by a high rate of recurrence in the indirect hernia as well as the direct type. Regardless of the type of repair, the rate of recurrence will be higher in direct than in indirect hernias. The authors concur in the opinion expressed by Lehman and Davis (5) that a Bassini type of repair (transplantation of the cord with suture of the transversalis fascia, conjoined tendon and internal oblique muscle to the inguinal ligament), should always be used in indirect hernias if there is the slightest weakness of the transversalis fascia. Transplantation of the cord should be done in practically all direct hernias.

Additional features include suture of the cremaster muscle to the internal oblique for additional support, which was recommended by Halsted in 1903. Halsted also suggested the use of a flap of the anterior rectus sheath in cases where the conjoined tendon was atrophied or weak. He also described a relaxing incision in the internal oblique aponeurosis as it joins the rectus, thus permitting the conjoined tendon to be sutured without tension to Poupart's ligament. During recent years, there has been an almost universal shift from the use of chromic catgut in the repair of hernias to the use of silk (as originally recommended by Halsted), or cotton. Unquestionably, the percentage of recurrence will be reduced by silk or cotton. The use of fascia as an additional detail in the repair of hernia is mentioned below.

In the repair of any hernia, it is extremely essential that the structures sutured in apposition consist largely of solid fascial tissue. Its importance is demonstrated by the experimental work of Seelig and Chouke (1923) who noted that suture of muscle to muscle, or even muscle to fascia, did not result in so strong a union as when both structures consisted of fascia. It is obvious then that when an inguinal hernia is repaired, the conjoined tendon instead of the internal oblique muscle should be sutured to Poupart's ligament if possible. Tension in suturing the structures in a repair should be avoided, since it is an important factor in the development of recurrence, particularly if catgut is used. To avoid tension at the suture line, a relaxing incision can be made in the rectus fascia above the conjoined tendon. Important in the repair of any inguinal hernia is the repair of the defect in the transversalis fascia, bringing it down to the inguinal ligament (Bassini).

In an effort to prevent recurrences which are apt to follow even expert repair, McArthur (1901) described the use of fascia from the external oblique aponeurosis as a suture to increase the solidity and permanency of the repair. The authors wish to emphasize the importance of using a strip of fascia about 0.5 cm. wide cut from the external oblique aponeurosis, as McArthur originally described. By leaving the central end attached at the pubic tubercle, a strip of ample length can be obtained to reinforce the suture line. This should be done on all hernias when the structures are weak, or when approximation by the sutures is ob-

tained only by tension. It has been shown that, if a strip of fascia is utilized after the McArthur technic, recurrences will be eliminated almost completely (6), especially if a relaxing incision is made in the internal oblique fascia near its attachment with the anterior rectus fascia. Strips of fascia lata removed from the lateral aspect of the thigh may also be used (Gallie and LeMesurier, 1921). The defect in large hernias may be so great that a satisfactory repair cannot be made without the use of these fascial strips which are used to reinforce the suture line, especially that approximating conjoined tendon and Poupart's ligament.

As stated previously, the development of strangulation makes immediate operation imperative. The decision as to the type of operation to be performed in such instances depends upon such factors as duration of strangulation, amount of intestine involved, and condition of the patient. Frequently, these factors will prevent the performance of a painstaking and orthodox repair; in fact, the patient's condition may be so precarious as to justify rapid closure without thought as to the possibility of recurrence.

Although herniotomy may be considered one of the simplest of the major operations, complications will appear in a surprisingly large percentage of cases. Very few complications will be encountered in patients under 20 years of age; after that age they increase in a direct ratio as the age increases. In a study of 2,000 herniotomies, Beekman and Sullivan (7) noted an incidence of 8.5 per cent of respiratory lesions; the incidence of atelectasis was 2.3 per cent, pneumonia 0.7 per cent, and pulmonary embolism 0.6 per cent. Although the incidence of pneumonia was greatest following general anesthesia, Beekman and Sullivan noted other respiratory lesions were decreased. For example, they found the incidence of all types of respiratory lesions to be 7.3 per cent following general anesthesia, 9.1 per cent following spinal, and 10.3 per cent following local anesthesia. The incidence of postoperative wound infection will vary from 1 to 5 per cent depending upon circumstances, but is observed by all surgeons to be much less following the use of silk or cotton. The mortality rate in inguinal herniotomy (exclusive of strangulated hernia), should be appreciably under 1 per cent. Complications of herniotomy, even in the aged, are reduced by the use of local anesthesia, silk or cotton sutures, and early ambulation.

In spite of the type of repair, recurrence will develop in 2 to 5 per cent of indirect and 4 to 8 per cent of direct hernias. In a series reported by Hagan and Rhoads (8), 50 per cent of the recurrences took place within two years following repair.

Sliding Hernia. Hernias of this type are caused by a slipping of the posterior parietal peritoneum on the underlying tissue, thereby allowing the colon to descend as a herniation (usually inguinal, rarely femoral). The identification of such hernias is rarely made, except at operation. Sliding hernias on the right side usually contain the cecum and appendix; on the left side, sigmoid. In either case, they are usually of the indirect type. If such hernias are small, no peritoneal sac may be present. As the mass enlarges, a fold of peritoneum descends with the colon, forming a sac on the anterior portion of the mass. Sliding hernias descend so readily that a truss is rarely satisfactory in maintaining reduction. Operative repair is usually difficult. If the hernia is small, the lack of a sac may lead the surgeon into the error of mistaking the colon for the sac and opening it. After mobilization of the colon, and separation of adhesions between it and the sac, it is frequently advisable to anchor the colon to the posterior wall of the pelvis. Repair of the defect may be difficult because of the large size of the opening through which the mass herniates and absence of adequate fascia to close the defect. The recurrence rate in sliding hernia is high, although Sensenig and Nichols (9) report only four recurrences in 53 cases observed two years after operation. (Presumably only about 50 per cent of recurrences will develop by that time.)

Femoral Hernia. This type of hernia occurs much more commonly in women than in men (ratio about 3:1) and is confined almost entirely to adults, although it is slightly less common even in women than the inguinal variety (Fig. 7). The hernia makes its descent into the femoral canal through the femoral ring, located in the floor of the peritoneal cavity. Weakness of Gimbernat's ligament, which bounds the femoral ring on the

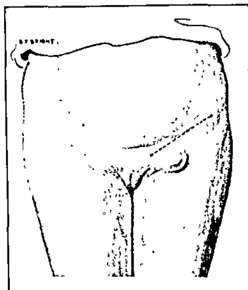

Fig. 7. Femoral hernia in a woman. Note that the mass which decends through the femoral canal is located below Pourpart's ligament, which is indicated by the dotted line.

inner side, is apparently the most important factor in the development of a femoral hernia. The fact that this ligament is more poorly developed in women than in men presumably accounts for the greater incidence of femoral hernia in women than in men. The *femoral canal* represents the narrow space between the femoral vein and the inner wall of the femoral sheath. Normally it is only about half an inch long and contains nothing more than a few lymphatic vessels and a little fat. As the hernia descends into the femoral canal it soon reaches the saphenous opening which offers little resistance, thereby allowing the hernia to appear in the soft tissues of the thigh. In general, these hernias are smaller than inguinal hernias and, indeed, may be present without a mass or other external manifestations.

The *clinical manifestations* of uncomplicated femoral hernia are not unlike those described for hernias in general. However, because of their small size, they are apt to contain only omentum and therefore present so few symptoms and signs that they are frequently unnoticed by the patient. Such hernias may even strangulate and be unnoticed externally. However, if a loop of bowel is strangulated, the manifestations of intestinal obstruction will be so obvious that laparotomy is demanded.

If the omentum becomes adherent to the sac, there may be a dragging type of dull pain. The pain may be due entirely to pressure in the nearby femoral nerve. When intestines descend into the sac, the pain is apt to be more severe and be colicky because of obstruction. The hernial mass appears below Poupart's ligament at the saphenous opening and rarely attains a size larger than that of a hen's egg. At times, the mass may extend upward over Poupart's ligament and thereby simulate inguinal hernia, inguinal lymphadenopathy, and the like. The similarity of a saphenous varix to a small femoral hernia should be emphasized because of the obvious difference in treatment. Although a saphenous varix is soft and compressible, as is a hernia, the varix disappears spontaneously when the patient lies down. When the patient coughs, an impulse but no protrusion will be palpated over the varix. The skin over the varix may be bluish; frequently there are varicose veins on the extremity.

Strangulation is frequently encountered because of the narrow sac and the sharpness of the edge of Gimbernat's ligament. For the same reason, the femoral ring is perhaps the most frequent site for *Richter's hernia,* which is apt to produce a strangulation of the small portion of the intestinal wall which is pinched in the neck of the sac. Cramping pain, perhaps of a disabling type, is present, even though the entire lumen is not blocked; other manifestations of strangulation are not apt to be present because the mesenteric vessels are not involved. Diagnosis may be extremely difficult because of the small size or absence of a hernial mass and the lack of complete obstruction. Tenderness is a very important diagnostic sign but may be the only significant local finding. Immediate operation, of course, is imperative because of the tendency for the rapid development of gangrene and perforation. In fact, any type of strangulation in femoral hernias is usually associated with the early development of gangrene on account of the narrowness of the ring.

The *treatment* of femoral hernia is surgical. A truss will rarely fit the patient and maintain reduction of the mass. Moreover, the mass frequently protrudes beyond the

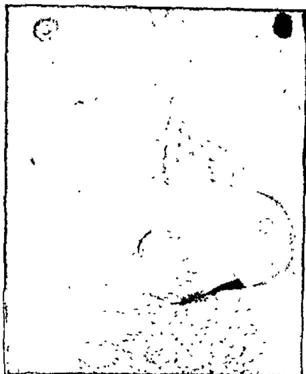

Fig. 8. Postoperative (incisional, ventral) hernia. The hernia developed two years after an operation for repair of a perforated ulcer. It is reducible and associated with only slight pain.

truss; strangulation is thereby encouraged. Even in the absence of symptoms, repair is wise to prevent likely and serious complications, such as strangulation and early gangrene.

Although repair by way of the inguinal route will be followed by fewer recurrences, this procedure adds somewhat to the intricacy of the repair and should not be attempted by the unskilled surgeon. The results through the femoral route alone should be satisfactory except in the large hernias. When the right lower quadrant is explored for intestinal obstruction or other abdominal symptoms of unknown origin and a femoral hernia found, the repair of the sac after reduction of the mass is done by a simple pursestring suture.

Postoperative (Incisional, Ventral) Hernia. This type of hernia is unfortunately common (Fig. 8), but can be prevented to a great extent by careful aseptic technic and proper closure of abdominal wounds. Suppuration of the wound is conducive to the formation of hernias but cannot always be avoided when intraabdominal abscesses are drained. Thus, hernia is apt to follow operations for drainage of intraabdominal abscesses (e.g., appendiceal abscess). Poor technic in closure; including insecure knots and tight sutures placed close to the edge of the fascia are common errors. Postoperative hernias are also prone to occur in fat people. Any pulmonary complication which results in frequent coughing during the first five or six postoperative days may lead to partial deep suppuration of the wound to pave the way for the development of a hernia, or even to produce a complete separation of the wound which usually demands immediate closure. Certain types of incisions are less apt to be followed by herniation than others. Transverse incisions are less likely to be followed by hernias than other types. The so-called "paramedian incision," made through the rectus fascia, retracting muscle outward, is less apt to be followed by a hernia than an incision in the midline, because the rectus muscle falls over the line of suture and supports it when the wound is closed. Obviously, incisional hernias are nearly always abdominal, but on rare occasions may be located elsewhere (e.g., transpleural hernia of the thorax).

If the fatty subcutaneous tissue is thick, the hernial mass may burrow for a considerable distance subcutaneously, especially downward, because of gravity. Occasionally, it may enlarge in a mushroom fashion until a large proportion of the contents of the abdominal cavity are contained in the sac. The omentum, and frequently loops of intestine, become adherent to the sac so that the greater portion of the hernia may become irreducible. When the hernia first develops, the patient nearly always complains of a dragging pain arising in the neighborhood of the scar, perhaps radiating deep into the abdomen. Early in the formation of the hernia, tenderness at the site of the defect is pronounced. When the hernia develops within a few days following laparotomy, because of partial rupture of the deep layers of the wound, the intestines herniating into the defect may, at times, become adherent and lead to postoperative obstruction. Usually, however, definite evidence of a hernia is not demonstrable, subjectively or objectively, for several weeks or months following operation. Besides the dragging pain mentioned above, other symptoms, including constipation, anorexia, cramping

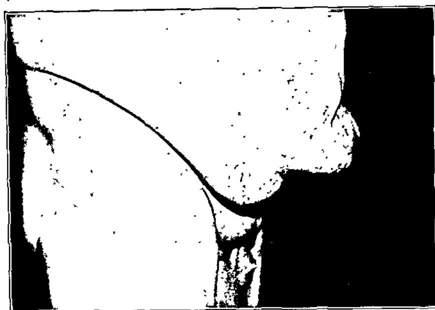

Fig. 9. Lateral view of an umbilical hernia in a man, aged 50. The mass had been present for 15 years, had never been strangulated, but for many years had been incompletely reducible.

pain, and even vomiting, may develop. Strangulation is not usual because of the large ring.

The *treatment* depends to a great extent upon the size of the hernia and the condition of the patient, especially his age. If the hernia is reducible and has a large opening, the patient may be fitted with a large elastic belt or support which, in general, may relieve the symptoms if applied correctly, i.e., when the patient is lying down and the hernia is reduced. If the belt does not relieve the symptoms, or the patient is young and still active physically, *operative repair will be indicated.* At operation, the contents of the hernia are reduced, and the sac, which is frequently multiloculated, *excised*; the peritoneum and fascia are then closed. When a large part of the abdominal viscera (ileum, colon, omentum, spleen, and so forth) have become herniated, the resultant decrease in the size of the peritoneal cavity may make reduction difficult. The fascia must be dissected free from fatty tissue, overlapped, and anchored with interrupted sutures of silk. If the defect is too large to allow satisfactory closure without undue tension, it may be necessary to resort to the use of patches of whole skin or more commonly to strips of fascia lata as reinforcing sutures.

In addition to autogenous fascia lata, numerous other substances have been recommended recently to aid in the repair of large hernias. Artificial prostheses, such as tantalum wire, and stainless steel wire mesh, have also been used to fill in the defect. In a comparative study of tantalum wire and stainless steel wire mesh Spencer and associates (10) report that neither proved superior to the other; they fragmented with equal frequency. When a whole-thickness skin graft is used, *there is danger of formation of cysts,* but these are usually prevented if the graft is inserted under tension. The greatest *disadvantage of the use of these substances is postoperative infection.* Actually they are rarely needed.

Umbilical Hernia. With few exceptions, hernias of this type are caused by a congenital defect of the abdominal wall at the umbilicus and appear either in infancy or in late adult life (Fig. 9). Normally, the umbilical ring closes after the cord is ligated, and its contents atrophy, resulting in scar tissue which forms a firm support at the umbilicus, covered by skin. Hernias at the umbilicus develop most commonly during *infancy* (up to two years) and are supposedly caused by an unusual strain causing rupture at a weak point, allowing a protrusion of a peritoneal sac, which is small and usually contains only omentum. The first evidence of *hernia rarely*

produces any demonstrable symptoms. Unless treated it may enlarge until intestine also protrudes into the sac. In children, the neck of the sac is small (1 to 1.5 cm. in diameter) but may attain a size two or three times as large. Up to two or three years of age spontaneous closure may follow if a strip of adhesive is placed transversely across the abdomen over the umbilicus tightly so that the skin folds inward. Almost constant fixation must be maintained for several months before closure of the defect may be expected. Even if this occurs, recurrence is possible years later. After the age of 18 months, this type of conservative therapy will be increasingly unsuccessful, regardless of whether or not it has been in use previous to this time. Cure can then be effected only by operation.

Umbilical hernias in adults occur usually in the latter part of life and are three or four times more common in women than in men. Relaxation of the abdominal muscles during pregnancy, obesity, and debilitating diseases appear to be important etiologic factors. The herniation may take place directly through the umbilicus or a short distance to either side. Occasionally there are several openings. The omentum first protrudes into the hernia, but as the sac enlarges, intestine (usually colon) also is included. Adhesion of the sac to the omentum and intestine takes place early and is usually so extensive that the hernial mass is lobulated or divided into compartments. The skin over the hernia is thin and very little subcutaneous tissue intervenes between it and the contents of the sac. For this reason, peristaltic movements are readily demonstrable if intestines are included in the sac. The symptoms of umbilical hernia in adults may not be pronounced, but include such complaints as constipation, dragging pain, and anorexia, especially if the hernia is large. Cramping pain, nausea, and especially vomiting indicate partial or complete obstruction. On account of the thin skin and protrusion of the mass, the skin becomes traumatized readily and ulceration may develop. The longer the hernia persists, the more pronounced is irreducibility and the more common is strangulation.

The *treatment* of umbilical hernia in adults is operative repair. Elastic belts or supports usually fail to relieve symptoms and are usually harmful if the hernia is irreducible, which is usually the case, at least by the time the patient comes to the physician for relief. Operation consists of an elliptical incision made in a transverse direction (Mayo), excising a portion of the redundant skin and subcutaneous fatty tissue. Occasionally, it may be advantageous to make the incision in a longitudinal direction. If the hernia is large, it may be advisable to use fascial sutures in its repair.

Congenital Umbilical Hernia of the Cord (Omphalocele, Amniotic Hernia). In this hernia there is a defect in the entire abdominal wall at the umbilicus. The only coverings are parietal peritoneum and amnion; the wall over the hernia is therefore transparent, allowing visualization of the contents of the hernia (Fig. 10). The child is born with a globular shaped herniation varying from one inch to several inches in diameter, which may contain any or practically all organs of the abdominal cavity, frequently including most of the liver. The most likely cause or explanation is persistence of the omphalomesenteric ducts. Unless corrected by operation the condition results in a fatal peritonitis. Immediate operation is essential. When the defect is large, it will be impossible to close fascia to fascia at the first operation. If so, the amnion and peritoneum should not be opened (Johns, 11). The skin should be undermined and approximated; several weeks or months later the resultant hernia is repaired. Postoperative chemotherapy is important.

Diaphragmatic Hernia. Diaphragmatic hernia is a protrusion of abdominal viscera into the thoracic cavity through an opening of the diaphragm. In a study of 605 cases, Harrington (12) noted that 80 per cent occurred through the esophageal hiatus; 14 per cent were traumatic (all except one in this group were on the left side); 5 per cent were hiatus hernias due to a congenitally short esophagus; 13 per cent associated with a short esophagus caused by esophagitis or malignancy; 3 per cent were through a congenital defect in the posterior quarter of the left diaphragm; 2 per cent protruded through the parasternal foramen of Morgagni and an equal number through the pleuroperitoneal hiatus (Fig. 11). Hernias are designated as being through the pleuroperitoneal hiatus when there is lack of complete fusion between

Fig. 10. Omphalocele. At the left, photo taken immediately after birth. In the middle, photo taken a few hours later, following operation in which the amniotic membrane and peritoneum were removed and the abdominal skin closed. At the right, photo taken at two weeks of age, one week after the second operation during which the contents of the sac (liver, transverse colon, and rest of the small intestine) were reduced, the fascia of the abdominal wall mobilized and closed, and the skin sutured. To have done both procedures at the first operation might have jeopardized recovery because of respiratory embarrassment due to the sudden increase of intra-abdominal pressure following replacement of the abdominal viscera. This increase can be better tolerated after the baby has become adjusted to the normal breathing of extra-uterine life.

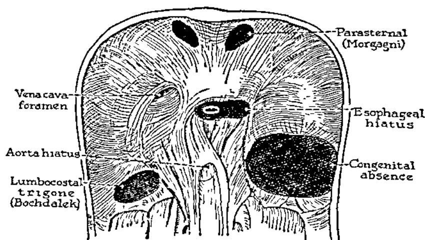

Fig. 11. The diaphragm viewed from below revealing numerous types of diaphragmatic hernias. Most of the traumatic hernias (not shown) will be on the left. (After Dorsey. Operative Technic, Appleton-Century-Crofts.)

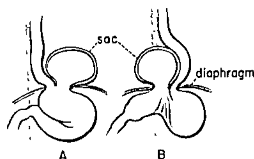
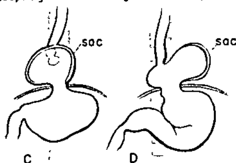
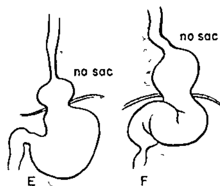
Fig. 12. Diaphragmatic hernia in a child of five years; roentgenogram after barium enema. Note that the colon, as well as the stomach, has herniated through the defect in the diaphragm. A, anteroposterior view. B, lateral view.



the septum transversum and the pleuroperitoneal membrane; when there is incomplete muscular formation of the diaphragm in this region of fusion the opening is called the "foramen of Bochdalek." Hernias through the former defect do not have a sac, whereas hernias through the latter do have a sac. Hernias through the two openings named above, those through the foramen of Morgagni as well as those associated with an absence of part of the diaphragm, are often spoken of as congenital (Fig. 12), and those through the esophageal hiatus as acquired; the former are usually present at birth, whereas the latter may not appear until late adult life.



Harrington (12) classifies hernias through the hiatus into four groups (Fig. 13). In the paraesophageal hiatus hernia (13 per cent of his series), the esophagus is of normal length and is not elevated above the diaphragm (A and B). The stomach herniates alongside the esophagus, perhaps with other organs. Such hernias are usually not large. In a second type of hernia, designated as esophageal (67 per cent), the esophagus is of normal length but does not extend down to the hiatus (C and D). Such hernias are apt to be large; herniated viscera may ascend into either or both sides of the thoracic cavity. Esophagitis is common in this type of hernia. Failures following repair are common in this group. Hernias with a short esophagus (E and F) constituted 18 per cent of Harrington's group; 5 per cent had a congenitally short esophagus, and 13 per cent had shortness secondary to esophagitis or tumor.



Traumatic hernias may be caused by tears, stab wounds, and the like. Very few of these will be associated with a sac.

The *clinical manifestations* of diaphragmatic hernia are varied and, in many instances, are absent, the diagnosis being made radiologically. When the herniation is secondary to a *congenital* absence of a large portion of the diaphragm, symptoms are usually severe and are manifested soon after birth. These manifestations consist of dyspnea, cyanosis, tachycardia, constipation, and occasionally symptoms of intestinal obstruction. Vomiting may be persistent. Hiccup is not uncommon. X-ray examination may reveal a displacement of the heart, thereby explaining the cardiac symptoms. Frequently, congenital hernias exist for years without producing any symptoms whatsoever.

The manifestations of the *acquired* type

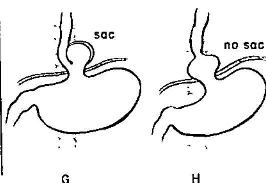


Fig. 13. Types of herniation through the esophageal hiatus. (Modified from Harrington.)

(hiatus hernia) are rarely so acute as those mentioned above. Pain radiating upward into the shoulder or downward into the peritoneal cavity may be the first complaint. Digestive symptoms, such as anorexia, nausea and vomiting, or regurgitation without premonition, are not uncommon. Symptoms are so inconstant that they may simulate those of peptic ulcer, cholecystitis, or coronary disease. Dysphagia, hemorrhage due to ulceration, and even cardiac symptoms due to pressure of the herniated mass may occur. Auscultation of the chest may reveal gurgling sounds over the left chest, but this may not be of great diagnostic aid, because of the transmission of such sounds upward from the stomach in normal individuals. A tympanitic note to percussion over the left chest should lead one to suspect diaphragmatic hernia. A roentgen examination, especially with the barium meal or enema, will usually lead to the correct diagnosis (Fig. 14). When the hernia is small, it may recede upon standing, and symptoms therefore become decreased. In such instances, the x-ray examination must be performed with the patient in the prone position, since gravity will pull the stomach downward while the patient is standing and thereby reduce the hernia. It should be emphasized that the demonstration of a hiatus hernia by x-ray is no indication that the patient's symptoms are due to the hernia.

The hernia destroys the sphincteric action of the diaphragmatic crux and the resulting reflux of gastric secretion produces an esophagitis in the majority of patients. Many of the symptoms including pain, pyrosis, and bleeding are caused by the esophagitis.

On some occasions, it may be difficult to differentiate true diaphragmatic hernia from an *eventration of the diaphragm.* In the latter instance the diaphragm is elevated to an unusual height and is rarely mobile, thereby indicating that a disturbance in the innervation exists.

As stated, *traumatic* hernias are caused by

Fig. 14. Two examples of esophageal hiatus hernia (x-ray after barium). The position of the diaphragm is indicated by the broken line ---D. A constriction of variable degree is produced at the hiatus.

Fig. 15. Traumatic diaphragmatic hernia. The patient, a male aged 34, had an auto accident five nonths previously. Injuries consisting of intracranial damage (unconsciousness for four weeks), and fracure of the humerus and ribs were so serious that nothing was done at that time for the hernia which roduced only mild dyspnea and pain upon breathing. When repaired, stomach and a large part of the mall intestine and colon were found in the thorax. Left, x-ray before barium. Note the marked shift of ne mediastinum to the right. Right, x-ray after barium.

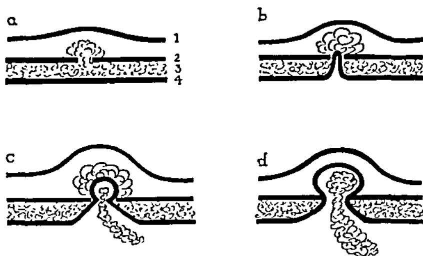

Fig. 16. Epigastric hernia and subserous lipoma. a, subserous lipoma, after breaking through sheath of rectus. b, subserous lipoma with some peritoneum pulled up into the fascial slit. c, subserous lipoma with a hernia sac containing some protruded omentum (epigastric fatty hernia). d, simple epigastric hernia, without lipoma. (Redrawn from De Quervain. Clinical Surgical Diagnosis, Wm. Wood.)

injury of the direct or indirect type (Fig. 15) and may or may not be associated with symptoms at the time of injury. Obviously, a sac is rarely present. Symptoms are dependent to a great extent upon the time and extent of herniation. The manifestations are similar to those described under the acquired type.

The *treatment* of diaphragmatic hernias is surgical, but on many occasions, small hernias produce such few symptoms that repair is not necessary. Either the thoracic or abdominal route may be used in the repair. Repair usually results in healing of the esophagitis because the sphincteric action is restored.

Interruption of the phrenic nerve may at times be a very helpful procedure in treatment, particularly in adults. Temporary interruption by crushing the nerve with a clamp will immobilize the diaphragm in an elevated position which will thus allow healing without a strain on the suture line. In the average esophageal hiatus hernia, permanent paralysis (by cutting the nerve) will rarely be indicated, except perhaps when the esophagus is congenitally short. Occasionally, in elderly debilitated patients, one may be justified in doing nothing more than crushing the nerve since this procedure is apt to alleviate or eliminate symptoms of small hernias. Cutting the phrenic nerve in elderly patients with a large hiatus hernia and with inadequate physical reserve to tolerate repair of the hernia, will yield very good results in over half the cases.

Internal Hernia. There are a number of fossae or depressions located chiefly on the posterior peritoneal surface of the abdominal cavity, as well as abnormal openings in the mesentery, into or through which small loops of intestine may rarely herniate. The most important of these are the duodenal (inferior, superior, and paraduodenal) and cecal (ileocolic, ileocecal, and retrocecal). Such hernias are diagnosed only at operation, which is usually performed because of symptoms of intestinal obstruction.

Miscellaneous Types of Hernia of the Abdominal Wall. There are many different kinds of hernia in this group, but all except the epigastric type are extremely rare. An *epigastric hernia* frequently consists of nothing more than a protrusion of properitoneal fat (properitoneal hernia) through a tiny opening in the linea albea (Fig. 16). Occasionally, a definite sac containing omentum forms and protrudes past the external fascia layer. They may or may not be reducible; on most occasions, a small tab of omentum remains attached at the neck of the sac. If the hernia is reducible, a protrusion may be detected upon coughing. Most epigastric hernias are asymptomatic. However, on rare occasions, they *produce pain in the epigastrium* which may be confused with various intraabdominal

lesions. In such instances, repair will be indicated. *Lumbar hernia* is one which appears in the lumbar region, usually through Petit's triangle or the space of Grynfelt. An *obturator hernia* passes through the obturator foramen of the innominate bone but usually presents no external manifestations. *Perineal hernias*, also extremely rare, occur usually in women and make their exit in the perineum at a variety of "weak points." *Sciatic hernia*, which is so rare as to be a surgical curiosity, passes out through either the greater or less sacrosciatic foramen. A *Spigelian hernia* is one presenting through the Spigelian (semilunaris) line; it is very rare.

THE MAMMARY GLAND

The Normal Mammary Gland
Chronic Cystic Mastitis
Cysts
Benign Neoplasms
Malignant Neoplasms
Infections
Miscellaneous Lesions

The mammary gland is a superficial and readily observable organ, yet early diagnosis of its lesions may be difficult, particularly neoplastic disease, to which it is especially prone. Simple clinical examination, such as inspection and palpation, while of primary importance, is often neglected. Accurate findings presuppose definite knowledge of normal structures.

THE NORMAL MAMMARY GLAND

The breast, one of the secondary sex organs in the female, begins to develop with the onset of puberty, when it rapidly undergoes enlargement due primarily to the growth of the parenchyma, consisting of acinous (secreting or lactiferous) cells and the collecting ducts. The supporting framework consists mainly of hyaline connective tissue around the ducts and the numerous fibrous strands which support this growing mass of tissue, extending outward toward the nipple and the skin and called the suspensory ligaments of Cooper.

No other organ varies so widely in size and configuration as the female mammary gland. These variations depend upon differences in the amount and thickness of the subcutaneous fat, of the degree of development and tenseness of the supporting ligaments, and finally of the size and extent of the parenchyma. The latter consists essentially of about 20 ducts, each emptying into the nipple and branching proximally into many smaller ducts and acini somewhat like clusters of grapes. On gross palpation the breast may be firm and elastic, or soft and compressible, depending largely upon the relative amount of subcutaneous fat, hyaline connective tissue and parenchyma. Thus, in the patient whose breast contains a thin layer of subcutaneous fat and little connective tissue, the parenchyma normally yields a nodular sensation on palpation, which is distinctly firmer than the subcutaneous fatty tissue. On the other hand, the firm, elevated breast, well supplied with supporting connective tissue, may encompass the parenchyma to such an extent that little or no nodularity is felt. The grossly nodular or shotty character exhibited by many mammary glands is usually described erroneously as chronic cystic mastitis, a condition which will be discussed later. Variations in size are normal unless true hypertrophy occurs to a degree embarrassing to the patient. The breast is often pendulous in both young and older women, particularly after repeated lactation.

In the center of the pigmented areola is the nipple, or teat, a rounded conical projection at the apex of which the ducts that drain the parenchymal tissue empty. The nipple is supplied with muscle fibers and is a truly erectile organ, responding often to mechanical stimulation but frequently remaining retracted, particularly in young girls. This retraction is of little significance, except that it may interfere with nursing during lactation. Retraction of the nipple as a sign of cancer is discussed below.

The female mammary gland develops at puberty in response to awakening endocrine activity and is also influenced during normal adult life by the cyclic variations in the pro-

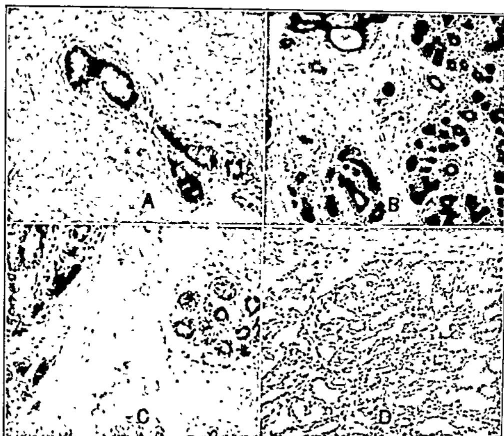

Fig. 1. The normal female breast; photomicrographs of the parenchyma under various physiologic conditions. A, before the onset of puberty. B, the hyperplastic breast during menstruation. C, the resting breast, showing the usual involution associated with the cessation of menstruation. D, the lactating breast; note the absence of stroma and the many acini filled with milk.

duction of ovarian hormones occurring each lunar month with the appearance of menstruation. More pronounced changes, of course, occur during lactation. The same sex hormones (estrin and progestin) which produce changes in the uterus also provoke changes in the breast. The patient is often made aware of these variations by a sense of fullness and pain in the breast before or during each menstrual period. Indeed, these changes have been confirmed by microscopic studies of the breast parenchyma, made at intervals. These histologic changes are shown in Figure 1. With the onset of lactation, the enlargement may be so rapid as to provoke considerable pain. Involution occurs with the subsidence of lactation. At the menopause, in most women, the parenchyma undergoes gradual involution or atrophy.

A careful routine is important in the examination of the female breast which should be done with the patient in both the sitting and the recumbent positions. Inspection with the arms extended overhead and with the patient bending forward is also advisable. Good illumination and exposure are essential. The parenchyma is first felt against the anterior chest wall and pectoral muscle with the tips of the fingers and the palm of the hand. Often a mass, or nodule, which might otherwise escape detection may be felt if the examiner stands behind the patient and palpates the breast with the palm of the hand. The skin over the breast is also examined, especially for retraction or attachment to the underlying parenchyma. No examination is complete without careful search for enlargement of the axillary lymph nodes. Palpation is most accurate if the finger tips are first placed on the outer side of the axilla before pressing against the chest wall and palpating downward and forward in the direction of the ribs (Fig. 2). By this maneuver the nodes are not pushed into the apex of the axilla before they can be palpated by the fingers. The axillary lymph nodes may be normally pal-

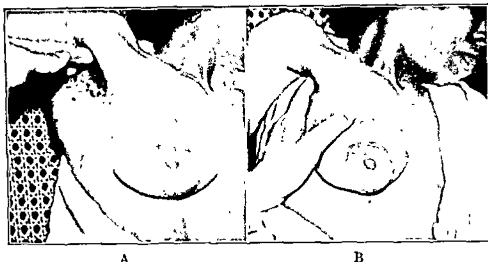

Fig. 2. Palpation of the axillary lymph nodes. A, the tips of the examiner's fingers are placed high in the axilla with the patient's arm abducted; the back of the hand lies along the upper end and head of the humerus. B, as the patient's arm is brought to the side the examiner's fingers are brought against the chest wall, palpating any nodes by rolling them between the pad of the finger tips and the ribs of the thoracic cage.

pable as small, shotlike structures. It is important for the novice not to mistake the rounded contour of the ribs for enlarged nodes. The lymph nodes above the clavicle are also noted because they become enlarged and palpable occasionally, especially in malignant disease.

Neoplasms are the most important of the many diseases which occur in the breast. Second are the inflammatory lesions or infections. Finally a miscellaneous group will be considered. These conditions apply almost entirely to the female breast.

The male breast, a tiny rudimentary structure composed of a few ducts and mostly connective tissue, is only rarely the seat of disease; inflammatory and neoplastic lesions occur, the latter not infrequently malignant. In any case, they present similar features and in most instances require the same treatment as in females. Details of breast lesions may be found in books on the breast (1, 2).

CHRONIC CYSTIC MASTITIS

In reality a term related to microscopy, this designation is usually, though erroneously, applied clinically to the exceedingly common "nodular breast." Other terms for this lesion include: cystic disease of the breast, Schimmelbusch's disease, chronic interstitial mastitis, chronic lobular mastitis, cobblestone breast, nodular breast, mastoplasia, *mastopathia*, *cyclomastopathy*, and adenosis.

Pathology. Despite differences of opinion among pathologists as to the classification of the microscopic changes, the following basic changes are most common, so common, in fact, that few adult breasts will fail to show one or more of them (Figs. 3, 4). 1. *Adenofibrosis* is a term which we prefer to apply to those types of chronic cystic mastitis in which the fibrous tissue predominates and the glandular elements are scarce and often atrophic. 2. In *benign parenchymatous hyperplasia*, there is a moderate proliferation of glands and ducts without much change in structure; there is often a stasis of secretory products. 3. In *precancerous hyperplasia*, the hyperplasia is advanced with cells of atypical shape, plication, layering of cells, and increased mitosis (Fig. 5). 4. In *cystic disease*, the cysts are large but hyperplasia is minimal. Years ago Bloodgood applied the term *blue dome cyst* to the larger solitary cysts, because of their bluish color when exposed. When they are present, hyperplasia is rarely significant, and cancer is seldom encountered.

These changes in the breast are generally considered to be due to the reaction of the breast to the cyclic activity of the female sex hormones. It would seem also that an essen-

Fig. 3. Chronic cystic mastitis. Photomicrograph (low power) of tissue in a lump removed from a 42-year-old housewife who first noted the tumor one year previously; there was no pain or increase in size. Examination revealed a lemon-sized nodular mass, freely movable but attached to and part of the parenchyma. Note the numerous cysts, some distended with fluid, others lined by hyperplastic epithelium; higher power magnifications are shown in Figure 4. Nowhere was malignant tissue seen although four blocks were cut from various portions of the lump. The periductile fibrosis and round cell infiltration were not marked.

Fig. 4. Chronic cystic mastitis showing the walls of two cysts. Photomicrograph (high power) from the same specimen, represented in Figure 3. A, note the papillary ingrowth into the lumen of the cyst, i.e., a beginning intracystic papilloma. B, note the hyperplasia of the small ducts adjacent to the wall of a dilated cyst; the cyst is filled with fluid and lined by flattened epithelium.

Fig. 5. Chronic cystic mastitis with precancerous hyperplasia. There is considerable cell alteration with papillary overgrowth, but no invasion. This nodule was present seven months when removed. The patient returned one year later with a cancer on the diseased side. When hyperplasia of this degree is found, simple mastectomy may be indicated to prevent cancer. It should be stated that this indication is controversial.

tial feature of many of these changes is their failure to follow exactly the ebb and flow of estrogenic excretion. Most important is the failure of normal involution, so that by repeated stimulation at each menstrual cycle, during pregnancy, and perhaps also by sexual excitement, the hyperplastic changes outstrip the hypoplastic or involutional process. The only, yet decisive, question to answer regarding these changes is this: What is the relation, if any, of the hyperplasia in chronic cystic mastitis to the development of malignant disease?

Relation of Chronic Cystic Mastitis to Cancer. Since cancer is, after all, an abnormal growth of pre-existing cells, it is but natural that the proliferating epithelium in chronic cystic mastitis would be suspected of being an early cancer. Indeed, the dividing line between benign hyperplasia and malignant neoplasia in general is not always a sharp one. There is much controversy as to whether or not chronic cystic mastitis is a precursor of cancer. Years ago Warren (3) made an extensive study of this relationship in the Massachusetts female population. He concluded that "the breast cancer attack rate for women with chronic cystic mastitis and related lesions in the age group from 30 to 49 years is 11.7 times the rate for the Massachusetts female population; in the group over 50 years of age 2.5 times as great; in the entire group 4.5 times as great"; and that "chronic cystic mastitis and chronic mastitis (noninfectious) predispose to the development of breast cancer." Geschickter (4) and Copeland (5) have arrived at the same general conclusions, but it should be added that there are many pathologists and surgeons who do not agree that such a relationship exists. It is our own opinion that there is a danger of development of cancer in chronic cystic mastitis, but this danger is most significant in the type identified as "precancerous hyperplasia," and practically absent in the types identified as "adenofibrosis" and "cystic disease," previously described.

Clinical Manifestations. It must first be emphasized that chronic cystic mastitis is a bilateral disease, particularly from the standpoint of pathology. Often, clinical examination reveals bilateral firmness and diffuse nodularity, but on many occasions there is one "predominating" lump. It is this predominant lump which receives the attention because it may be cancer.

The *pain* is usually slight and brings the patient to the doctor only because it has aroused a fear that such a symptom may be a sign of cancer, even though no lump may

have been felt. Actually, of course, pain is not a manifestation of cancer except in the terminal stages when ulceration and infection have occurred. Indeed, severe pain is generally indicative of the presence of other lesions, such as acute mastitis and abscess. The pain in chronic cystic mastitis is rarely constant, being worse at some period during the menstrual cycle, usually just before or during the flow. In a few patients, however, the pain may be severe enough to be disabling and demand relief; under such conditions it is called mastodynia (p. 882).

Discharge from the nipple in chronic cystic mastitis is relatively uncommon, being encountered in less than 10 per cent of cases. In a study made by Hinchey (6), the discharge was bloody in about half the cases, and serous or greenish-brown in the remainder. The latter have no clinical significance. Discharge is more frequent in duct papillomas, and it is usually bloody; for example, Geschickter (4) noted a bloody discharge in 47 per cent of 204 cases studied. When duct papillomas are in or just beneath the nipple, they may be palpable, but when located in the depth of the breast, they are rarely palpable because of their small size. A significantly large proportion of these lesions is believed to undergo malignant change.

Examination reveals diffuse induration and nodularity. Tenderness is often noted throughout the breast but is usually most prominent over one or more of the nodules. As stated previously, there is usually a predominant nodule that is more important than the chronic cystic mastitis itself, because it might be a cancer. From day to day there is apt to be variation in the location of the tenderness, and actually in the size of the nodules; in general, the signs are most prominent just before and during the menstrual flow if the patient is still menstruating. There may be slight increase in size of the affected breast, but the lesion tends to develop in small breasts relatively free from fat. The nodules are poorly defined and are firm, but not stony hard. Since the surface is not smooth, they cannot be distinguished from malignant nodules.

Treatment. Treatment may be conservative or operative depending upon whether or not the presence of carcinoma can be eliminated. On certain occasions it will not be difficult to exclude malignancy. For example, if the patient is in her early twenties, and has bilateral tenderness and nodularity primarily during the menstrual period, conservative measures are indicated, particularly if the predominant masses change in size from time to time. At times, support with a properly fitted brassiere will relieve the pain although it will not influence the pathologic process. Female and male hormones have been used but are often ineffectual. It is well known that pregnancy and lactation have a beneficial effect on chronic cystic mastitis; if symptoms are severe, pregnancy should be encouraged.

If carcinoma cannot be excluded, *surgical excision* of the predominant nodule will be indicated. The excision should be carried out with a wide margin of adjacent breast tissue so that, if carcinoma is present, it will not be cut across during the excision. Moreover, excising adjacent tissue will include enough breast tissue to confirm the diagnosis of chronic cystic mastitis, since numerous small cysts will usually be found. A frozen section should be performed; if carcinoma is present, radical resection, including excision of the axillary contents and both pectoral muscles, should be carried out. Occasionally the pathologist will be uncertain from the frozen section as to whether or not the lesion is malignant. Under these circumstances, the surgeon must wait for the paraffin section. If the frozen or paraffin section reveals a severe degree of hyperplasia with much layering of cells, pyknotic nuclei, and mitosis, simple mastectomy is usually advisable (3, 7), on the theory that carcinoma is present somewhere in the breast or will develop. It should be added, however, that this point is controversial.

CYSTS

Cyst formation, as already mentioned, is one of the pathologic features of chronic cystic mastitis. These cysts are usually small, multiple, and often undetectable clinically, although they too contribute to the breast's nodular character. Usually they are noted only on gross or microscopic examination of the cut tissue. Occasionally, larger single cysts are encountered which are evident clinically as a lump, such as has already been described.

Although the contents of these cysts are serous, *they are under much pressure and are* firm; thus they may be mistaken for solid tumors, often imparting a hardness suspicious of carcinoma. The true diagnosis in such instances may be made by aspiration of the cyst or by operation. Occasionally the wall of a large cyst of this type presents a bluish, translucent appearance when exposed at operation; hence the term "blue dome cyst" given by Bloodgood. Aspiration of these cysts is usually curative. Carcinoma is rarely found in them.

A *galactocele*, or true retention cyst, due to a duct obstruction and containing retained milk is relatively rare and has little clinical significance because it usually empties spontaneously. If it does not empty, the contents will become inspissated; removal may then be indicated.

BENIGN NEOPLASMS

The breast area may be the site of neoplasms found in skin and subcutaneous tissue anywhere, such as lipoma, fibroma, and angioma. In the parenchyma, the most important benign tumor is the adenoma.

Intraductal Papilloma. Bleeding from the nipple justifies an immediate clinical diagnosis of intraductal papilloma; excision is necessary because of the possibility of malignant changes in this lesion. If the papilloma that is the source of the bleeding is palpable, it is excised locally. If no lump is palpable, the papilloma can often be located at operation by cutting down on a tiny probe inserted into the duct from which bloody fluid emerges or, at most, by removing merely the area of the breast from which the bleeding is expressed on pressure. In this way, sacrifice of the nipple and most of the breast is avoided. The papilloma should be submitted to frozen section (Fig. 6); if it is malignant, a radical excision is carried out. In a few patients, malignant disease will be detected only on paraffin section; in such an event, a second operation for removal of pectoral muscles and the axillary lymph nodes will be indicated.

Adenoma (Adenofibroma). Although the histologic appearance varies, this tumor usu-

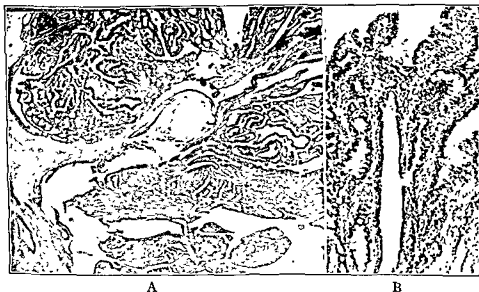

Fig. 6. Intraductal papilloma. The patient, a 37-year-old housewife, first noticed several months previously a discharge from the nipple which occasionally became blood-tinged but which never ceased. On examination a reddish discharge could be expressed from the nipple and a small tumor could be felt just below the areola. At operation the tumor was excised. A, photomicrograph showing a portion of the papillary growth as well as the stalk of the papilloma. The wall surrounding the tumor is only shown at the base of the stalk; it is probably the wall of a dilated duct rather than of a cyst. B, a high power view showing the character of the papillae and the hyperplasia of the cells. Despite this hyperplasia in this particular case no evidence of carcinoma was found in any part of several sections.

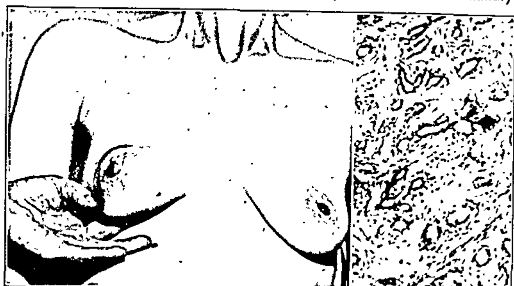

Fig. 7. Fibroadenoma. The patient was a 27-year-old woman. A lump had been noted two years previously; it had not increased in size but became slightly painful preceding each menstrual period. Note the lack of skin attachment although the tumor has been displaced by the examiner's fingers. At operation the tumor was not attached to the skin or parenchyma and shelled out very readily. Microscopic section of various parts of the tumor revealed features of adenoma, fibro-adenoma as well as of chronic cystic mastitis. The photomicrograph above shows this resemblance.

ally contains a much greater proportion of fibrous than epithelial elements. Indeed, the adenomatous tissue may be so slight as to form single layers of epithelial cells surrounded by great masses of connective tissue, thus giving rise to the term *intracanalicular fibroadenoma*. The fibromatous element may be diffuse connective tissue or hyaline periductile fibrous tissue, which is more elastic and translucent. Mucoid degeneration may occur, imparting to the tumor the designation of *adenomyxoma*. Other variations have been described. The epithelial cells resemble those lining the ducts although occasionally the acinous cells seem to give rise to the tumor. In any case, the tumor is clearly circumscribed and separated from the rest of the breast parenchyma by a loose layer of connective tissue, a characteristic which can often be detected clinically on palpation.

Clinical manifestations are not produced by an adenoma until a lump is discovered which is usually accidental. In most instances the mass is felt while the patient is bathing, or is noticed on examining her breast after some slight trauma. This latter fact accounts for the frequent belief on the part of many patients that the tumor followed an injury to the breast. Adenofibroma is largely a tumor of early adult life (Fig. 7) and is frequently encountered in young women and girls just after puberty. If the patient has known of the existence of the lump for a number of months or years, she may notice a definite, though slow, increase in size. Only rarely is the tumor multiple. Rapid growth may occur during lactation, due to the same stimulus which affects the rest of the breast; many women, indeed, first notice the lump during such a period. On examination, a firm encapsulated tumor is felt, which is quite distinct from the rest of the breast parenchyma. The mass is usually much larger and more definite than the lumps noted in chronic cystic mastitis, except when a single cyst is present. Perhaps the most diagnostic features of an adenofibroma are the smooth *rounded surface* and the extreme mobility, which at times is so pronounced that the tumor appears to "move" away from the examining fingers, with no more contact than a gentle touch.

Treatment always consists of surgical excision, just as in the case of any definite lump in the breast. While a lump may perhaps be observed for a time in the case of a young girl, surgical excision is practically always indicated in most women over 25 and in every woman over 35 years of age. The operation is quite simple and healing should take place with a relatively insignificant scar. Excision

Fig. 8. Sarcoma of the breast. The patient, aged 37, had known of the existence of a small tumor in the breast since the age of 13. For the past year it has been steadily and rapidly growing to its present size. At operation the tumor was found attached to the pectoral muscle. It is important to remember that such a tumor does not metastasize to the axillary lymph nodes and for this reason a simple mammectomy is sufficient. The prognosis is good. This tumor, originating in a fibroadenoma, is not to be confused with fibrosarcoma, which may also, though rarely, occur in the breast; its features have already been described.

enables a true diagnosis to be made, particularly if malignant disease is to be ruled out.

MALIGNANT NEOPLASMS

Mammary cancer is common and accounts for nearly 18 per cent of all deaths in women (8). Nearly all of these tumors are of epithelial cell *origin (carcinoma); sarcoma* (Fig. 8) comprises but 3 to 5 per cent of them. The female breast is predominantly affected (100:1). As with carcinoma elsewhere, advancing *age is the most predisposing* clinical factor, few cases occurring before the age of 35. After this age the incidence rises sharply, half of all cases being noted beyond the age of 50. The etiology of cancer of the breast is unknown, except for the possible role of sex hormones as shown by the greater virulence of the growth during pregnancy. Indeed, experimental cancer has been produced by repeated injections of estrin. The relation between skin irritation in Paget's disease and cancer is more definite; a detailed description of Paget's disease of the nipple will be found on page 877. Trauma and previous lactation have no proved etiologic connection with the disease, although cancer tends to grow quite rapidly when it occurs during lactation, due presumably to the *abundant blood supply.*

Pathology. A variety of types have been described arising from both duct and acinous epithelium. Classification is usually based on *the relative proportion of fibrous and* epithelial elements, the rapidity of growth, and particularly the microscopic arrangement of the cancer cells; especially their tendency to *form definite glandlike structures. In general,* three main types are described: medullary, scirrhus, and adenocarcinoma, but other lesser terms, such as comedocarcinoma and cancer cyst, *are also used to describe special* tumors.

Medullary (encephaloid) carcinoma or carcinoma simplex is a cellular and, in general, a rapidly growing *tumor which often,* however, exhibits periods of relatively slow progression. It is composed of an undifferentiated type of cell which does not form glandlike structures (Fig. 9), is rather *soft in* consistency, and occurs more often at an earlier age than the other types. The tumor

Fig. 9. Photomicrograph of a breast tumor showing medullary carcinoma. Note the invasive character of the growth.

is rather circumscribed and on cut section contains little scar tissue in contrast to the next type of tumor, scirrhus.

Scirrhus, as its name implies, is composed largely of fibrous tissue with a paucity of epithelial elements. Indeed, the predominance of scar tissue, which often seems to be engulfing the cancer cells, gives one the impression that the body is attempting to overcome and strangle the tumor. The large amount of fibrous tissue also gives the tumor its characteristic "stony-hard" sensation on palpation. It is just about as frequent as medullary cancer, but grows more slowly, metastasizes much later, and occurs more frequently in women of more advanced age.

Adenocarcinoma is so-called because its cells are arranged in the form of alveoli or acini. Many tumors of this group grow rapidly and metastasize widely within a year; others may be present for years before metastases occur. The tumor is more bulky than the scirrhus type, sometimes invades the skin and leads to extensive ulceration even before it spreads elsewhere. Colloid carcinoma is a form of adenocarcinoma in which much colloid material is present. It is rare and exhibits even a lower degree of malignancy than adenocarcinoma. Comedocancer is a descriptive term applied to tumors in which tiny bits of material may be squeezed from the cut surface of dilated ducts, many of which contain masses of tumor tissue. Cancer cyst is a term applied to a malignant tumor which, on cut section, is found to contain a cystic area due either to degenerative changes, to a dilated duct, or to an intracystic papilloma which has become malignant.

The *spread of cancer of the breast* occurs primarily by direct permeation into small lymphatic channels of the breast lobule (Fig. 10), into vascular channels, and into the subcutaneous tissue, fascia, muscle, and skin. When the tumor cells enter the skin lymphatics, they may be evident as small nodules just beneath the surface, giving to the skin an appearance similar to the studded breastplates carried by the knights of old, to which it owes its name, *en cuirasse*. This is often noted in the late stage of cancer, also in the skin as metastasis after removal of the cancer. Metastasis by way of the larger lymph channels occurs first to the regional axillary lymph nodes, occasionally the supraclavicular nodes, and to the internal mammary chain of the anterior mediastinum. Spread also takes place in a diffuse manner, particularly along fascial lymphatics which penetrate the pectoralis muscles and the chest wall, as well as the sheath of the upper end of the rectus. The internal mammary nodes are particularly apt to be the seat of metastasis if the tumor is located in the medial portion of the breast. Distant metastases occur by way of the blood stream, mainly to the liver and bony skeleton, particularly to the spine and long bones. It

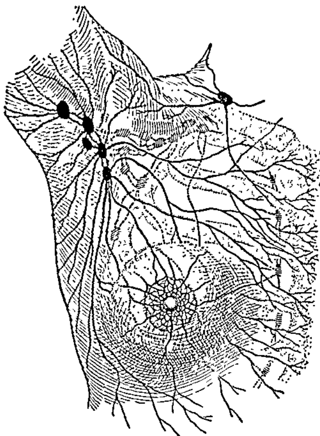

Fig. 10. The lymphatics of the mammary gland and the nodes into which they drain. (From Homans. Textbook of Surgery, Charles C Thomas.)

should be emphasized that vascular spread of the tumor cells is the mechanism responsible for the patient's death.

Clinical Manifestations. Since pain is seldom noted in early carcinoma of the breast, the first manifestation is usually a *lump* which is firm, poorly circumscribed and has a slightly nodular surface. Perhaps the most valuable single manifestation is *skin retraction*, which is present in about 80 to 85 per cent of cases and is often demonstrable only by shifting the tumor from side to side with the examining fingers (Fig. 11). It is caused by the cancer shortening the fibrous skeleton (Cooper's ligaments) just under the skin. When the tumor is extremely early, or located deep in the breast, this sign may be absent. Retraction of the skin over a malignant tumor is on rare occasions exhibited by three or four lesions which are not malignant. One of them is localized fat necrosis, which is described on page 880. The second is an abscess of subacute or chronic development due to infection with a pyogenic organism or to tuberculosis. Plasma cell mastitis occasionally results in skin retraction. A scar from a small laceration or incision may obviously result in retraction, but the presence of the scar will always identify the cause. When the tumor is located in or near the center of the breast, *retraction of the nipple* may be present (Figs. 12, 13). However, caution is urged in the use of this sign as an indication of cancer, because it is often congenital; when observed, the other nipple should be examined because congenital retraction is usually bilateral. Retraction of the nipple, to be of significance, must be of recent origin and unilateral, for in many women both nipples are always retracted. The *pig skin* or *orange peel* appearance of the skin over a tumor of the breast is another important, but later, clinical sign of cancer, often present together with retraction of the skin and like it made more prominent by relaxing

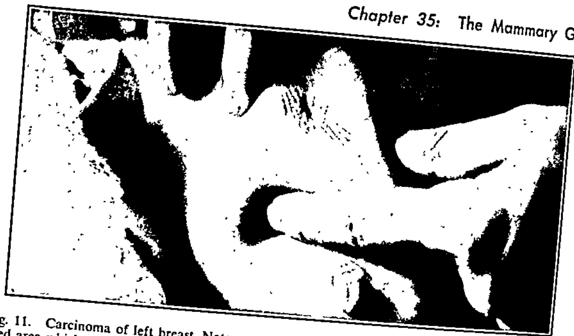

Fig. 11. Carcinoma of left breast. Note retraction of the skin. The lump lay directly beneath the retracted area which was firmly fixed to the tumor. The patient was 65 years old and first noted the lump three months previously. No axillary metastases were felt or discovered at operation. The tumor proved to be a fibrosing type of adenocarcinoma.

the skin over the tumor. This sign probably is produced by a depression of the openings of many sweat glands and hair follicles or by a local edema of the skin overlying the tumor (see Fig. 14). Edema may be present over an acute inflammatory tumor, but there is no difficulty in differentiating such an edema from that produced by cancer because of the lack of other signs of inflammation. Edema in cancer is unfortunately a late sign. Still later in the course of the disease, the tumor invades the overlying skin, and soon a necrotic ulcerating mass is formed. Regional *lymph node enlargement* in the axilla, or especially in the

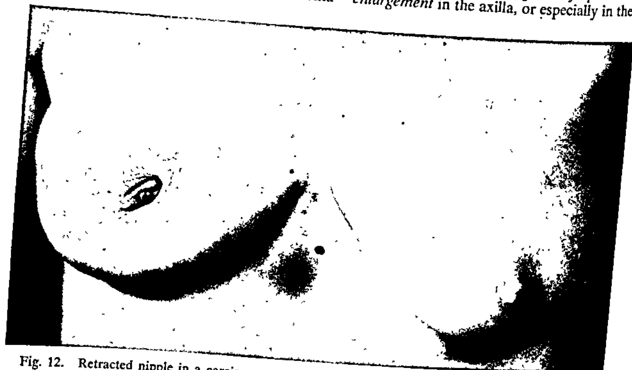

Fig. 12. Retracted nipple in a carcinoma of the breast. In this patient the tumor was located in the central portion of the breast but the mass measured only 2 cm. in diameter. (After Cole and Rossiter in Lewis Walter's System of Surgery, W. F. Prior.)

Fig. 13. Retraction of the nipple in carcinoma of the breast. In this patient the retraction is of a different type than that illustrated in Fig. 12, because the cancer has actually grown outward into the nipple. The mass is 5 cm. in diameter and occupies the entire thickness of the breast.

supraclavicular region, is another late manifestation of cancer in that it indicates metastasis, except when the enlargement is secondary to an infection, such as that associated with an ulcerating tumor. *Discharge from the nipple* occurs in slightly less than 5 per cent of patients with carcinoma. Since the discharge in carcinoma of the breast is bloody in only about half the cases (Hinchey) it is important to remember that the presence of a serous discharge does not eliminate the diagnosis of malignancy. The discharge is more apt to be bloody in intracystic papilloma, which is a frequent precursor of cancer, as already mentioned.

A diagnosis of cancer must be seriously considered whenever a single painless lump is noted in the breast of a woman past the age of 30 or 35 years. Operation is advised if for no other reason than to establish or rule out such a diagnosis. If the surgeon is not sure from his clinical examination that the tumor is benign, the patient should be prepared as if for radical operation rather than for local excision.

Treatment. At present the only hope of curing cancer is the total eradication of the malignant tissue by actual removal or by destruction *before it has spread* beyond range of such therapy. The former is achieved by surgical excision, the latter by radiotherapy (deep x-ray or radium). Adequate surgical excision is the procedure of choice in mammary cancer while in the operable stage.

The earlier mammary cancer is seen, the greater the clinical problem of deciding at the time of operation whether the tumor is benign or malignant. In such cases, the pa-

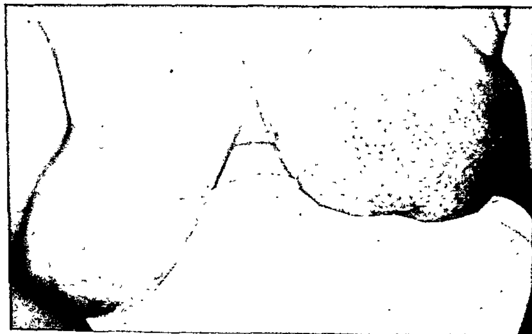

Fig. 14. Carcinoma of the breast with "orange peel" skin.

tient should be prepared as if for radical resection, and the tumor excised with a wide margin or normal tissue. This policy, unfortunately, has been used as a routine procedure. There has been an increasing tendency to subject all tumors to this procedure and await a diagnosis by frozen section before deciding on the type of operative procedure. Although such an approach is advisable and decisive in borderline cases, it should not be adopted as a routine method for several reasons. First, if the tumor is clinically malignant, cutting into it or around it is basically unsound. Second, the expense of frozen section can be saved in most cases if the surgeon himself performs a gross examination of the bisected tumor; he should be trained adequately to detect or exclude cancer in this way in the vast majority of cases. Third, the great fear of doing a radical resection for benign lesions (local inflammation and fat necrosis) is exaggerated because of the rarity of such lesions. Fourth, should competent gross examination prove equivocal, frozen section may also fail to reveal the true diagnosis. In such cases, permanent section will be necessary and a second operation can be carried out a few days later should the lesion prove to be malignant. Clinical follow-up studies in such two-stage procedures have apparently shown that they do not diminish the likelihood of a five-year survival if the biopsy has been *excisional* (Davis, 9). However, if it has been by aspiration or *incisional* biopsy several days before the radical operation, the probability of a five-year survival is sharply reduced.

The operation of choice in carcinoma of the breast, which has been adopted by most surgeons over the world, was first described independently in 1894 by Willie Meyer and W. S. Halsted. The nature of this procedure must be clearly understood and meticulously followed in studying the end results, which, indeed, have been shown to vary with the care with which this operation has been carried out. An *adequately* performed radical resection means a careful, sharp, and meticulous axillary dissection, denuding the axillary vessels, the chest wall, and the sheath of the latissimus dorsi all in one single specimen (en bloc). A wide area of skin around the tumor must also be removed. Just as important is extensive undermining of the skin flaps so as to excise sufficient subcutaneous tissue under them; this is necessary to ensure the inclusion of all mammary parenchyma which often extends widely under the skin beyond the breast itself. Wide excision of the skin often makes a skin graft essential (Fig. 15).

The importance of early operation in mammary cancer is shown by the excellent five-year survival rate following radical resection of the breast. For example, Harrington (10) reports a five-year survival rate of 51.2 per cent in 8,074 patients treated at the Mayo Clinic by radical resection; in this series, the five-year survival rate was 78.3 per cent in patients without axillary metastasis, and 32.5 per cent in patients with axillary metastasis.

It should be mentioned that a few clinicians, stimulated by the work and publications of McWhirter (11) over the past many years, believe that simple mastectomy and

Fig. 15. Skin graft following radical mastectomy. In 20 to 30 per cent of patients having a radical mastectomy for carcinoma a skin graft will be necessary. Operation was performed 10 days previous to this photograph. Note the site (almost healed) to the left of the umbilicus, where the graft was obtained. The graft should be performed at the time of radical mastectomy to shorten convalescence.

x-ray therapy to the axilla will yield just as good results as radical mastectomy. However, most clinicians strongly recommend radical mastectomy.

The problem of therapy in late, inoperable mammary cancer is a real one and should be based primarily upon the reduction of pain and other symptoms by any palliative means available. Radiotherapy (12, 13), particularly over metastatic bone involvement, is often effective for the relief of pain. In a few cases, such therapy is dramatically successful and may not only relieve symptoms but even prolong life. The use of testosterone, estrogen, and other hormones has also been extensively tried and in some instances is particularly effective (14, 15). Removal of, or radiation over, the ovary (16) has also been tried and is occasionally successful. More recently, bilateral adrenalectomy (17) and even hypophysectomy (18, 19) have been employed and, in a few cases, have led to dramatic regression and perhaps even disappearance of metastatic tumors. Why this occurs in some cases and not in others is unknown. Moreover, it is not known why the response, even in the most successful instances, is not sustained. In all such cases, even if temporary palliation is achieved, the tumor nearly always resumes its growth and the patient eventually succumbs.

Following radical mastectomy, slight to moderate *swelling of the arm and forearm* usually develops. Occasionally it is severe (even without recurrence of tumor in the axilla or mediastinum) and produces considerable disability. The excision of lymphatics is unquestionably related to the condition, but is not the sole causative factor. X-ray therapy and postoperative wound infection have been considered important in etiology, but practically all investigators studying this lesion do not find significant evidence of this relationship. In a study made by Fitts and associates (20), about the only significant factor found consistently was moderate obesity. The condition can be prevented to a great extent by wrapping the extremity with an elastic bandage for a few weeks, prophylactically or as soon as swelling appears. The patient should be instructed to sleep at night with the extremity elevated on a pillow. If swelling is allowed to exist over an extended period of time the edematous area becomes indurated (because of fibrosis) and then is very difficult to treat.

Some surgeons believe that the standard type of radical operation, as originally designed by Halsted, should be extended. For example Handley (21) and Urban (22) have recommended that when the cancer is located in the inner quadrant of the breast the internal mammary chain of lymph nodes should be removed with the breast along with a segment of the chest wall en bloc. Wangensteen (23) has recommended a super-radical operation in which, in addition to a radical breast operation, the sternum is split and the lymphatics in the mediastinum removed. More time will be required to determine the efficiency of these two procedures.

Paget's Disease of the Nipple. Paget's disease (Fig. 16) really consists of two lesions, a skin disease and a true carcinoma of the ducts of the breast. Since the skin lesion is observable first, carcinoma should be suspected whenever it is encountered. Most skin lesions of the nipple are benign and clear up in a few weeks with ordinary care, especially cleanliness. If the lesion is due to Paget's disease, it will not heal but will progress and finally lead to a destructive ulceration of the entire areola. A biopsy is justified in doubtful cases in order to establish the diagnosis.

In Paget's disease of the nipple, microscopic section shows an infiltration in the skin lesion of cells which are large and deeply staining, with sharp, round, vesicular nuclei and vacuolated cytoplasm (Fig. 16A). They are found under the epidermis and may extend outward, but remain in the superficial part of the lesion. It is believed by some observers that unless this peculiar cell (often called the "Paget cell") is present, a diagnosis of Paget's disease is unjustified. While this cell has a distinctly malignant appearance, it is entirely unlike the disease process present in the deeper tissues; the latter consists of a duct cell carcinoma arising in the terminal portions of the lactiferous ducts.

The *treatment* of Paget's disease of the nipple is the same as that for carcinoma of the breast, i.e., radical mastectomy. The prognosis is particularly good for patients without obvious metastases, since many of these tumors are slow to metastasize. However, if

Fig. 16A. Paget's disease of the nipple. This is a very early case in a 58-year-old woman. A tiny ulcer of the nipple, as shown in the photograph, first appeared four months previously; it healed at intervals, but always recurred. After operation several blocks of tissue were examined microscopically but no evidence of carcinoma was found, although the typical histologic picture of Paget's disease was noted in sections of the ulcer. This is shown in the low and high power photomicrograph as shown below the photo; note the characteristic appearance of the so-called "Paget cell."

the tumor has already extended and growth is active, the prognosis is no better than for any other case of carcinoma of the breast. Early removal of the lesion is, therefore, particularly important.

INFECTIONS

Inflammatory diseases of the mammary gland are similar to infections elsewhere, but a few are characteristic of the breast itself because of their location in the parenchyma of the organ.

Acute Mastitis. This lesion starts as an acute deep infection, usually of one portion of the breast, and may be accompanied by evidence of systemic invasion, such as a chill and fever. In most instances, the infected area rapidly softens and suppurates, forming an abscess of the breast. The organism is frequently the staphylococcus. Although it may occur in the nonlactating or virgin breast, acute mastitis is more common in pregnancy, particularly during lactation. Often the abscess is secondary to "caked breast" (p. 881). The infection probably enters through fissures or abrasions about the nipple and travels along the lymphatics of the ducts to the depths of the gland. Heat, redness, local pain, and tenderness rapidly develop; the pain is usually so severe that the patient seeks

Fig. 16B. Paget's disease of the nipple. In this patient, a woman of 59, a dermatitis of the nipple has been present for four years, and an eczematous ulceration of the areola for five months. A biopsy performed at "4 o'clock" where a crust is visible, revealed carcinoma. A radical resection was performed.

early relief. Less commonly, the lesion is deeply seated and reaches the surface more slowly or may penetrate beneath the breast and form a submammary abscess.

Treatment, such as cleanliness and protection of the nipple, will prevent fissures and abrasions and thus prevent infection by eliminating the portal of entry. Once the infection is present, the treatment is the same as that of acute inflammation elsewhere; early chemotherapy may prove rapidly curative and prevent suppuration. Otherwise heat, elevation, and rest are employed, followed by incision and drainage as soon as suppuration occurs. It is important that incision for drainage be made in a radial direction from the nipple in order to avoid cutting across the ducts. Incision must be carefully made, preferably under general anesthesia, and should be large enough to drain the cavity adequately. Since the abscess is apt to be multilocular, it is important to explore the ramifications of the cavity gently in order to insure complete drainage. Counter drainage is often necessary. The infection frequently burrows extensively, thereby accounting for its tendency to form a chronic draining sinus because of inadequate drainage or the presence of necrotic tissue. If the abscess is submammary, a more lateral circular incision may have to be made. In view of the increased resistance of the staphylococcus to penicillin, selective chemotherapy by isolating the organism and testing it for sensitivity may be essential in the refractory cases.

Chronic Mastitis. A chronic draining sinus, which may be multiple, is usually the result of an inadequately drained abscess of the breast; a history of the acute process is often obtained. However, the possibility of tuberculosis or fat necrosis should always be considered, particularly from the history; it is often ruled out only by microscopic examination of excised tissue. If the lesion is actually due to a pyogenic infection, heat, selective chemotherapy, elevation, and more efficient drainage may result in healing. Often, however, especially in the neglected cases, the destruction of tissue has been so great that total mammectomy may be indicated.

Tuberculosis. Tuberculosis of the breast, though rare, may be difficult to diagnose even if it is merely secondary to disease elsewhere. The usual history is that of a painless lump of long duration which finally suppurates, opens, and results in one or more sinuses

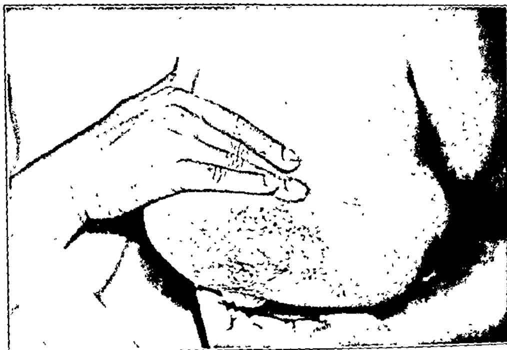

Fig. 17. Tuberculosis of the breast. Note the ulcers which are the sites of draining sinuses which open and close at intervals. The patient, aged 40, had known of a lump for many years. Several years previously it became painful, was incised, and pus obtained. A second abscess appeared recently; pus was aspirated, showing no organisms on smear or culture, and gave an equivocal guinea-pig test (the animal died too soon). The diagnosis is based on the presence of tuberculosis elsewhere (lungs, tarsus). Excision of the breast with the diseased tissue has been advised; definite identification of the lesion can be established only by this means, or biopsy (aside from the tests already mentioned).

which fail to heal (Fig. 17). If the pus is obtained before secondary infection has occurred, the organism may be found on smear; injection of pus into guinea pigs should reproduce the disease. Otherwise, biopsy of the diseased tissue is the only certain method of diagnosis. Treatment consists of excision of the diseased breast and the use of streptomycin and associated ancillary drugs.

MISCELLANEOUS LESIONS

Injury. Trauma to the mammary gland is rare and poses no special problem in diagnosis or treatment except when a swelling is noticed thereafter. In most instances, the association is a coincidence, the lump having been present previously but overlooked until the trauma caused the patient to palpate her breast. In some cases, a true hematoma may be the cause of such a swelling; in a few instances, the swelling may be due to fat necrosis.

Fat Necrosis. This lesion produces a firm, palpable mass, frequently with skin retractions and is, therefore, easily mistaken for carcinoma. There will be a history of trauma preceding the development of the lesion in 30 to 40 per cent of cases; accordingly, the lesion is often spoken of as traumatic fat necrosis. Early in the course of the disease, the mass is soft, but as fibrosis develops it becomes harder. "Orange peel" skin and retraction of the nipple rarely occur. Enlarged nodes are often encountered in the axilla but they are not as hard as metastatic nodes from a carcinoma. Occasionally sinuses develop, often following incision of a soft fluctuant area erroneously thought to be an abscess. The diagnosis is usually made only after excision, upon bisecting the tumor. The presence of an irregular mass of slightly reddened tissue containing liquid fat, is characteristic. The microscopic section shows deposition of scar tissue and round cell infiltration, besides the necrotic fat. It has no relation to cancer.

Treatment is surgical, primarily because carcinoma cannot be excluded. The mass should be excised widely, including skin if attached, and the specimen submitted to frozen section. However, the diagnosis is usu-

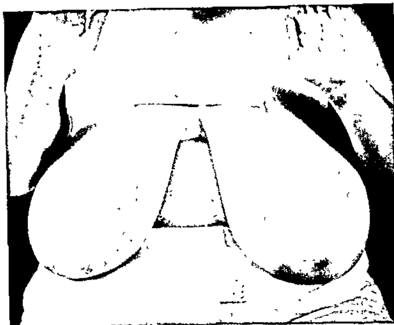

Fig. 18. Simple hypertrophy of both breasts. This patient was 35 years old and had developed a gradual enlargement of both breasts beginning 10 years previously.

ally made readily on gross examination because of the presence of areas of necrosis and liquefaction of fat, without the grayish granular surface so typically seen in carcinoma.

"Caked Breast." At any time during lactation, one segment of the breast may become hard and somewhat tender, but without other signs of inflammation. The lesion is rather common and is generally called "caked breast." It usually subsides spontaneously but may give rise to suppuration. The pathogenesis of the lesion is somewhat in dispute, but obstruction of the involved secreting parenchyma is generally considered to be an important factor. In addition to the local retention of milk, which produces an entirely different picture from a galactocele, infection is also supposed to play a role. The entrance of organisms of low virulence through the nipple is supposed to result in a local but mild type of mastitis, similar in nature to acute mastitis which has already been described. *Treatment* is directed toward relief of the lesion in order to minimize the danger of suppuration. A supporting bandage is usually sufficient, but gentle massage and the use of the breast pump may also be indicated. When there is evidence of infection, treatment is carried out as described elsewhere.

Simple Hypertrophy. Enlargement of the breast, starting in the female at puberty, ordinarily ceases when the breast has reached a moderate size. Occasionally, the growth stimulus continues until the breasts are greatly enlarged and interfere seriously with the comfort and even the health of the patient. On other occasions, the hypertrophy does not develop until several years after puberty (Fig. 18). The etiology is poorly understood, but is presumably related to endocrine dysfunction. Pain in the shoulders and neck is common, caused presumably by the excess weight of the breasts. If supporting bandages do not give relief, a plastic operation with partial amputation of the breasts may be necessary; results following this procedure are very good.

Premature (precocious) enlargement, usually of one breast, is rare but is seen occasionally in young girls before puberty and is presumably due to precocious endocrine stimulus. There is often a history of trauma which brings the patient to the doctor; occasionally severe spontaneous pain occurs (puberty mastitis). The enlargement is rarely pronounced and causes no difficulty because of its size. Recognition of the nature of the swelling will enable a true diagnosis. Reassurance

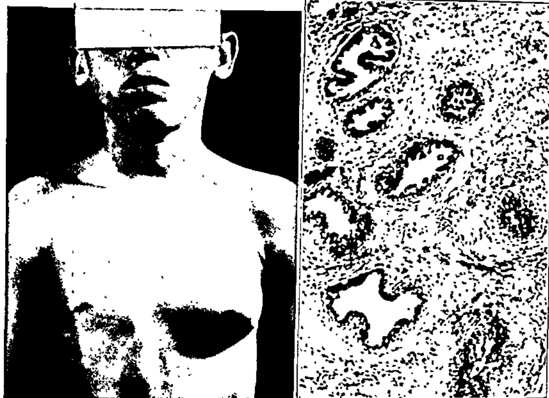

Fig. 19. Gynecomastia affecting the left breast. The photo is of a boy 14 years old. The swelling of the breast was first noted one year previously; slight pain and tenderness were present. The photomicrograph on the right is from another patient but is typical for this lesion. There is mild hyperplasia and lymphocytic infiltration.

is usually all that is necessary. Complete surgical excision is obviously contraindicated; with the advent of puberty both breasts develop symmetrically, in most instances. In young boys, however, a similar phenomenon requires excision (see Gynecomastia).

Mastodynia. This ill-defined term applies to pain in the breast which is often of severe and disabling character. As already mentioned, this symptom is nearly always due to an associated chronic cystic mastitis. Occasionally, however, palpation of the breast reveals little or no abnormality. Such cases have been called neuralgia of the breast and may be similar to other true neuralgias (see Chap. 27). Psychogenic factors probably play an important part. Treatment is often unsatisfactory; mammectomy may be justified occasionally, especially in women past the childbearing period, but even this may be unsuccessful in the relief of pain.

Gynecomastia. Enlargement of the mammary gland in the male is called gynecomastia (Fig. 19) and is caused by an endocrine dysfunction, often by an increased output of estrogen or diminished production of testosterone; it is most commonly observed shortly after puberty. When both breasts are involved, tumors of the testicle (less commonly of the adrenals or pituitary gland) may be the causative factor. Occasionally the enlargement is due to inflammatory changes of a chronic type or to a cystic disease somewhat similar microscopically to chronic cystic mastitis in the female. Symptoms may be absent or consist of slight pain or discomfort. The unilateral tumors should be excised even if small in size, particularly because of the danger of cancer, which does occur occasionally in the male breast. If cancer is present, clinically or microscopically, a radical resection should be carried out. In young boys, gynecomastia may be a psychogenic problem and requires simple excision, with preservation of the nipple for cosmetic reasons. In bilateral gynecomastia, endocrine therapy with

testosterone reduces the hypertrophy, but recurrence takes place when the therapy is stopped.

Aberrant and Accessory Breast. These congenital anomalies are rare and usually produce few clinical manifestations.

The aberrant breast is a misplaced portion of normal parenchyma, located usually in the anterior axillary fold; unlike the accessory breast it is not associated with a separate nipple. It is usually mistaken for a benign tumor; excision may be indicated, particularly if carcinoma is suspected.

Accessory breasts usually consist merely of a more or less well-developed nipple without any secreting tissue. They occur along the "*milk-line*" *which extends from the axillary* to the inguinal fold. Simple excision is sometimes indicated, usually for psychic reasons only.

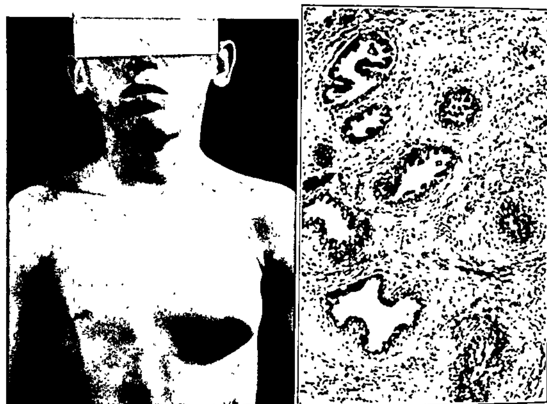

Fig. 19. Gynecomastia affecting the left breast. The photo is of a boy 14 years old. The swelling of the breast was first noted one year previously; slight pain and tenderness were present. The photomicrograph on the right is from another patient but is typical for this lesion. There is mild hyperplasia and lymphocytic infiltration.

is usually all that is necessary. Complete surgical excision is obviously contraindicated; with the advent of puberty both breasts develop symmetrically, in most instances. In young boys, however, a similar phenomenon requires excision (see Gynecomastia).

Mastodynia. This ill-defined term applies to pain in the breast which is often of severe and disabling character. As already mentioned, this symptom is nearly always due to an associated chronic cystic mastitis. Occasionally, however, palpation of the breast reveals little or no abnormality. Such cases have been called neuralgia of the breast and may be similar to other true neuralgias (see Chap. 27). Psychogenic factors probably play an important part. Treatment is often unsatisfactory; mammectomy may be justified occasionally, especially in women past the childbearing period, but even this may be unsuccessful in the relief of pain.

Gynecomastia. Enlargement of the mammary gland in the male is called gynecomastia (Fig. 19) and is caused by an endocrine dysfunction, often by an increased output of estrogen or diminished production of testosterone; it is most commonly observed shortly after puberty. When both breasts are involved, tumors of the testicle (less commonly of the adrenals or pituitary gland) may be the causative factor. Occasionally the enlargement is due to inflammatory changes of a chronic type or to a cystic disease somewhat similar microscopically to chronic cystic mastitis in the female. Symptoms may be absent or consist of slight pain or discomfort. The unilateral tumors should be excised even if small in size, particularly because of the danger of cancer, which does occur occasionally in the male breast. If cancer is present, clinically or microscopically, a radical resection should be carried out. In young boys, gynecomastia may be a psychogenic problem and requires simple excision, with preservation of the nipple for cosmetic reasons. In bilateral gynecomastia, endocrine therapy with

tosterone reduces the hypertrophy, but recurrence takes place when the therapy is opped.

Aberrant and Accessory Breast. These ngenital anomalies are rare and usually oduce few clinical manifestations.

The aberrant breast is a misplaced portion normal parenchyma, located usually in the terior axillary fold; unlike the accessory east it is not associated with a separate pple. It is usually mistaken for a benign mor; excision may be indicated, particularly carcinoma is suspected.

Accessory breasts usually consist merely of more or less well-developed nipple without ly secreting tissue. They occur along the nilk-line" which extends from the axillary the inguinal fold. Simple excision is somenes indicated, usually for psychic reasons ly.

SURGICAL DISEASES OF THE THORAX

Thomas H. Burford and Thomas B. Ferguson

Thoracic surgery has grown remarkably in scope and effectiveness during the past two decades. In this chapter, consideration is given to those conditions of the thorax which are of interest to the surgeon exclusive of the esophagus and the heart, pericardium, and great vessels.

THORACIC CAGE

Malformations. Many of the malformations are of no surgical importance because they produce no symptoms. There are some, however, which deserve attention. Occasionally there is a complete or partial absence of the anterior thoracic wall which may be associated with ectopia cordis. The overlying skin in such cases may or may not be absent. Sometimes this condition is severe enough to necessitate a plastic repair but it is, after all, rather rare. Another condition, known as funnel chest (pectus excavatum), occurs, in which there is a more or less marked depression and concavity of the sternum. In most cases, this condition is accompanied by no symptoms, but occasionally serious pressure effects on the heart and great vessels, the esophagus, and even the liver may occur. This deformity is not always congenital but may result from trauma. Surgical correction has been recommended both for decompression of the mediastinum and for cosmetic reasons. The operation consists of resection of the deformed costal cartilages and elevation and fixation of the sternal plate. Results of the procedure are generally excellent.

Fractures and Dislocations of the Sternum. These lesions are occurring with increasing frequency as a result of vehicular accidents. In simple sternal fractures or dislocations with displacement, early open reduction with wire fixation yields the best results. Sternal injuries associated with the "crushed chest" syndrome will require immediate temporary stabilization with balanced traction or some other effective expedient to assure proper aeration of the lungs.

Inflammations of the Chest Wall. Inflammations of the chest wall, in a few respects, have characteristics which distinguish them somewhat from inflammations of other parts of the surface of the body. Of the ordinary pyogenic infections *subpectoral* abscess and *subscapular* abscess are both worthy of special mention. The former arises from an infection which begins in the loose areolar tissue beneath the free border of the pectoralis major or minor muscles. It is sometimes secondary to an infection of the axillary lymphatics or to an abscess of the breast. When a swelling is apparent, it is found under the outer border of the pectoralis major muscle. In many cases, only a fullness is made out in that region without any local redness of the skin. Adduction and outward rotation of the arm are especially painful; but in the severe cases any movement of the arm is painful. The constitutional symptoms are often very marked. The lesion is often overlooked and it is necessary, therefore, to bear the possibility of it in mind in connection with infec-

tions of the hand, arm, or breast in which the constitutional effects persist after local drainage seems to have been adequately established. The treatment of the condition is to establish free drainage. For this purpose it is usually necessary to make an ample incision along the external border of the pectoralis major muscle and usually it is necessary to divide some of the fibers of that muscle. Chemotherapy may be used with surgery as discussed elsewhere.

Subscapular abscess is more rare than *subpectoral abscess*. It is often mistaken for a tumor of the chest wall, partciularly of the scapula. Even when the abscess is produced by pyogenic organisms there may be practically no local evidences of inflammation except fluctuation. Few of these cases are tuberculous in nature. Ample drainage is imperative.

Osteomyelitis of the Sternum and Ribs. Osteomyelitis of the sternum, though rare, was frequently fatal before the development of antibiotic therapy. It is now seldom seen, and the mortality is much lower than formerly. Primary osteomyelitis of the ribs is also rare but it occurs often enough to deserve some attention. When it occurs, the best treatment is removal of the infected portion of the rib. Prompt recovery ordinarily follows this procedure. Secondary osteomyelitis is rather frequent, especially after operations for drainage of an empyema cavity at which a portion of a rib has been resected. In the great majority of cases, healing occurs without any marked symptoms, but sometimes small sequestra get into the abscess cavity and result in the establishment of a chronic fistula which runs the course of a typical foreign body infection with closure for a few weeks at a time followed by a recurrence of signs of local inflammation and a reopening of the fistula with the discharge of pus In such cases, it is often necessary to resect the involved portions of the rib.

Tuberculosis of the Sternum and Ribs. Tuberculosis is the most common inflammatory disease of the ribs and sternum except for those which follow compound fractures. It occurs most frequently in middle life and almost always originates with rupture of a tuberculous lymph node in the mediastinum. Frequently, an abscess will travel a long distance to open spontaneously. It seldom discharges into the pleura. Like cold abscesses elsewhere, the local evidences of inflammation are usually not marked. Frequently, the first feature noticed by the patient is a soft swelling which fluctuates but is not red. If the swelling is aspirated, the characteristic curdy pus will be obtained. If a sinus is already present, necrotic bone can sometimes be felt with a probe. An x-ray examination, particularly after the injection of lipiodol into the sinus, is often helpful in making a diagnosis. If the disease is confined to a single rib its wide removal frequently results in satisfactory and complete healing. Heliotherapy and hygienic treatment are of great value as supplementary aids. If a costal cartilage is involved, it is necessary to remove the entire cartilage. Streptomycin used in conjunction with surgery has resulted in a very greatly improved outlook for the patient with a tuberculous sinus.

Syphilis and actinomycosis of the bony chest wall occur but will not be given any special consideration here because of their comparative rarity.

Tumors of the Chest Wall. Nearly all of the common benign tumors have been recognized as arising in the chest wall. The most important tumors, however, are those which arise from the bones. Simple osteomas have been described but nearly always cartilage is also present and, therefore, for the most part such tumors are really enchondromas. A large proportion of them are malignant. This is particularly true of the cartilaginous tumors which arise from the costal cartilages. Occasionally they arise in the scapula. They often become of enormous size even when they are benign, and the symptoms which they produce, for the most part, are those of pressure against other structures and visible deformities. They are usually hard, rounded, and lobulated but frequently, in parts of the tumor, softening occurs from mucoid degeneration. Although they are slow to metastasize, they show a marked tendency to recur after extirpation (Fig. 1). The most difficult features of the diagnosis are the determination of the extent of the tumor and of whether or not it is malignant. Even when suspected of being benign and of limited extent the extirpation of these tumors should never be

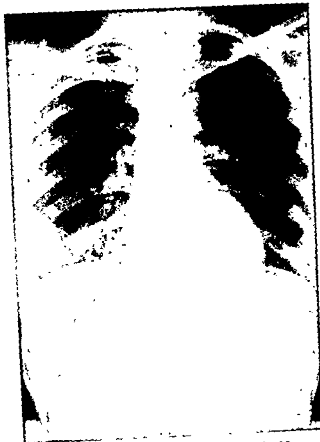

Fig. 1. Chondrosarcoma of rib. This 28-year-old woman complained of pain in the right lower chest. Biopsy of the mass revealed chondrosarcoma. Metastatic lesions are already present in the left lung. The patient went downhill rapidly and expired.

undertaken lightly because it is often necessary to remove large portions of the chest wall in order to get completely around the neoplastic tissue. The most frequent malignant tumor arising in the chest wall is a sarcoma. Practically all varieties of sarcoma have been observed in this region. It is noteworthy that many cases in which a diagnosis of simple chondroma has been made were subsequently proven to be sarcomas. In a series of 213 cases of tumors of the bony chest wall analyzed by Hedblom, 131 were sarcomas. The usual origin is in the ribs. Carcinoma of the chest wall, exclusive of that which arises in the mammary gland or in the skin, is never primary.

Injuries of the Thorax. For convenience, the injuries of the thorax are usually classified as: (*a*) nonpenetrating and (*b*) penetrating.

NONPENETRATING INJURIES. These are of importance chiefly because of the injury which may occur to important intrathoracic structures without any external evidence that such injuries have occurred. It is very common to find fractures of the bony cage without external evidence of injury to the skin. It is still more important, however, to realize that extensive injury of the intrathoracic viscera may occur without any fracture of the bony chest wall. Such a possibility is particularly prevalent in the elastic resilient thorax of a baby or a young child. There are three complications which deserve particular attention and should always be considered. These are intrathoracic hemorrhage, a dangerous degree of tension pneumothorax, and mediastinal emphysema. If a picture of shock occurs an hour or more after the injury, the possibility of *intrathoracic hemorrhage* should be strongly considered. In lacerations of the lung, hemoptysis usually, but not always, occurs. But intrapleural hemorrhage can occur from other vessels than those in the lungs, particularly intercostal arteries, the internal mammary artery, and so forth. Pneumothorax may occur alone or in association with a collection of blood. If the pneumothorax comes from a type of injury to the bronchial tree which permits the entrance of air into the pleural space but prevents its exit, very alarming symptoms of dyspnea may occur. This condition of *tension pneumothorax* requires prompt aspiration of the contained air in order to save the patient's life. *Mediastinal emphysema* usually occurs after a laceration of the trachea or of a main bronchus. It is not so likely to occur after a simple laceration of the lung. The air may travel from the mediastinum throughout the entire body. In a severe example of this sort all of the subcutaneous tissues may crackle, even as far down as the feet, and marked swelling of the face is present. Another complication is a laceration of the diaphragm which permits abdominal viscera to enter the thorax. The existence of this complication may not be recognized until some years later. Massive atelectasis also occasionally occurs. A severe type of nonpenetrating injury is seen as the result of a crushing injury in which much of one side of the chest wall may be pushed into the thoracic cavity. It is, of course, associated with multiple fractures of the ribs and, usually, extensive intrathoracic complications.

Fig. 2. Decortication of the lung. This patient had a hemothorax treated ineffectively with recurrent thoracentesis. Left, shows the air-fluid level, and the thick membrane which is preventing the lung from expanding. Right, shows the resulting expansion obtained by thoracotomy and removal of the limiting membrane.

In the treatment of nonpenetrating injuries of the thorax, consideration must first be given to the immediate care of shock and to a careful examination of the patient for any evidence of injury to viscera, thoracic, abdominal, or brain, and to the presence of multiple fractures. If, after a blood transfusion for the treatment of shock, a patient's condition improves and then grows worse again, the question of a continuing intrapleural hemorrhage should be strongly considered with the idea of opening the thorax *to find the bleeding vessel. It is not wise to* provide open drainage for a hemothorax because of the infection which will inevitably result.

Experience in World War II showed clotting of blood within the pleural cavity to be more frequent than heretofore suspected. If blood accumulates in the pleural cavity at the time of injury and is not removed, it will clot and produce a thick limiting membrane preventing expansion of the lung (1) (Fig. 2). Accordingly, effort should be made to remove blood early after injury to prevent clotting. When discovered later, the pleural cavity will have to be opened, the clot removed, and the lung decorticated of the restraining fibrinofibrous membrane. The ideal time for operation is three to five weeks after injury.

Costal fractures should rarely, if ever, be strapped with adhesive tape. Intercostal nerve block with procaine posterior to the fracture sites is a much more efficient and physiologic procedure. A flail chest resulting from anterior and posterior fractures of the same rib or ribs will, however, very frequently be stabilized by pressure strapping.

By eradicating pain, mobilizing the chest wall, and thus re-establishing an efficient breathing and coughing mechanism, intercostal nerve block will do much to prevent *massive atelectasis. If massive atelectasis de-*velops, it should be actively treated at once. If turning the patient with the involved side up and vigorous coughing do not reaerate the lung promptly, bronchoscopy should be done. For the patient who cannot or will not raise tracheobronchial secretions adequately, the method of tracheobronchial catheter aspiration as described by Haight (2) is frequently lifesaving. The patient with a severe thoracic injury should have a tracheostomy to reduce the work of breathing and the dead space and to facilitate the removal of the copious secretions (3).

If there is evidence of injury to any of the abdominal viscera or to the brain they should be treated in accordance with the indications present.

Penetrating Wounds of the Chest. Penetrating wounds differ from those which are nonpenetrating chiefly in the fact that the former are more likely to be associated with infection. In addition, the element of open pneumothorax is likely to be added which, in itself, may be a very serious complication. Infection caused by penetrating wounds is often due not only to the direct introduction of pathogenic bacteria but also to the retention of a foreign body in the thoracic viscera with more or less destruction of tissue by the missile. All of the complications already mentioned for nonpenetrating injuries can occur after those which penetrate. The experiences in World War I and World War II showed that the first and most important indication is to close a sucking wound of the chest after débridement of the edges. This procedure avoids the serious mechanical consequences of an open pneumothorax. Closure of a sucking wound is indeed an important first-aid procedure and should be achieved by means of a firm occluding bandage. If a frank empyema develops, it should be treated by adequate drainage as in the case of an empyema which arises as a complication of pneumonia. At all times after the wound is closed, the patient should be carefully watched for the possible development of serious pressure effects from entrapped air under pressure or from too much fluid in the chest. Small missiles, such as rifle or pistol bullets, are usually comparatively innocuous even when retained in the lung. Large, jagged fragments of metal, however, ordinarily should be removed and if there is positive evidence of retained particles of clothing which have been carried into the thorax, these should also be removed. Under no circumstances should indiscriminate probing of the wound be carried out. Metallic foreign bodies can almost always be accurately localized with the x-ray. Splinters of bone driven into the lung may cause trouble later by being the focus of one or more pulmonary abscesses. If the fragments of bone are large enough to be detected with the x-ray it is usually better to remove them than to wait for an abscess to develop. Under no circumstances, however, should a thoracotomy be performed for the removal of foreign material until after the patient has recovered from initial shock following the injury. Various special technics were devised during both World Wars for the removal of retained projectiles in the chest. Special and more comprehensive works on thoracic surgery should be consulted for a description.

Hernia of the Lung. This condition is rare and will not be extensively considered. Occasionally, it is encountered as a congenital defect but more often it follows an injury of a sort which has permitted the lung to escape through an intercostal space. When the hernia is of any size it should be repaired by a plastic operation on the chest wall.

DISEASES OF THE PLEURA

Acute Empyema. The most important surgical condition of the pleura is empyema, more properly designated as *empyema thoracis*. This is a condition in which pus is present in the pleural cavity and it is, therefore, an abscess of the pleura. It is most important to distinguish this condition from a collection of serous or serohemorrhagic fluid.

With the advent of penicillin there occurred a very marked reduction in the incidence of empyema following all types of pneumonia. Today an established thoracic surgeon may not see a case of empyema for an entire year. Similarly, in those that do occur the process is less acute and less damaging to the patient. Unfortunately, this attenuation often leads to bizarre loculations and other features which may make the empyema more difficult to diagnose and manage.

Technical improvements in pulmonary surgery as well as the antibiotics have markedly reduced the incidence of empyema following thoracic operations and trauma.

Empyema (suppurative pleurisy) is most often due to one of the pyogenic organisms. Tuberculous empyema is common and even such conditions as actinomycosis, streptothricosis, and blastomycosis may be associated with an empyema caused by those specific organisms. It is practically always a complication of some type of pneumonia except when it occurs as the result of a penetrating wound of the thorax or, more rarely, by spreading upward into the thoracic cavity of an abscess beneath the diaphragm. The type of pneumonia which precedes the development of the empyema may be different in different cases. For example,

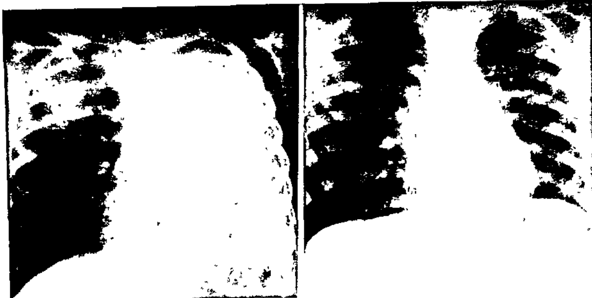

Fig. 3. Treatment of early empyema of childhood by closed drainage. This seven-year-old boy developed extensive staphylococcal pneumonia following the chicken pox. Left, shows the pneumonitic infiltration bilaterally with pleural fluid on the left. Thoracentesis revealed cloudy yellow fluid which contained staphylococci on smear. He was treated with closed catheter drainage of the pleural space and antibiotics. Right, shows the chest after recovery. There are a few pneumatocoeles in the left upper lobe, a characteristic for this disease.

when due to a pneumococcus, the empyema usually is a sequel of a lobar pneumonia; when due to a streptococcus, it is most often a complication of a bronchopneumonia; when caused by other pyogenic bacteria, it is usually a complication of some type of suppurative inflammation of the lung, such as pulmonary abscess or bronchiectasis. The pneumococcal and streptococcal varieties are more common in children than in adults.

Staphylococcal empyema in children requires special mention. Since the pneumonitis is usually associated with multiple small peripheral abscesses which may rupture with the development of a pyopneumothorax, it is mandatory to institute closed catheter drainage of the pleural space just as soon as the effusion appears and staphylococci are identified (Fig. 3).

Symptoms and Diagnosis. A suspicion of the presence of an empyema should always be aroused in any case of lobar pneumonia if the temperature comes down to normal for a day or two and then begins to rise. Formerly, many cases which illustrated this phenomenon were diagnosed as unresolved pneumonia. It is now, however, generally recognized that unresolved pneumonia is a comparatively rare condition and that nearly all cases which were formerly given that diagnosis are, in reality, examples of empyema. In not all cases of postpneumonic empyema does the temperature come down to normal before the empyema begins, but in the majority of pneumococcal infections such a phenomenon occurs. In the streptococcal cases, this tendency is less evident. In any case of inflammation of the lung in which there is a sudden increase in the temperature with greater prostration of the patient, the beginning of empyema should be suspected. It is not always easy to be certain in such a case whether the increase in temperature is due to a spread of the pneumonia or to the beginning of empyema. Evidence of a fresh involvement of the other lung is some indication that the condition is really a spread of the pneumonia. The ultimate diagnosis of an empyema, however, will depend upon an exploratory aspiration. Pain and tenderness are rarely present unless the chest wall itself is invaded. If the empyema has been produced by the spontaneous rupture of a pulmonary abscess, the signs and symptoms are usually much aggravated and often there will be air as well as fluid in the pleural cavity which may be recognized on an

x-ray examination if the patient is placed in a suitable position to show a fluid level, i.e., with the x-ray tube so placed that its rays are directed through the body in a horizontal direction. Such a condition is often spoken of as *pyopneumothorax*.

The physical signs of an ordinary acute empyema are practically those which are found in connection with any collection of fluid in the pleural cavity. Occasionally, in the acute cases if the effusion is large and if it has come on rapidly, the affected side may show a bulging. More often, however, the affected side appears smaller and flatter than the other because of nature's attempt to immobilize that side of the chest. In the early cases, there may be a marked displacement of the mediastinal contents to the healthy side. In long-standing cases, however, the displacement of the mediastinum may be toward the affected side. In the acute streptococcal cases, there may be extreme dyspnea and cyanosis because of the concomitant presence of extensive bilateral pneumonia. In the ordinary postpneumonic pneumococcal cases, dyspnea and cyanosis are not extreme. In cases of encysted emypema, the physical signs usually vary from those elicited when the empyema has originated in the free pleural cavity. In interlobar empyema, the physical signs are often confusing and may be mistaken for a pulmonary abscess. In most cases of the latter type, bronchial fistulas are present and therefore a fluid level with gas above it may be seen on an x-ray examination occupying the ordinary position of an interlobar fissure. Otherwise, the x-ray examination in cases of empyema is not usually distinctive from the findings present in any pleural effusion.

The constitutional disturbances are essentially the same as with any other acute infection. In children, the temperature is usually high (40° C. or 104° F.). As the empyema becomes more chronic, however, the temperature, which is of the septic type with remissions, generally has a lower daily maximum. A rather high polymorphonuclear leukocytosis is nearly always present. Clubbing of the fingers and toes is often seen in the subacute and chronic cases.

The systemic symptoms caused by empyema may be masked completely by prior or present antibiotic therapy.

COMPLICATIONS. The most common complications of empyema are bronchial fistula, perforation of the thoracic wall (empyema necessitatis), suppurative pericarditis, peritonitis, blood-stream infection, bilateral empyema, mediastinal abscess, and various miscellaneous complications such as meningitis, brain abscess, and multiple arthritis. The pneumococcal cases are much less likely to be complicated by other lesions than are the streptococcal cases. In listing the complications as has been done here, the opinion is implied that empyema is a complication of pneumonia rather than that pneumonia is a complication of empyema. Likewise, when the empyema occurs in association with one of the acute exanthemata, it is a sequel to the pneumonia which has complicated the main disease.

TREATMENT OF ACUTE EMPYEMA. In the treatment of every case of acute empyema there are two fundamental considerations. One is to save life and the other is to prevent chronicity. It is unfortunate that the treatment of acute empyema has been clouded by strong advocacy of various detailed methods. In its true sense, empyema is an abscess of the pleural cavity. When an abscess is present in that locality it should be treated like abscesses in other parts of the body, namely, by drainage. Much of the confusion in the literature about the treatment of empyema has arisen because a clear and precise discrimination has not been made between a fully developed abscess and one in its formative stage. In other parts of the body, drainage of infections which are destined to become abscesses is not considered until the abscess has actually developed to maturity. Experience has clearly shown that premature drainage of such infections is very likely to be accompanied by disastrous results to the patient.

In the case of infections of the pleural cavity a particular situation exists which makes it increasingly dangerous to establish wide free drainage before a definite abscess has been formed. The special reasons which obtain in the case of acute infections of the pleural cavity are concerned with the special physiology of the region involved. Since res-

piration is dependent upon the creation of a negative pressure in the thorax, at least at some time in the act of inspiration, it is apparent that any opening into a free pleural cavity is likely to result not only in embarrassment of the respiration but also of the circulation to some extent because of the dependence of the filling of the auricles of the heart upon a negative pressure. During the formative period of an empyema the danger of interference with the normal intrathoracic pressure relationship is particularly great because at such time the patient is usually suffering from a more or less extensive pneumonia and a consequent marked reduction in his vital capacity. If the patient is already cyanotic and orthopneic, his vital capacity may be so low that it may approach the tidal air requirements. In other words, under such conditions, in spite of maximal inspiratory effort, the patient can take in scarcely more than enough air needed to carry on life, even at rest in bed. There is, therefore, practically no reserve upon which he can draw to compensate for any further embarrassment of his respiration. Even a very small opening of the pleural cavity under such circumstances may be fatal because the effect of any opening in the pleural cavity is not confined to the lung of one side unless it is adherent to the chest wall or unless the mediastinal tissues are sufficiently stabilized by inflammatory thickening to prevent a shift of the mediastinum to the opposite side. On the other hand, a person with a normal thorax can withstand a much larger opening in his pleural cavity because he can compensate for the larger opening by drawing upon his respiratory reserve. In other words, in a thorax in which there are no adhesions and no stabilization of the mediastinum, the size of the pleural opening which can be withstood by the patient depends largely upon that individual's vital capacity. During the formative period of an acute empyema there is not much stabilization of the mediastinum, and any adhesions which have formed are still delicate and easily broken, with the result that the creation of an open pneumothorax by establishing a free open drainage is equivalent to doing that in a thorax which has no protection against it. If, therefore, the vital capacity is very low because of the presence of an extensive pneumonia, such an individual may die promptly of asphyxia if a free opening is made into his pleural cavity which is allowed to communicate with the outside air. On the other hand, if the infection has developed into a definite abscess and has become an empyema in the true sense, an opening for drainage is accompanied by practically no respiratory disturbance. This absence of deleterious result is because of several features. One is that under such circumstances the opening is made into an abscess rather than into the free pleural cavity. There are, therefore, no serious pressure effects on either one or both lungs. Moreover, it happens that an empyema seldom becomes a true abscess until after the pneumonia has cleared to a considerable extent. The patient's vital capacity is, therefore, higher and even if there were pressure effects they would be of less consequence because the patient would be more able to withstand them.

In view of the foregoing remarks, it should be evident that the creation of an open pneumothorax by the establishment of free open drainage should never be undertaken unless definite frank pus has been demonstrated by aspiration (Fig. 4). Experience has indicated that when definite frank pus is present there is no ascertainable difference in the results whether one uses an open drainage at that time or some method of drainage which will exclude the influence of the outside air. The principle involved in the latter method is known as closed drainage. The obvious and most important conclusion to be drawn doubtless is that patients are not very likely to die of acute empyema itself. Many will die, however, from an injudicious operation if the surgeon *creates an open pneumothorax during the formative period of the empyema.* The two most important principles to bear in mind are: 1. not to create an open pneumothorax during the time when pneumonia is present; and 2. to provide adequate drainage when it has been decided that drainage is necessary. A third principle is to successfully maintain the nutrition of the patient. If, in a given case, an aspiration (thoracentesis) reveals only turbid fluid, it is very unwise to create an open drainage. Instead, the patient should be treated either by aspiration as often as seems necessary to relieve serious pressure

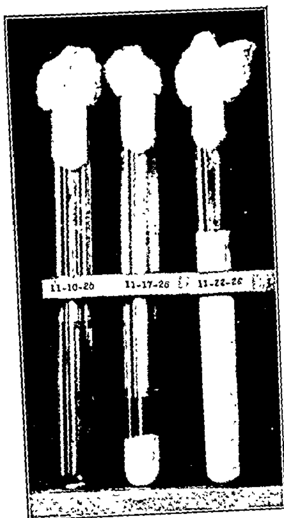

Fig. 4. Changes in the exudate in a case of streptococcal empyema. The tube on the left shows a seropurulent exudate. In the middle tube will be seen one from the same patient obtained seven days after that in the first tube and the tube on the right shows exudate obtained 12 days after that in the first tube. The seropurulent exudate has become transformed into one that is frankly purulent. Open drainage of the first exudate would be very dangerous; of the second, less dangerous; of the third, practically without danger. (From Graham, Singer and Ballon. Surgical Diseases of the Chest, Lea & Febiger.)

effects or by some method of continuous closed drainage. The simplest procedure to accomplish the latter is the insertion of a catheter through a cannula passed through the chest wall. After the cannula is withdrawn, the catheter, if it is of the same size, will fit snugly into the opening. The end of the catheter can be placed under water to prevent a free communication between the outside air and the pleural cavity, or gentle suction can be arranged so that the exudate will be constantly aspirated through the tightly fitting catheter.

If the aspiration of the pleural cavity reveals definite frank pus, an open drainage can be performed immediately, either by an intercostal incision or by the removal of a segment of rib one or two inches long. If the patient is a baby it is desirable not to make the opening too large. If an intercostal drainage is made it must be expected that in a large number of cases a subsequent rib resection will be necessary.

The important contributions of Tillett and his associates in the field of bacterial enzymes may greatly alter the management of pleural sepsis. These investigators have developed proteolytic enzymes of bacterial origin (streptokinase and streptodornase) which, in many instances, appear to effectively dissolve fibrin in the pleural space with break down of loculations permitting re-expansion of the lung. While most thoracic surgeons still feel that open drainage after the formation of thick pus is the surest, quickest, and safest way to cure an established empyema thoracis, there is no denying that many cases will respond well to a combination of antibiotic therapy with enzymatic débridement and repeated pleural aspirations.

Drainage should be maintained until the cavity is obliterated. The tube should not be removed until actual measurements have shown that the capacity of the cavity is approximately only 10 ml. An empyema should never be considered to be healed until there is positive evidence that the cavity itself is obliterated. In most cases of acute empyema, complete healing should occur in a period of from five to six weeks after the exudate has become definitely purulent. In many cases, healing will occur more promptly. In fact, in cases of pneumococcal empyema healing often occurs after one or two aspirations. One may expect that such an event will occur in from 10 to 25 per cent of cases of pneumococcal empyema. This tendency is more evident in children than in adults.

Chronic Empyema. It has already been said that one of the primary objects in the treatment of acute empyema is to prevent chronicity. Chronic empyema is less common in children than in adults. One of the most frequent causes of the condition is the failure

to provide adequate free drainage. The use, therefore, of methods of continuous closed drainage through small catheters should not be carried on too long in the treatment of an acute empyema because of the danger of permitting the condition to pass into a chronic state. It is important, therefore, that the drainage of an acute empyema should be at the most dependent portion of the cavity and that any tube used for the purpose should be of sufficient caliber to permit an easy exit of the pus.

Other important causes of chronic empyema are the presence of foreign bodies, communications with the lung or bronchial fistulas, cavities that cannot be obliterated spontaneously because of too much fibrosis of the lung and too much rigidity of the mediastinum, tuberculosis, or similar infections. Draining sinuses which persist after an empyema are not necessarily due to the presence of a chronic empyema. Such sinuses, for example, may lead to bronchial fistulas which are immediately beneath the chest wall but which have not closed spontaneously. Again the sinus may lead only to a necrotic portion of rib.

In establishing a diagnosis of chronic empyema it is desirable to determine not only the presence of a chronic empyema cavity but also to gain some idea of its size, location, and the possible cause of it. By the injection of a sufficient quantity of lipiodol through the external sinus, if one is present, some idea may be gained about the location and size of the cavity. If the case is one in which there is no external communication, aspiration with the introduction of from 50 to 100 ml. of air will usually enable one to outline the cavity in a fairly suitable manner. The diagnosis of tuberculosis or other granulomatous infections can usually be made by the excision of a piece of pleura for microscopic examination.

TREATMENT. Since, in the majority of cases of chronic empyema, the cause has been inadequate drainage, the treatment of a chronic case usually will be begun by the procedure of instituting adequate and satisfactory drainage in the most dependent portion of the cavity. This will often require the resection of segments of one or two ribs. In many cases even when the empyema cavity is of two or three years' duration, it may become obliterated within two or three months after the creation of satisfactory drainage. In nearly all cases, the cavity will at least become greatly reduced in size even if it is not completely obliterated (Fig. 5).

If, after the lapse of two or three weeks of adequate drainage, the cavity shows no signs of becoming obliterated, then some form of radical procedure must be considered. In such cases, the failure of the cavity to become healed is due to the fact that the overlying chest wall is too rigid to be pulled downwards to the lung and that the lung is too rigid to be pulled to the chest wall by the contraction of the scar tissue. The obliteration of an empyema cavity always occurs by progressive formation and contraction of scar tissue from the periphery toward the center of the cavity. All of the radical surgical procedures used for the treatment of chronic empyema are based on a principle of freeing the rigid walls of the cavity to permit them to come together and unite by the formation of scar tissue. If the empyema is relatively early, experience gained during World War II showed that decortication is very successful, just as in cases of clotted hemothorax. If the empyema is of long standing and the walls are comprised of scar tissue several centimeters thick, then the ribs, intercostal bundles, and outer empyema wall must be removed (Schede operation). In such an operation it is essential that the procedure should be sufficiently radical. Nothing is to be gained by halfway measures. It is essential that no overhanging edges of the empyema cavity should be allowed to remain. The cavity must be converted into a saucer with sloping edges in order to have it become satisfactorily obliterated by being filled up with soft tissues of the chest wall.

Spontaneous Nontuberculous Pneumothorax. Formerly it was a common belief that spontaneous pneumothorax was necessarily an indication of pulmonary tuberculosis. Now, however, it is well known that this condition often occurs in individuals who have no active tuberculosis. In such instances, it is usually due to the rupture of an emphysematous bleb beneath the visceral pleura or to the rupture of a cyst in a case of congenital cystic disease of the lungs. The treatment of such cases depends upon the degree of col-

Fig. 5. Chronic loculated empyema resembling lung abscess. This 66-year-old man had a febrile episode followed by chest pain and productive cough. Thoracentesis revealed thick pus. He was treated by rib resection and open drainage. The cavity closed over the next two months without further surgical treatment, and the patient remained well.

lapse. If the pneumothorax is less than 10 per cent, the air may be aspirated with a needle and the patient observed closely for recollapse. If the pneumothorax is greater than this, or if the patient is dyspneic, trocar thoracotomy with insertion of an intercostal tube should be done. When the tube is connected to a closed drainage apparatus, rapid re-expansion of the lung will occur. Patients with two or more episodes of collapse of the same lung should have an operation with resection of the offending blebs, and powdering (poudrage) of the pleural surfaces with an irritant to obliterate the pleural space permanently (Fig. 6). Patients with bilateral episodes of pneumothorax should have op-

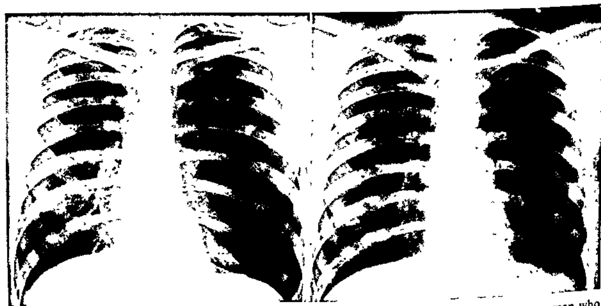

Fig. 6. Recurrent spontaneous pneumothorax due to apical blebs. The patient was a young man who had had a previous pneumothorax on the left side treated by closed catheter drainage. Left, shows the degree of collapse of the left lung on the second admission. The blebs can be seen at the apex. He was treated by thoracotomy, resection of the apical bullae, and poudrage. Right, shows the postoperative result.

Fig. 7. Solitary fibrous mesothelioma of the pleura. This 47-year-old man complained only of increasing shortness of breath. Left, shows the tumor before resection. Right, is the postoperative result. The tumor, which weighed 3500 grams, was completely removed.

eration on the recently affected side to prevent the future possibility of a fatal simultaneous bilateral collapse. Infections other than tuberculosis, such as pulmonary abscess, are sometimes associated with a spontaneous pneumothorax because of a rupture of the lesion into the pleural space. A complicating empyema almost invariably occurs in the latter case. As mentioned previously, staphylococcal pneumonitis with effusion in children is attended in a very high percentage of cases by tension pneumothorax, and for this reason closed tube drainage of the chest is mandatory during the effusion stage.

Tumors of the Pleura. Primary tumors of the pleura, both benign and malignant, are relatively rare. The commonest benign tumor is the fibrous mesothelioma (5). This is a circumscribed slowly-growing tumor which may reach large size before being discovered (Fig. 7). It is associated in a high percentage of cases with severe arthralgia Total surgical removal and cure is usually possible. Other rare benign tumors include lipoma, fibroma, and angioma.

The vast majority of malignant tumors involving the pleura are metastatic. Carcinoma of the lung frequently involves the pleura by direct extension, and breast cancers often metastasize to the pleura by way of the internal mammary lymph chain. A true primary malignant tumor is the papillary mesothelioma. The normal mesothelial cells undergo malignant change and spread along the surface in a series of papillary projections. Pleural effusion is always present and is usually excessive in amount. The prognosis is very poor.

There are other conditions which sometimes simulate tumors of the pleura. Occasionally in pneumothorax cavities, fibrin bodies are formed which are roughly spherical in outline and often appear in x-ray films like tumors. Areas of calcification in the pleura may sometimes be mistaken for a new growth. Again, various kinds of cysts of the pleura have been described, of which some are echinococcal in origin but others are due to congenital defects.

The problem of diagnosis of pleural tumors and the differentiation from benign processes is at times difficult. Sooner or later a pleural effusion almost always develops, which may or may not be bloody. The presence of blood does not necessarily mean that a malignant process is present. There are a large number of inflammatory conditions which give rise to pleural effusion and which must be considered when a diagnosis of pleural tumor is entertained. Smears and cultures of the aspirated fluid will help to rule out a tuberculous or pyogenic infection. The fluid should be examined for cells by exfoliative cytology technics or by centrifuging the fluid

and making paraffin blocks of the sediment. In almost all cases where a malignancy is present, identifiable tumor cells will be found. In fact, if such studies are negative on several occasions, then the diagnosis of tumor should be seriously questioned. The problem of an undiagnosed pleural effusion is difficult. Needle biopsy of the pleura has been used, but the tissue obtained is small. It is probably best in such cases to proceed directly with exploratory thoracotomy. In this way, ample tissue for diagnosis can be obtained and decortication can be done if the lung is trapped under a limiting membrane.

With advanced malignancies of the pleura, rapid reaccumulation of fluid frequently poses a therapeutic problem because of dyspnea. This is especially true with papillary mesotheliomas and metastatic breast cancers. The production of fluid can usually be controlled by the intrapleural use of radioactive gold or nitrogen mustard. An occasional patient will require surgical removal of the involved pleura to obliterate the pleural space.

THE MEDIASTINUM

The mediastinum is very important surgically because within that space are located the heart, the giant vessels, the trachea and its bifurcation, the esophagus, and important nerve trunks. For practical purposes it is well to bear in mind the four anatomic divisions of the spaces—superior, anterior, middle, and posterior, according to the relations which they present to the pericardium.

Mediastinal Emphysema. It is important to realize that the persistence of a pressure less than that of the atmosphere is necessary for the proper functioning of many of the mediastinal structures. Serious elevations of pressure in the mediastinum therefore may result in physiologic disturbances which may be sufficiently extreme to cause death. One source of such an increased mediastinal pressure is the gradual accumulation of air within it, a condition known as mediastinal emphysema. This condition is caused by a rupture of subpleural alveoli and dissection of air back along the bronchovascular structures to the hilum of the lung, and from there to the subcutaneous tissues of the suprasternal notch. Here the condition may be recognized early by swelling and crepitation. Conditions in which mediastinal emphysema is seen as a complication include asthma, influenza, pertussis, and pneumonitis. It sometimes occurs following indirect trauma to the chest.

The diagnosis is not difficult if the condition is kept in mind. The patient may complain of severe substernal pain simulating heart disease. Subcutaneous air first makes its appearance in the neck, but may spread to involve large areas of the body. Auscultation of the chest will reveal a crunching sound synchronous with the heart beat, caused by compression of the mediastinal air by motion of the heart (Hamman's sign). The blood pressure may be normal or low, depending upon the degree of mediastinal tension and circulatory obstruction.

Emergency treatment is necessary if there is severe circulatory compromise. Decompression is done by making a collar incision in the neck and opening the fascial planes leading into the superior mediastinum. In addition, tracheostomy is sometimes advisable.

Mediastinitis. Many of the acute infections of the mediastinum represent the spread of infection from the mediastinal lymph nodes. Probably most of the acute infections of the mediastinum occur as injuries to the esophagus. These result from the perforation of the esophagus by sharp foreign bodies which have been swallowed and also from perforations in association with benign stricture or carcinoma of the esophagus. The antibiotics, particularly penicillin, have proved remarkably effective in the control of mediastinal infection. The development of diffuse mediastinal phlegmon is now a rare occurrence, and abscesses which require drainage are far less frequent than formerly. Perforations occurring as a result of instrumentation, if small, may often not require operation of any sort provided the endoscopic examination was done for non-neoplastic disease and if antibiotic is given promptly and in adequate dosage. Perforations occurring in cases of carcinoma of the esophagus are best handled by doing an immediate resection and esophagogastric anastomosis. Large perforations in nonmalignant esophageal disease should be closed immediately with either two layer suture of the perforation or resection and anastomosis as dictated by the pathology. An

abscess of the mediastinum may often be recognized on x-ray examination by an undue prominence of the mediastinal shadow, particularly in the upper part. Since most of the mediastinal abscesses occur in the superior mediastinum, the majority of them can be reached successfully for drainage through an incision in the neck. The location of such an incision will depend considerably upon the location of the abscess, especially whether it is in the anterior or posterior part of the mediastinum. Sometimes the usual collar incision for thyroidectomy will be adequate. In other cases, especially those due to a perforation of the esophagus, an approach along the anterior border of the sternocleidomastoid is preferable.

Chronic infections of the mediastinum are often tuberculous and they frequently originate from tuberculosis of the spine. They are, therefore, often in the posterior mediastinum. If secondarily infected, they demand drainage usually through a posterior mediastinotomy incision. If they are not secondarily infected, they should be aspirated and treated like tuberculous abscesses elsewhere. The possible connection with tuberculosis of the spine should always be borne in mind so that appropriate treatment will be given to that condition also.

Mediastinal Tumors. With the development of thoracic surgery, mediastinal tumors have become of increasing importance because of the possibility of extirpating many of them successfully. The most common effect of a mediastinal tumor, regardless of its type, is pressure on one or more important structures. In malignant tumors there may be, in addition to pressure effects, actual involvement of organs by extension or metastasis.

The most common result of increased mediastinal pressure caused by a tumor is dyspnea which is due probably not so much to compression of the air passages as to compression of the large veins. The vein which is particularly affected is the superior vena cava. Signs of obstruction of this large vein are usually present at some time in the case of any large mediastinal tumor. The specific signs of compression of the superior vena cava are cyanosis, orthopnea, dilatation of the superficial veins of the thorax and later, pulmonary edema, pleural and pericardial effusion. Determinations of the venous pressure in such cases show an increase. Subcutaneous edema of the head, neck, and upper part of the thorax occur in the more severe cases of superior caval obstruction, likewise headache, vertigo, deafness, epistaxis, tinnitus, and even loss of consciousness with epileptic convulsions may occur. The resulting effect depends somewhat upon whether the obstruction has occurred above or below the orifice of the azygos vein. If the obstruction is above the azygos orifice the symptoms are less severe than if it is below that point. The symptoms just mentioned may occur with any mediastinal tumor of sufficient size. In malignant tumors there will also be present signs and symptoms resulting from the development of metastases in other organs.

Mediastinal tumors, like many of the tumors in the chest, can only be diagnosed by surgical exploration and pathologic examination. Experience has shown, however, that, statistically speaking, most mediastinal neoplasms are characteristically found in a certain mediastinal compartment, although certainly some overlap occurs. For this reason, they are most conveniently discussed with respect to location.

Superior Mediastinum. The most common tumor of this region is a substernal extension of an adenomatous goiter of the thyroid gland. They are usually connected to the cervical thyroid, and their blood supply is that of the normal gland. They are therefore best removed through a transverse cervical incision. Because of excessive size, about 5 per cent of these tumors will require an additional median sternotomy to facilitate removal. Rarely, aberrant parathyroid tumors and bronchogenic cysts will occur in the superior compartment.

Anterior Mediastinum. The principal tumors here are thymomas and teratoid tumors. Both exist as benign and malignant forms. Thymomas are a poorly understood group of neoplasms, and histologically there may be great difficulty in classifying the tumor and estimating the degree of malignancy. Also, an unexplained relationship exists between benign thymomas and myasthenia gravis, in that some patients with the disease are improved by removal of the gland. Teratoid

and making paraffin blocks of the sediment. In almost all cases where a malignancy is present, identifiable tumor cells will be found. In fact, if such studies are negative on several occasions, then the diagnosis of tumor should be seriously questioned. The problem of an undiagnosed pleural effusion is difficult. Needle biopsy of the pleura has been used, but the tissue obtained is small. It is probably best in such cases to proceed directly with exploratory thoracotomy. In this way, ample tissue for diagnosis can be obtained and decortication can be done if the lung is trapped under a limiting membrane.

With advanced malignancies of the pleura, rapid reaccumulation of fluid frequently poses a therapeutic problem because of dyspnea. This is especially true with papillary mesotheliomas and metastatic breast cancers. The production of fluid can usually be controlled by the intrapleural use of radioactive gold or nitrogen mustard. An occasional patient will require surgical removal of the involved pleura to obliterate the pleural space.

THE MEDIASTINUM

The mediastinum is very important surgically because within that space are located the heart, the giant vessels, the trachea and its bifurcation, the esophagus, and important nerve trunks. For practical purposes it is well to bear in mind the four anatomic divisions of the spaces—superior, anterior, middle, and posterior, according to the relations which they present to the pericardium.

Mediastinal Emphysema. It is important to realize that the persistence of a pressure less than that of the atmosphere is necessary for the proper functioning of many of the mediastinal structures. Serious elevations of pressure in the mediastinum therefore may result in physiologic disturbances which may be sufficiently extreme to cause death. One source of such an increased mediastinal pressure is the gradual accumulation of air within it, a condition known as mediastinal emphysema. This condition is caused by a rupture of subpleural alveoli and dissection of air back along the bronchovascular structures to the hilum of the lung, and from there to the subcutaneous tissues of the suprasternal notch. Large perforations in nonmalignant esophageal disease should be closed immediately with either two layer suture of the perforation or resection and anastomosis as dictated by the pathology. An

pends upon the degree of malignancy. Occasionally, a dumbbell or hourglass tumor will be encountered where the intraspinal component causes spinal cord compression.

SURGICAL CONDITIONS OF THE DIAPHRAGM

The chief function of the diaphragm is to assist in the creation of a negative intrathoracic pressure by the enlargement of the thorax, which is produced when it descends on inspiration. The diaphragm is also important because it separates the abdominal from the thoracic cavity. It is present only in mammals. A congenital absence of the left half has been reported on several occasions, a condition which does not seem to be incompatible with health and long life. Spasms of the diaphragm are responsible for the condition known as *hiccup* or *singultus*.

Eventration of the Diaphragm. Normally, the right leaf of the diaphragm lies about 1 cm. higher than the left. In some individuals, however, one leaf, usually the left, is abnormally high. This constitutes the condition known as *eventration of the diaphragm*. Into the saclike formation which results, one or more of the abdominal organs are likely to be displaced, especially the stomach, colon, or spleen. The usual causes of such a condition, when not produced by operations on the phrenic nerve, are congenital atrophy, neuromuscular degeneration following injury, neuritis or other involvement of the phrenic nerve, certain infectious diseases and changes in the musculature of the diaphragm in association with pseudohypertrophic lipomatosis and myositis. This condition is not incompatible with good health. Its chief importance lies in the possibility of confusing it with a true diaphragmatic hernia. It is recognized by the high position of the diaphragm and by the fact that the abdominal viscera are seen to be below it rather than above it. A small pneumothorax created for diagnostic purposes will often settle the diagnosis definitely between an eventration and a hernia of the diaphragm. Ordinarily the condition demands no surgical treatment.

Diaphragmatic Hernias. These may be divided into the nontraumatic and traumatic. The nontraumatic hernias are essentially congenital and are due to the passage of an abdominal organ through a congenital opening in the diaphragm. The traumatic varieties may occur not only from penetrating injuries but also from a tearing of the diaphragm away from its attachments to the thoracic wall. Such hernias, for example, may occur after a severe automobile injury in which there has been no penetration of either the thorax or the abdomen (Fig. 9). Another classification is that which comprises congenital, acquired, and traumatic hernias (see also Ch. 34).

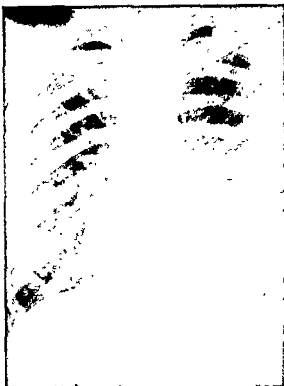

Fig. 9. Traumatic hernia. This 32-year-old man was in an automobile accident six months prior to examination. His complaints were dyspnea and dysphagia. At operation there was a large tear in the diaphragm, with herniation of most of the stomach into the left thoracic cavity. There was complete recovery following surgical repair.

The most common symptoms of diaphragmatic hernia are abdominal pain, vomiting relieved by a change in position, symptoms of intestinal obstruction, dyspnea, dysphagia, hemoptysis, cyanosis, and pain in the left shoulder. Frequently abnormal tympany is found over the lower part of the thorax. Displacement of the heart to one side is also frequently noted. X-ray examination with a barium meal almost always reveals the true

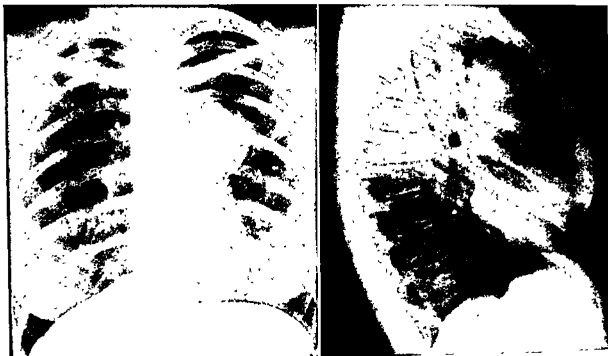

Fig. 8. Mediastinal tumor (teratoid). This 26-year-old woman had no symptoms. The lesion was discovered on a survey x-ray film. Pathological examination revealed hair, skin, bronchial epithelium, and pancreas. There was no evidence of malignancy.

tumors are among the more common types of mediastinal tumors. The benign dermoid cyst contains epithelial elements, such as skin, hair, and teeth, while true benign teratomas will contain elements of all three germ layers in varying combinations. Any of these elements may undergo malignant degeneration, with subsequent invasion of the capsule and surrounding structures.

Both thymic and teratoid tumors will usually present to one side or the other, so that removal can be done through a thoracotomy without having to cross the sternum. The benign forms are encapsulated and are easily removed with complete cure (Fig. 8). With the malignant forms, total removal is usually not possible and the prognosis is very poor.

MIDDLE MEDIASTINUM. Tumors of the lymphoma group (lymphosarcoma, Hodgkin's disease, and so forth) are the most common mediastinal tumors encountered, but are usually not amenable to surgical extirpation and are treated by some form of nonoperative therapy. Cysts of bronchogenic and pericardial origin are found in this area. Bronchogenic cysts are closely related to the trachea or main stem bronchi and may cause pressure on the air passages. Occasionally, rupture into a bronchus occurs with discharge of the cyst contents. Pericardial cysts are characteristically found in the pericardiophrenic angle. They are filled with a clear fluid and almost never cause symptoms. Both types of cysts should be removed if their presence is known, because operation is necessary for an exact diagnosis.

POSTERIOR MEDIASTIUM. Tumors in this area are related either to the esophagus or to nerve structures. Esophageal and gastroenteric cysts are usually in close association with the esophagus, and thus may cause dysphagia. They can usually be completely removed without having to resect the esophagus. Neurogenous tumors are either somatic in origin, arising from the intercostal nerves, or autonomic, arising from the sympathetic chain (6). There are a number of different histologic cell types in each group, with several gradations of malignancy. The most common benign tumor is the neurilemmoma, derived from the intercostal nerve sheath. The most malignant type is the neuroblastoma (sympathicoblastoma), which arises from primitive autonomic nervous tissue and is seen almost exclusively in infancy. Ease of removal of a posterior neurogenic tumor de-

pends upon the degree of malignancy. Occasionally, a dumbbell or hourglass tumor will be encountered where the intraspinal component causes spinal cord compression.

SURGICAL CONDITIONS OF THE DIAPHRAGM

The chief function of the diaphragm is to assist in the creation of a negative intrathoracic pressure by the enlargement of the thorax, which is produced when it descends on inspiration. The diaphragm is also important because it separates the abdominal from the thoracic cavity. It is present only in mammals. A congenital absence of the left half has been reported on several occasions, a condition which does not seem to be incompatible with health and long life. Spasms of the diaphragm are responsible for the condition known as *hiccup* or *singultus.*

Eventration of the Diaphragm. Normally, the right leaf of the diaphragm lies about 1 cm. higher than the left. In some individuals, however, one leaf, usually the left, is abnormally high. This constitutes the condition known as *eventration of the diaphragm.* Into the saclike formation which results, one or more of the abdominal organs are likely to be displaced, especially the stomach, colon, or spleen. The usual causes of such a condition, when not produced by operations on the phrenic nerve, are congenital atrophy, neuromuscular degeneration following injury, neuritis or other involvement of the phrenic nerve, certain infectious diseases and changes in the musculature of the diaphragm in association with pseudohypertrophic lipomatosis and myositis. This condition is not incompatible with good health. Its chief importance lies in the possibility of confusing it with a true diaphragmatic hernia. It is recognized by the high position of the diaphragm and by the fact that the abdominal viscera are seen to be below it rather than above it. A small pneumothorax created for diagnostic purposes will often settle the diagnosis definitely between an eventration and a hernia of the diaphragm. Ordinarily the condition demands no surgical treatment.

Diaphragmatic Hernias. These may be divided into the nontraumatic and traumatic. The nontraumatic hernias are essentially congenital and are due to the passage of an abdominal organ through a congenital opening in the diaphragm. The traumatic varieties may occur not only from penetrating injuries but also from a tearing of the diaphragm away from its attachments to the thoracic wall. Such hernias, for example, may occur after a severe automobile injury in which there has been no penetration of either the thorax or the abdomen (Fig. 9). Another classification is that which comprises congenital, acquired, and traumatic hernias (see also Ch. 34).

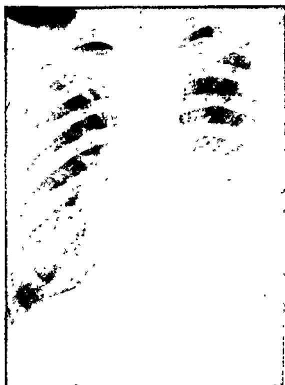

Fig. 9. Traumatic hernia. This 32-year-old man was in an automobile accident six months prior to examination. His complaints were dyspnea and dysphagia. At operation there was a large tear in the diaphragm, with herniation of most of the stomach into the left thoracic cavity. There was complete recovery following surgical repair.

The most common symptoms of diaphragmatic hernia are abdominal pain, vomiting relieved by a change in position, symptoms of intestinal obstruction, dyspnea, dysphagia, hemoptysis, cyanosis, and pain in the left shoulder. Frequently abnormal tympany is found over the lower part of the thorax. Displacement of the heart to one side is also frequently noted. X-ray examination with a barium meal almost always reveals the true

condition. The great danger of diaphragmatic hernia is that of strangulation. It is probably desirable, therefore, to operate on all cases, even if only mild symptoms are present, lest severe or even catastrophic manifestations, such as massive hemorrhage, take place (7).

Operative repair of this condition can often be performed through either an abdominal or a thoracic incision. In many cases, it is helpful to make the approach through both incisions. It may be difficult to separate adherent intestine and to make a satisfactory reduction without the combination of both incisions. In any case, the operation will be made much easier if the diaphragm previously has been paralyzed on the affected side by crushing the phrenic nerve in the neck. Previous operation on the phrenic nerve ordinarily should be performed two or three days before the operation for the repair of the hernia. In some cases the repair is easy but in many it is exceedingly difficult. Especially is that true in those cases in which the diaphragm has *been torn away from the anterior chest wall.* In nearly all cases it will be found helpful to use sutures of living fascia obtained from the patient's own fascia lata. Ordinarily the lung rapidly expands to fill up the space formerly occupied by the herniated viscus.

Wounds of the Diaphragm. Whenever recognized, penetrating wounds of the diaphragm should be promptly closed because of the possibility of the subsequent development of *a diaphragmatic hernia.*

Tumors of the Diaphragm. Primary neoplasms of the diaphragm are very rare. In a careful review of the literature for the past 50 years Binney (1931) could find but four instances of primary tumor of the diaphragm. One of these was reported as multiple fibromyoma, another as fibromyosarcoma, another as sarcoma, and the fourth as lipoma.

DISEASES OF THE TRACHEA

Surgical diseases of the trachea are uncommon. Foreign bodies lodged in the trachea should be removed bronchoscopically. *Fistulas* that occur between the trachea and esophagus are either congenital or acquired. The congenital variety is usually associated with an atresia of the esophagus, making it possible to detect the malformation soon after birth. The treatment is surgical, with one-stage closure of the fistula and restoration of esophageal continuity. Acquired tracheo-esophageal fistulas are most commonly seen as a complication of advanced carcinoma of the upper esophagus, where surgical closure is rarely possible. Tumors of the trachea are very rare. The benign tumors which have been described include papillomas, fibromas, lipomas, intratracheal thyroid tissue, lymphomas, chondromas, and chondroosteomas. The benign tumors usually occur in the upper third of the trachea or in the region of the bifurcation. They can usually be best treated through the bronchoscope.

Of the malignant tumors of the trachea, carcinoma is the most common, but the actual number found in this location is still very small. They usually arise in the lower third and are almost always of the squamous variety. Cough, hemoptysis, and wheezing are the predominant symptoms. Metastases usually occur late. Early perforation is to be ex*pected from those malignant* tumors which arise in the posterior wall. The *treatment* of these tumors is generally unsatisfactory by any method. Removal of the involved portions of the tracheal wall and the application of a dermal graft to the defect gives the best chance of cure. Palliative measures include bronchoscopic removal of all gross tumor and radon seed implantation, or the use of high voltage roentgen therapy to the area. *Nitrogen mustard given intravenously* may be helpful in the control of symptoms by reducing the tumor and relieving obstruction.

DISEASES OF THE BRONCHI

In considering surgical conditions of the bronchi, it is essential to understand some of the specific effects of conditions which obstruct or cause inflammation of a part of the bronchial tree. Because of the relatively straight direction of the bronchus of the right lower lobe, foreign bodies which are aspirated are more likely to fall into that bronchus than into any other part of the bronchial tree. An obstructive lesion that is complete is almost always followed by an absorption of *air in* that portion of the lung to which the particular bronchus leads, with the result that the condition of atelectasis occurs. In the dog

there is collateral circulation of air in different lobules, and occasionally even between different lobes of the lung. It would seem also that some evidence exists that in man similar collateral circulation of air occurs. In spite of this interesting fundamental physiologic fact, clinically in the human being, atelectasis of a lobe almost always occurs as a result of complete obstruction of the bronchus of that lobe.

Inflammation of the bronchi of a suppurative character often produces purulent inflammations of the lung, especially if there is a more or less complete obstruction of the bronchus by a foreign body or by some other agent. Obstructive lesions are not always foreign bodies, they may be new growths or they may be scars resulting from severe inflammation of the bronchus. When destructive inflammation of the wall of a large bronchus occurs, the cartilage in the wall is more or less destroyed and the condition of bronchiectasis results. Only the large bronchi have cartilaginous walls.

It is important to emphasize the fact that the normal drainage from the lung is through the tracheobronchial tree. This is brought about chiefly by two mechanisms, of which one is the expulsive action of the cilia of the epithelium lining the mucous membrane, and the other is the act of coughing. Likewise, it should be recalled that under normal conditions the bronchi are constantly changing their size and direction with each act of respiration, i.e., on inspiration, the bronchi enlarge and become lengthened. This lengthening tends to make many of them in the lower lobes more perpendicular and corresponding changes occur in the direction of the bronchi in other parts of the lung. The movements just mentioned are dependent upon the action of the peribronchial muscle. It becomes apparent, therefore, that an inflammatory process or any other factor which alters the normal action of the bronchial muscle is likely to have some effect not only on the act of respiration itself but also probably on the normal mechanisms for the expulsion of secretions from the bronchial tree. Again, consideration should be given to the fact that although coughing is one of the important mechanisms for the expulsion of products of inflammation of the bronchial tree, too violent coughing may be harmful because each act is necessarily preceded by a deep inspiration which may spread the products of inflammation into previously uninvolved alveoli of the lung. There is at the present time an insufficient amount of knowledge concerning the various points just discussed to permit one to be dogmatic. Much diagnostic information can be obtained by bronchography (Fig. 10, 11).

Foreign bodies. Aspiration of foreign bodies into the bronchus may occur at any age but is most frequently seen in young children. The majority of foreign bodies are objects which should never have been put into the mouth, although certain foods, such as peanuts, are frequent offenders. More foreign bodies pass into the right bronchus than into the left because of the anatomic arrangement of the bronchi. The symptoms and signs produced by a foreign body depend upon the size and shape of the object, its ultimate location in the bronchus, and whether partial or complete obstruction of the bronchus is present. All foreign bodies will cause cough at the time of aspiration, but this may happen without the realization that a solid object went down. Wheezing, particularly during expiration, is a valuable clue. If the foreign body is opaque, it can be accurately localized on the chest films. If it is nonopaque, indirect evidence of its presence can be detected on inspiratory and expiratory chest films which may demonstrate obstructive emphysema of the lung behind a partially blocked bronchus. Complete block of the bronchus will invariably lead to distal atelectasis. The treatment of foreign bodies in the bronchi is bronchoscopic removal as soon as the diagnosis is made. This should be done by an expert trained in foreign body removal. In this way, 98 per cent of foreign bodies can be extracted. Occasionally, a thoracotomy and direct opening of the bronchus will be necessary. Retention of an undetected foreign body may lead to hemoptysis, lung abscess, or bronchiectasis at a later time. Peanuts are particularly likely to result in gangrenous changes in the lung because of the irritating fatty acids which are formed during decomposition. Once stenosis of the bronchus or irreversible septic changes in the lung have oc-

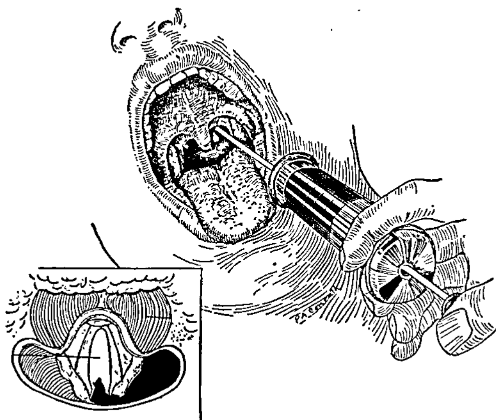

Fig. 10. The aspiration method of injecting lipiodol (J. J. Singer). The method of introducing the iodized oil into the posterior pharynx while the patient breathes deeply; the inset shows how the oil collects in the interarytenoid fossae. It then trickles between the vocal cords and is aspirated into the bronchial tree. In little children the method can seldom be used; for them bronchoscopic injection of the lipiodol is preferable. (From Graham, Singer and Ballon. Surgical Diseases of the Chest, Lea & Febiger.)

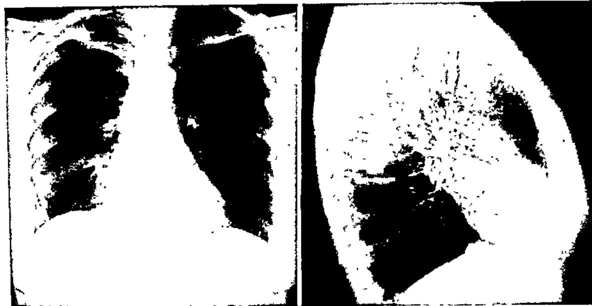

Fig. 12. Right middle lobe atelectasis. This patient, a 62-year-old woman, had a chronic cough for 12 years. At operation the right middle lobe bronchus was compressed by a ring of enlarged, chronically infected lymph nodes. Note the complete atelectasis of the lobe on the lateral x-ray projection.

curred, resection of the lobe or segment involved will be required to effect a cure.

Bronchostenosis. In the opening paragraph of this section some of the mechanical factors involved in bronchostenosis have already been discussed. The symptoms and physical signs differ according to the location of the stenosis. The amount of dyspnea is naturally dependent to a great degree upon the amount of lung involved. As might be expected, therefore, a stenosis of the trachea or of both bronchi at the bifurcation results in more dyspnea than if the lesion involves the bronchus of only one lobe. Some degree of cough is usually but not always present. Inspiration is prolonged, difficult, and wheezing. Expiration, as a rule, is much less difficult. Stridor is loud in stenosis of the trachea and of the bifurcation but it is usually absent in lesions lower down.

The physical signs of an obstruction of a bronchus are essentially those of atelectasis (Fig. 12). Again those features vary depending upon the amount of lung involved. If a main bronchus is completely obstructed, the whole lung may show evidence of massive atelectasis. The patient complains of pain on the affected side, the intercostal spaces on that side are narrowed, there is more or less limitation of respiratory movement, and the heart and mediastinal contents are found to be drawn over toward the affected side. The diaphragm on that side is elevated, the breath sounds are usually absent or diminished, and the percussion note is correspondingly dull.

The ordinary x-ray examination reveals an opacity in the region of the atelectasis, a deflection of the mediastinal contents toward the affected side and usually also a compensatory emphysema of the other lung. Bronchoscopy should be done to determine whether the stenosis is due to a foreign body, an inflammatory stricture, or a tumor, or to ascertain whether the obstruction is due to pressure on the bronchus from the outside caused by perhaps a tumor of the mediastinum. If the tumor is found within the bronchus itself, a biopsy made at the time will reveal its character. At times, bronchograms are helpful in outlining a stenotic area that is outside bronchoscopic vision.

The treatment of bronchial stenosis will, of course, depend considerably upon the nature of the stenosis. If it is due to a foreign body, the latter should be removed through a bronchoscope. Likewise, benign tumors can often be removed in that way. If, however, it is due to a carcinoma of the bronchus, the treatment should be of a different sort which will be found discussed under Tumors of the

Fig. 11. Normal bronchial tree as outlined by

chial fistula is that hemorrhage, which may be severe, occurs from its opening occasionally. In most cases, however, the chief complaint of the patient is the inconvenience caused by wearing a dressing and the impossibility of immersing the fistula under water because of the danger of drowning by the direct entrance of water into the lungs through the external opening.

There is a tendency for all bronchial fistulas to become healed spontaneously. When successful, this occurs as a result of the circular contraction of the peribronchial tissue and of scar tissue around the opening of the fistula. If a large bronchial fistula becomes adherent to the skin it is less likely to become closed than if it is situated deeply. It is well not to hurry too much in the ordinary closure of bronchial fistulas because the great majority of them will close spontaneously if an opportunity for them to do so is given over a period of several months. If, however, a decision has been made to close a fistula by surgical methods, the operation should be preceded by an attempt to make an exact diagnosis of the condition of the fistula. One should attempt to find out particularly its size, its extent, and whether or not a foreign body is present within. All of this information can usually be obtained by injecting the sinus with lipiodol. Surgical closure of the fistula is based on the application of a variety of principles. In some cases, repeated cauterizations of the opening of the fistula are sufficient but usually not in the chronic cases in our experience. Another principle is to mobilize the lung from its attachments to the chest wall and to close the fistula with several rows of sutures after the mobilization has been effected. Such a procedure usually will permit the circular contraction of scar tissue, which is helpful in the closure. Another principle which is very effective is the transplantation of a vascular flap of muscle into the opening of the fistula. This latter procedure is especially helpful in cases in which the bronchial fistula leads into a pulmonary cavity of considerable size. In some cases, a partial resection of the lung will be necessary. The incidence of bronchial fistula, both as disease, such as lung abscess, and following surgical operations on the lung, has been greatly reduced since the introduction of antibiotics.

Bronchiectasis. Bronchiectasis is a chronic disease state characterized by dilatation of the bronchi and infection of the bronchial walls and surrounding peribronchial tissues. It may appear as a primary disease, or may develop secondarily distal to a chronic bronchial block, such as caused by a retained foreign body or stricture. The cause of primary bronchiectasis is not known. There is little evidence to support a congenital origin for the bronchial dilatations, although bronchiectasis occurs in a high percentage of patients with situs inversus. These individuals also usually have severe sinus disease (Kartagener's triad) (8). Most pathological studies indicate that primary bronchiectasis, like the secondary type, is probably the result of infection of the bronchial wall and surrounding lung. This infection causes a persistent lymphadenopathy and chronic bronchial compression which leads to distal pneumonitis and eventually to dilatation of the bronchi. These bronchi drain poorly and accumulate purulent secretions which, in turn, extend the infectious process, and a vicious cycle is set in motion. This theory is supported by good evidence. In almost all cases there is a preceding history of pulmonary infection. Frequently the disease develops after a severe bout of childhood pertussis or bacterial or virus pneumonitis. There is a definite relationship between sinus disease and bronchiectasis, and the distribution of the bronchial involvement principally to the lower lobes suggests that purulent secretions from the upper respiratory tract can "seed" the infection into the bronchi in the area of drainage.

The pathological changes seen in the lungs of patients suffering from bronchiectasis vary greatly, depending primarily on the amount of infection present. The bronchial dilatations are generally confined to the medium sized segmental bronchi and may be saccular (Fig. 13) or tubular in configuration, although most cases contain elements of both types. Purulent material, often foul, is retained in these pockets. The bronchial wall is thickened and irregular, and miscroscopic examination will show a chronic inflammatory response and even focal abscess formation. Each involved bronchus is surrounded by an area of chronically infected lung. A varying

Lung. If the stenosis is due to an inflammatory stricture, there will usually be an associated bronchiectasis which will require the sort of treatment discussed under that heading. If, on the other hand, it is due to the pressure of a mediastinal tumor upon the wall of the bronchus, appropriate treatment for the mediastinal tumor should be undertaken.

Bronchial Tumors. Most tumors arising in the bronchi are carcinomas, discussed under Tumors of the Lung. Benign tumors also occur in the bronchi, mostly polyps or adenomas, arising from the bronchial epithelium. There is much confusion about which should be regarded as benign, for many so-called benign adenomas are potentially malignant. Tumors of this type have rarely been completely removed through the bronchoscope by electrocoagulation and in other ways, and opinion is increasing that such limited removal is unsatisfactory. A lobectomy or a total pneumonectomy will give more assurance against a recurrence in cases in which malignant changes have occurred. A differentiation between a benign and a malignant tumor of the bronchus is not easy to make from a bronchoscopic biopsy.

Broncholithiasis (Lung Stones). This condition is by no means as infrequent as a survey of the literature would indicate. We have noted their appearance in approximately 2 per cent of our cases of chronic pulmonary suppuration. The expectorated stones usually have about the same relative proportion of calcium phosphate and calcium carbonate that is contained in bone. They are usually multiple, although occasionally they may be single. In one of our own cases, the patient coughed up 126 stones during a period of six months. They vary in size from merely granular particles to stones which may weigh several grams. They are irregular in outline. They are often found in individuals with healed pulmonary tuberculosis but they may also be present wtih a variety of other conditions, such, for example, as all forms of pulmonary suppuration, tumors, cysts, actinomycosis, and even with silicosis. It is possible that, in many cases, broncholiths are concrements which have ulcerated through into a bronchus or into the lung from calcified tracheobronchial and bronchopulmonary lymph nodes.

Associated with the stones usually are frequent and severe attacks of coughing, sometimes with pain in the chest. Following the expulsion of the stone there may be blood in the sputum which occasionally is sufficient to be classed as a severe hemorrhage. The bleeding is probably due to the trauma of the mucous membrane produced by the sharp stone. Sometimes, if they are of sufficient size, the stones may be seen in an x-ray film, but usually they cannot be distinguished from calcified areas in the neighboring lymphatic nodes. Ordinarily, the condition demands no special treatment. It is to be emphasized, however, that sometimes, because of the element of hemoptysis, such patients are wrongly diagnosed as having active tuberculosis. Occasionally, bronchoscopic removal of broncholiths is indicated.

Bronchial Fistula. Any abnormal communication between the bronchial tree and another surface or organ is termed a bronchial fistula. The most common site for such a fistula is between some part of the bronchial tree and the pleural cavity. Often, however, fistulas are noted in patients who have recovered from an operation for empyema or a lung abscess with the bronchial opening communicating directly with the skin. They naturally vary greatly in size depending upon whether they lead directly from a large bronchus or from some one of the finer divisions of the bronchus. They may be either acute or chronic. For the most part, the small ones heal spontaneously in a relatively short period of time. It is only the larger ones which tend to remain chronic. Bronchial fistulas occur with any form of inflammation of the lung in which there is destruction of tissue. They are, therefore, especially likely to be found in cases of pulmonary suppuration of various kinds and also in pulmonary tuberculosis. The bronchial fistula may secrete mucus or mucopus or the product of the organ with which it communicates, e.g., bile in a bronchobiliary fistula. The character and the amount of the secretion from a bronchial fistula are considerably altered by the condition of the upper respiratory tract. When the patient develops a coryza or an acute infection of a nasal sinus, the mucous membrane of the fistula becomes congested and the secretion is greatly increased.

One of the most serious features of a bron-

ish sediment which consists of pus cells, fat rests, Dittrich plugs, and detritus. The expectoration of blood is frequent, sometimes it amounts to only a streaking of sputum but at other times it may be a severe hemorrhage. Fever, sweats, and chills are common complaints. These occur intermittently and between such attacks the patient may feel reasonably well. They are probably due to repeated attacks of inflammation of the pulmonary parenchyma adjacent to the bronchiectasis. It is not uncommon for a patient with bronchiectasis to be required to go to bed with a bout of fever for a week or ten days at a time, at irregular intervals, two or three times a year. The introduction of antibiotics has done much to control secondary infection and lessen the quantity and purulence of the sputum in these patients.

The physical findings in bronchiectasis are suggestive but not specific. Patients with well-established disease are usually thin and pale. Mouth breathing and adenoid facies suggest concomitant sinus disease. The breath is unpleasant, and the cough loose and rattling. Moist rales and bronchi can usually be heard over the lower lobe areas. In severe cases, clubbing of the nails is present, and there may even be cyanosis.

All patients suspected of having bronchiectasis must have bronchoscopy and bronchograms to confirm the diagnosis. Bronchoscopy is needed to determine the presence or absence of a foreign body or a stenosis and gives an indication of the areas of involvement by the distribution of the pus. Studies on the aspirated material also will help rule out tuberculosis as the primary disease. Bronchography is always necessary to confirm the diagnosis and to establish the anatomic limits of the disease, a highly important point when surgery is contemplated.

TREATMENT. The treatment of bronchiectasis is both medical and surgical. Medical measures of great value are postural drainage, antibiotics, and control of sinus disease. The removal of secretions that have collected in the bronchiectatic pockets of the lower lungs is greatly facilitated by placing the head down for a few minutes several times a day and allowing the secretions to flow down hill where they may easily be coughed out. Antibiotics are used to control the purulence of the sputum and prevent secondary infections. They may be given intramuscularly and by aerosol spray. Severe sinus infections should be treated vigorously to abolish the postnasal drainage into the lungs. Occasionally, patients will be relieved of symptoms by a change to a warm, dry climate.

Although conservative measures are helpful, most cases with well-defined alterations in the bronchi will require surgery for relief of symptoms. The risk of bronchiectasis surgery today is practically nil, and complete relief or marked improvement can be expected in 75 to 80 per cent of the cases. The patients should have accurate mapping of the lungs by bronchography and a period of medical preparation by the measures mentioned above to reduce sputum production to a minimum before operation. Patients with extensive involvement on both sides are not surgical candidates. The principal areas which may require removal are the lower lobes on both sides, the lingular segment of the left, and the middle lobe on the right. Occasional patients with limited bilateral disease can be helped by staged bilateral operations.

DISEASES OF THE LUNG

Congenital Abnormalities. Various abnormalities of the lung have been described. Occasionally, an entire lung is absent (Fig. 14). More frequently, a condition has been described in which one lung has maintained its fetal state and has never expanded (hypoplasia). Rarely, a portion or an entire lobe will develop as a mass of small cystic structures which may or may not retain some bronchial communications. The blood supply to these areas is usually anomalous and frequently is a systemic artery coming directly from the aorta. This condition has been termed pulmonary sequestration. A similar but more diffuse condition is congenital cystic disease of the lung. The cysts are usually small but may reach large size and may be distributed extensively throughout both lungs. There is a high association of this abnormality with cystic changes in the pancreas, kidney, and liver. Again, there may or may not be bronchial communications with the cysts, but when there are, infection frequently develops. Some cases diagnosed as lung abscess in children are, in reality, infected cysts. Surgery is

Fig. 13. Above, extensive cystic bronchiectasis of left lung. This 41-year-old woman had a chronic cough all her life. Sputum production was great. She was treated by left pneumonectomy. Below right, shows section of lung, with bronchi enlarged to form cystlike cavities.

degree of distal atelectasis is usually present (9).

The chief complaints of the patient are cough, expectoration, foul breath, hemoptysis, and fever. The amount of sputum is variable, but it may exceed 1,000 ml. per day. It often has an odor due to putrefaction which is rather characteristic and which makes the patient with the disease often abhorrent to those with whom he is in contact. Characteristically, the sputum, when collected in a glass vessel, is seen to separate into three layers, the upper of which is nearly colorless or slightly greenish and contains air bubbles, pus, and mucus. The second layer contains many of the products of the first layer but has less air. The third layer contains a green-

Fig. 15. Pulmonary abscess caused by Friedländer's bacillus. This 54-year-old man developed fever and cough. Left, shows presenting film. Klebsiella organisms were recovered from sputum, and treatment with streptomycin and tetracycline instituted. Right, taken one month later shows almost complete clearing. The patient had no further difficulty.

6. Miscellaneous factors of various kinds may also produce abscess of the lung, such as actinomycosis and blastomycosis.

Many different kinds of bacteria have been found in cases of pulmonary abscess. Besides the ordinary pyogenic bacteria, it is common to find various types of spirochetes and fusiform bacilli. Anaerobic bacteria are also common. *Klebsiella pneumoniae* (Friedländer's bacillus) can cause necrosis and cavitation of large areas of lung without causing very much surrounding inflammatory response (Fig. 15).

The most common site of pulmonary abscess is in the right lower lobe. If a lung containing a true abscess is cut open, a distinct pyogenic membrane will be seen. There will be numerous bronchial openings; fibrin and pus will be contained within the cavity, the lining of which is usually not smooth and is gray or brown in color. The term "gangrene" is applied to a condition in which a whole lobe or a whole lung is found to have undergone liquefaction necrosis without any sharp line of demarcation between normal and diseased tissue, and with a greenish black or brownish black appearance of the diseased tissue. During the formative period of a pulmonary abscess there is an extensive zone of edema and some extravasation of blood around the area. When the abscess is well developed there is a central cavity of considerable size, sometimes small and at other times very large, the wall of which is composed of more or less necrotic epithelial tissue. In more advanced cases of longer duration, the wall of the abscess cavity may be several millimeters thick and composed of dense fibrous tissue. Usually several smaller abscesses are present in the zone surrounding the main abscess. Blood vessels are sometimes observed to cross through the cavity unsupported by epithelial tissue, giving the impression of ropes or cords which have been strung across. Sometimes they are thrombosed but when not they may give rise to the sudden massive hemorrhages which often complicate the condition of pulmonary abscess.

A common complication of pulmonary abscess is empyema from rupture of the abscess in the pleural cavity with the formation usually of pyopneumothorax because air also escapes into the pleural cavity. Brain abscess and meningitis, mediastinal abscess, and suppurative pericarditis are all complications which occur with some frequency. Hemorrhage is sometimes severe enough to be fatal. Extension of the infection to other parts of the lung is a frequent cause of death in such cases. Clubbing of the fingers and toes and amyloid degeneration are complications seen with chronic pulmonary abscess but seldom

Fig. 14. Agenesis of the lung. Congenital abscess of the left lung in a 16-year-old boy. He has no pulmonary symptoms. Medical help sought at an early age because of the external chest deformity. Note the marked shift of the heart to the left, and the stump of the left main bronchus.

necessary for cure in the more localized types of cystic disease. In the diffuse form, the patients usually do not survive.

Variations may occur in the location of the fissures and even in the number of lobes in each lung. Incomplete interlobar fissures are not uncommon. An azygos lobe may be formed by an abnormal course of the azygos vein through the substance of the right upper lobe rather than the usual mediastinal course. It occurs in slightly less than 1 per cent of the population. The need for recognition is primarily to avoid confusion with other conditions. Occasionally, an azygos lobe may be the seat of tuberculous or cancerous disease.

Variations in the pulmonary arterial and venous supply are very common. The tremendous upsurge in pulmonary resection in recent years has made necessary the accurate anatomic documentation of all possible variations. The studies of Kent and Blades (10), Boyden (11), and others have been most valuable in this regard.

Pulmonary Abscess. Pulmonary abscess may be defined as the gross destruction of lung tissue resulting from a parenchymal infection. The various etiologic factors may be grouped under six headings: 1. surgical operations; 2. aspiration of foreign material; 3. pneumonia; 4. wounds of the lung; 5. carcinoma of the bronchus, lung, and esophagus; 6. miscellaneous factors.

1. Of the surgical operations, those performed in the mouth are especially dangerous. Particularly is this the case with the operation of tonsillectomy performed under general anesthesia, although actually, as was shown by Moore, the chance of the development of a pulmonary abscess is only about one in 2,500 to 3,000 tonsillectomies. If the operation of tonsillectomy is performed under a deep general anesthesia, the chance of developing pulmonary abscess is greater probably because there is likely to be aspirated into the lung a larger amount of blood and pus than if the normal swallowing and coughing reflexes are preserved.

2. Again, it is well known that the aspiration of peanuts is likely to be followed by an extensive bronchitis, with the subsequent development of more or less extensive gangrene because of the irritating qualities of the fatty acids formed in the decomposition of the peanut.

3. Pneumonia is often stated as a frequent cause of pulmonary abscess. This statement is mainly due, however, to the fact that any inflammation of the lung in its early stages is likely to be diagnosed under the inclusive term of pneumonia. The term pneumonitis would be preferable. Actually, there is little evidence that ordinary lobar pneumonia is very often the precursor of pulmonary abscess. On the other hand, streptococcal pneumonia, especially that type which was present in the severe epidemics of 1917 and 1918, is often associated with pulmonary abscess.

4. Wounds of the lungs seldom produce an abscess.

5. Carcinoma of the bronchus is nearly always associated with single or multiple pulmonary abscesses at some time in its course. It is a matter of the greatest importance to bear in mind because a pulmonary abscess in a person of middle age, which has come on with no apparent reason, is often due to a carcinoma.

variety. The fever in the severe cases may reach 104° to 105° F. After drainage becomes established, either spontaneously or otherwise, the fever will diminish. In the presence of rapidly developing gangrene, the symptoms of prostration may be very marked. The sputum, although scanty in the formative period of the abscess, may later become profuse. In some cases more than 500 ml. of pus may be expectorated in 24 hours. The color is not characteristic, but it is not uncommon for the sputum to show streaks of blood and sometimes a considerable hemorrhage occurs. The presence of a foul odor is dependent upon active putrefaction.

It is desirable, of course, always to examine the sputum for tubercle bacilli and for other specific types of infection, such as actinomyces. The bronchoscope is of value in ruling out the presence of a foreign body or endobronchial tumor. It also helps to locate the abscess and moreover it sometimes facilitates the drainage of the tracheobronchial tree. For all of those reasons, a bronchoscopic examination should be recommended in every case of pulmonary abscess. The use of an aspirating needle in cases of suspected pulmonary abscess is dangerous because of the possibility of creating an empyema. It is always important to remember that the abscesses may be multiple and that consequently the localization of a single one does not necessarily complete the diagnosis.

The *treatment* of a case of pulmonary abscess will vary considerably according to the conditions which are present (12). Because of the effectiveness of the various chemotherapeutic and antibiotic agents now available, many more abscesses go on to resolution and/or spontaneous endobronchial evacuation and cure than formerly. The first consideration is the prompt administration of adequate doses of an antibiotic or antibiotics to which the infecting organisms are sensitive. Close x-ray scrutiny is kept on the status of the process and with the development of a fluid level the patient should be bronchoscoped. One is able in this manner to bring about improved endobronchial drainage with resultant improvement. Postural drainage, i.e., having the patient lie over the bedside with the head and chest dependent, will assist in the evacuation of pus. In the majority of cases, such a regimen will eventuate in either spontaneous resolution with healing and recovery or a "settling down" into a chronic state. The latter is characterized by a residual cavity or an area of infiltration which persists. In either event, the patient continues to cough and raise purulent sputum even though the systemic manifestations will have greatly abated. This status is generally reached from four to six weeks after onset and indicates that no further improvement may be anticipated from nonsurgical measures. Such patients are best treated by removing the involved lobe or portion of lobe (Fig. 17). An occasional case will require drainage because of age, debility or the rapid development of a cavity with marked evidences of sepsis.

Lung abscess remains a serious disease but with the skilful application of modern methods the mortality should not exceed 5 per cent.

Hydatid Disease (Echinococcus Cysts). Because of its rarity in this country, no extensive discussion of this condition will be given here. Echinococcus infections have

Fig. 17. Lung abscess treated by lobectomy. This 27-year-old man developed pneumonitis of left lower lobe, followed by increased production of purulent sputum. Left lower lobectomy was done after a period of medical treatment.

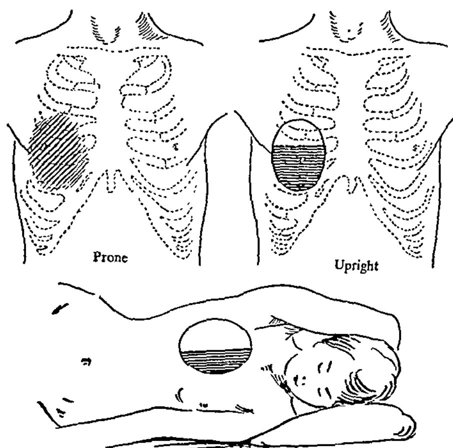

Fig. 16. Diagram to show the advantage of change in position in the demonstration of the fluid level in a suspected abscess cavity by the use of the roentgen ray. (From Graham, Singer and Ballon. Surgical Diseases of the Chest, Lea & Febiger.)

with the acute disease. In any case of chronic pulmonary abscess, more or less marked bronchiectasis is probably always present.

The principal *symptoms* of pulmonary abscess usually occur in the following order of frequency: productive cough with the sputum often blood stained, fetor, fever, chills, sweats, pain in the chest, and loss of strength and of appetite. The formative stage of pulmonary abscess usually has a duration of a few days to two or three weeks. There may be no sputum during that time. As soon as a communication with a bronchus is effected, foul expectoration occurs. In acute cases, the patient is sometimes able to indicate the site of the abscess by the location of the pain. Empyema may complicate the picture early in the disease. Mediastinal abscess and brain abscesses, however, are usually later complications. Clubbing of the fingers and toes is a complication of the chronic form of the disease.

In the examination of the patient, x-ray films are of paramount importance. Ordinary physical examination may reveal the presence of a large cavity but the accuracy of diagnosis is much greater with suitable x-ray examination. The most important finding in the x-ray examination is the presence of a fluid level within the lung field. In many cases, however, the fluid level cannot be demonstrated and in such cases only a region of induration will be detected. In searching for a fluid level it is of the greatest importance to have the patient in such positions as will demonstrate it. If the patient lies on the film either prone or supine, the level will almost certainly fail to be seen. It is necessary to have the patient either in a horizontal position with the diseased side uppermost, or in a sitting position (Fig. 16). Films taken in both of the two latter positions are preferable to a single one. There is usually a leukocytosis of approximately 20,000 with a relative increase in the polymorphonuclear

the responsible etiological factor, there is no very convincing evidence that any of them, except cigarette smoking, deserve much consideration. It is true that for many years a high incidence of the disease has been recognized in the Schneeberg miners whose work results in the production of large quantities of radioactive dust containing sharp-angled particles rich in arsenic. But this set of conditions involves only a small number of workers and cannot possibly have any bearing on the widespread increased incidence of bronchiogenic carcinoma. The same can be said of the more recently discovered high incidence of the disease in chromate workers (16).

There is much evidence, however, to indicate that excessive cigarette smoking may be a very important factor. Although some cigarettes were smoked in the last century, the extensive use of them began at about the time of World War I. The possibility of an etiological relationship has been suggested by many, especially Tylecote (1927), and Ochsner and De Bakey (17) but what was needed was at least a large scale statistical study of patients with lung cancer. Two such studies have now been made independently, one by Wynder and Graham (18), and the other by Doll and Hill (13) of England. Wynder and Graham's study was based on 684 proved cases, and that of Doll and Hill on 709 cases. Both were published in 1950. They came to the same conclusions, namely, that in practically all cases in men there is a history of excessive cigarette smoking over a period of more than 20 years and that it is very rare to find a case in a nonsmoker. Doll and Hill even state that above the age of 45 the chance of developing bronchiogenic carcinoma is approximately 50 times as great among those who smoke 25 or more cigarettes a day as among nonsmokers. Probably the carcinogenic agents reside in the tars in the cigarette smoke. The type of carcinoma chiefly related to smoking is the squamous (epidermoid) or an undifferentiated form.

The adenocarcinoma has characteristics which seem to make it a totally different tumor from the squamous variety, not only in respect to its microscopic appearance. From the statistical studies, it seems to have little or no relationship to cigarette smoking, and its incidence is about as great in females as in males. Presumably, therefore, the etiological factors for this carcinoma differ from those thought to be important in the development of squamous (epidermoid) carcinoma.

Metastases. Bronchiogenic carcinoma spreads, as does cancer elsewhere, into the neighboring lymphatics and may travel into both the mediastinal nodes and outward toward the periphery of the lung. The cartilages in the walls of the larger bronchi seem to offer the same amount of protection against the spread of the growth as does the cartilage in the larynx. There is, therefore, not an early extension through the wall of the bronchus unless the tumor arises in one of the smaller bronchi without cartilaginous walls. Tuttle and Womack (1934), in a study of the cases in the Barnes Hospital, showed that metastasis through the blood stream into distant organs occurs more often when the carcinoma arises in a smaller bronchus near the periphery of the lung than when it originates in one of the larger bronchi in the hilus region. Of particular importance in regard to the question of metastasis is the frequency of secondary deposits in the brain (about 25 per cent), in an adrenal (about 30 per cent), and in the kidney (about 25 per cent). Others have also noticed the curious frequency with which bronchiogenic carcinoma metastasizes to the adrenal glands. Sometimes the first notable symptom is due to a distant metastasis, as in the brain.

Symptoms and Diagnosis. There are no pathognomonic symptoms. When it is recalled that the tumor usually arises in a large bronchus, it will be realized that the early symptoms are those of bronchial irritation which results in cough and expectoration. As the cancer becomes ulcerated, blood will appear in the sputum. This is seen most commonly only as streaks. A large hemorrhage is rare. In most cases, as the tumor grows, the symptoms and signs of atelectasis of a lobe or a segment of a lobe appear because of bronchial obstruction. The patient then will have not only cough and sputum but a feeling of discomfort and tightness which may amount to actual pain in his chest. Sooner or later in almost all cases, infection will occur in the atelectatic portion of lung. To the other symptoms there will then be added those of

been discussed elsewhere in this book in more detail. From the standpoint of the thorax, it is important to realize that, next to the liver, the lung is the most frequent site of hydatid cysts but they are much less frequent than in the liver; for example, the condition occurs with a frequency to the liver about seven times greater than in the lung.

Many pulmonary hydatid cysts produce no striking *symptoms*, even if they may be very large. Cough is perhaps the most common symptom produced, but unless the cyst is ruptured into a bronchus, the cough is not severe. It is intermittent and accompanied by very little expectoration. If, however, a rupture into the bronchial tree has occurred, the contents of the cyst will be expectorated in the sputum. Frequently, there also will be hemoptysis of varying degrees. If the cyst is near the diaphragm, coughing is likely to be more pronounced even if it has not yet ruptured into a bronchus. The amount of dyspnea will be determined largely by the size of the cyst and the amount of pressure which it produces. The most common site of the cyst is in the right lower lobe. One of the principal dangers of rupture into the bronchial tree is that of severe allergy. This may be so severe as to cause death.

The *diagnosis* of pulmonary hydatid cyst is made on the finding of a spherical shadow by roentgen examination and by the principal laboratory methods of diagnosis which have been discussed elsewhere, such as 1. the intradermal test of Casoni; 2. the complement fixation test of Weinberg; 3. the examination of the blood for the presence of an eosinophilia; and 4. the examination of the contents of the cyst and of the sputum for the characteristic hooklets and fragments of cyst membrane. It is dangerous to aspirate a cyst because of the possibility of a severe allergic reaction from absorption by leakage into the lung or thoracic cavity.

The *treatment* of pulmonary hydatid disease is surgical excision wherever possible. This may be done by dissecting out the cyst itself or by removal of the diseased lobe. Care should be taken to avoid rupturing the cyst during removal because spillage of the contents can lead to anaphalactoid shock and death. Very large or tense cysts should be aspirated before removal.

TUMORS OF THE LUNG

Carcinoma. The most important tumor of the lung is carcinoma. Practically all, if not all, carcinomas arise in a bronchus. For that reason, primary carcinoma of the lung is usually called bronchiogenic carcinoma. Although some pathologists have classified this tumor into many varieties depending upon the morphologic appearances seen microscopically, the most common types are squamous or epidermoid, undifferentiated, and adenocarcinoma. The so-called round cell carcinoma can probably just as well be included in the undifferentiated group as to demand a separate classification.

Incidence. The incidence of bronchiogenic carcinoma has increased enormously in the last 40 years. Doll and Hill (13) found that in the 25 years between 1922 and 1947 in England and Wales the number of deaths ascribed to this condition increased fifteenfold. In the United States, there was an eightfold increase between 1914 and 1935. Cancer of the lung has increased so much during the past several years that it is now the second most common cancer in males, being surpassed only by cancer of the skin. In 1956, there were 31,000 cases (estimated) in the United States (14).

The condition is much more common in males. Various published statistics show its incidence to be from 10 to 20 times more frequent in males than in females. It occurs most *commonly in the sixth* decade of life. Most cases belong to the microscopic classification of squamous (epidermoid) or undifferentiated carcinoma. In our own series at the Barnes Hospital, 95 per cent are in those categories and adenocarcinoma comprises most of the remainder.

Etiology. The enormously greater incidence of bronchiogenic carcinoma in males suggests that perhaps the female sex has a relative immunity against it. But Kemler and Graham (15) found that human tumors from male patients could be transplanted with equal ease into the eyes of guinea pigs of both sexes, using Greene's technic. Evidently, therefore, female sex factors have nothing to do with the greater incidence in men.

Although the exposure to the influence of many different agents has been proposed as

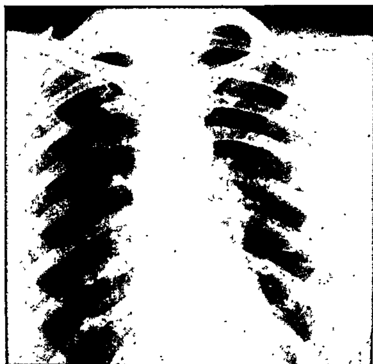

Fig. 18. (Cont.) X-ray variability of bronchogenic carcinoma. Above, superior sulcus tumor, right apex. This tumor involved the brachial plexus, causing shoulder pain. Below, cancer developing in the right middle lobe in a patient being treated for proven tuberculosis of right upper lobe.

Fig. 18. X-ray variability of bronchogenic carcinoma. Above, left hilar mass. This form is the most easily recognized on x-ray. Below, complete atelectasis of left lower lobe due to endobronchial cancer.

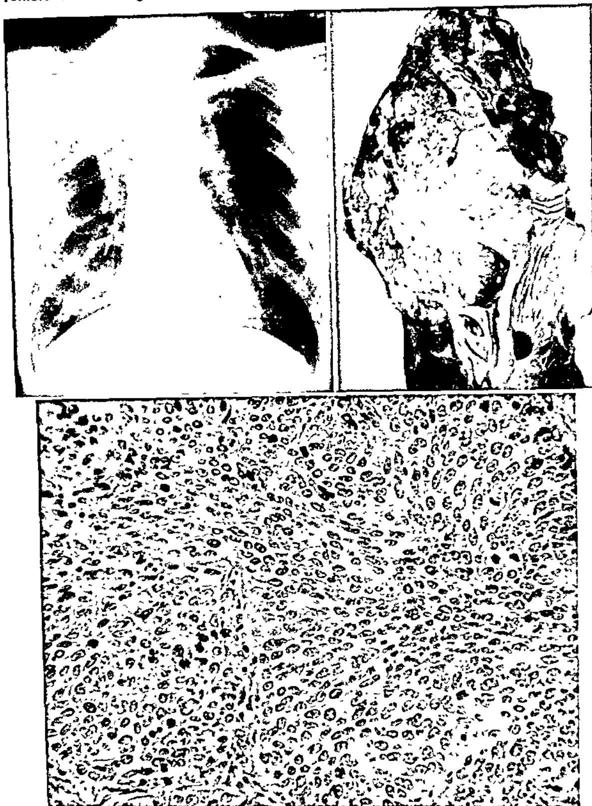

Fig. 19. Epidermoid carcinoma right upper lobe. This 55-year-old patient complained of cough and minimal weight loss. Because of the x-ray appearance, above left, tuberculosis was suspected. All diagnostic studies were negative. At operation a tumor of the right upper lobe was found which completely blocked the bronchus. Above right, shows the cut surface of the tumor. Below, a photomicrograph showing the histologic picture of a poorly differentiated epidermoid cancer.

pulmonary infection. Late occurrences are the involvement of nerves, such as the phrenic, the recurrent laryngeal, the brachial plexus, and the nerves of the chest wall. When the latter nerves are invaded by the cancer the pain is generally severe.

Ordinary x-ray examination (Fig. 18), although important, will usually reveal only an area of atelectasis and sometimes evidence of complications, such as pulmonary abscess and pleura effusion. In only a small percentage of cases does the x-ray examination reveal the tumor itself and then usually only one which is located peripherally. Bronchography with the injection of lipiodol is sometimes helpful in locating the bronchial obstruction. Bronchoscopy with biopsy of a suspicious lesion is the most important single diagnostic procedure, but it gives positive results in only slightly more than half the cases because many of the tumors are beyond the reach of the bronchoscope. The chance of a positive diagnosis can be increased to about 80 or 85 per cent by a combination of bronchoscopy and the cytological examination of bronchial washings and sputum by an expert. There will remain from 15 to 20 per cent of cases in which an exploratory operation will be required in order to establish the diagnosis.

Treatment. At present, the only successful treatment of bronchiogenic carcinoma is by surgical removal (Fig. 19). In general, the operation of choice is total pneumonectomy with wide removal of tracheobronchial lymph glands. However, some patients with poor respiratory reserve because of advanced age, emphysema, or poor cardiac function may be made "respiratory cripples" by the loss of a whole lung. In such cases, it is probably wiser to be less radical and to remove only the involved lobe. It is now possible by suitable tests of respiratory function to determine in advance whether or not the patient is likely to be badly crippled by the loss of a lung. The immediate operative mortality for pneumonectomy in cancer patients is now only about 5 or 6 per cent. The percentage of five-year survivals after the operation is encouraging but undoubtedly it will become much higher when patients come earlier to the surgeon. In a study completed in 1957 of 158 cases of total pneumonectomy performed at Barnes Hospital, 34 or 21.5 per cent have survived more than five years after surgery. The first patient to undergo successful pneumonectomy for carcinoma is alive and well 24 years after operation, despite the fact that two lymph nodes were invaded by cancer. The percentage of five-year survivals after pneumonectomy quoted above is similar to that obtained in other chest surgery clinics. Thus, for example, Overholt and Schmidt (19) had 24.4 per cent and Wiklund (20), in a recent report from Crafoord's clinic at Stockholm, stated that there were 25 per cent five-year survivals in their cases.

One of the most discouraging aspects of bronchiogenic carcinoma is the fact that, although the condition is curable by surgical removal, less than 50 per cent of the patients reach the thoracic surgeon at a time when there is any possibility of performing a radical resection. In our own cases a pneumonectomy has been carried out in only about 30 per cent of those in whom a positive diagnosis was established. The principal reason for the delay seems to be that physicians are too much inclined to make a diagnosis of atypical or virus pneumonia and to treat the patients with antibiotics. If the complicating infection is thereby improved, an unjustified optimism occurs and still more valuable time is lost in establishing the diagnosis of cancer.

Bronchial Adenoma. There is another bronchial tumor, much less common than the epidermoid bronchiogenic carcinoma, which usually arises in a major bronchus. It may have either a pedicle or a sessile attachment to the bronchial wall. Sometimes part of the tumor is intrabronchial and the rest extrabronchial with perhaps the largest portion outside the bronchus. These tumors are usually roughly spherical and on bronchoscopy they appear pink because of their vascularity. They may produce marked bronchial obstruction with resulting atelectasis, bleeding, and infection. They are found in both sexes about equally and at any age, even in childhood. A biopsy may reveal one of several more or less characteristic features, of which the most common is a collection of cells with small amounts of cytoplasm and relatively large nuclei. A section may closely resemble atelectatic fetal lung. Often the cells appear to be in cords and sometimes to have a glan-

SURGICAL ASPECTS OF PULMONARY TUBERCULOSIS

It is remarkable that so rational an idea as the employment of surgical measures for the treatment of pulmonary tuberculosis should have been so long in establishing itself. As far back as 1820, James Carson of Liverpool proposed the use of artificial pneumothorax. Apparently, however, the first actual use of artificial pneumothorax in this disease was made by Carlo Forlanini in 1888. Even then, the method did not become of general use until it was popularized in the early part of this century by Brauer. Today the combination of medical and surgical treatment is restoring more tuberculous patients to useful society than ever before.

Pulmonary tuberculosis is a disease characterized by the formation of cavities within the lung. Nature's process of obliteration of any cavity in the lung is by immobilization and more or less collapse of the affected side of the chest by drawing the ribs together, by pulling up the diaphragm, and by pulling the mediastinal contents over to the affected side. When these phenomena can occur to a satisfactory degree the cavity will often be spontaneously obliterated. There are many cases, however, in which nature's efforts fail because the structures to which the lung is attached by adhesions are sufficiently unyielding to prevent the spontaneous collapse of the cavity. In the preantibiotic era, the basis of all surgical methods used in the treatment of pulmonary tuberculosis was the theoretical assistance given to nature by overcoming some of the resistance to the spontaneous contraction of the lung. These methods, therefore, are commonly spoken of under the general term of *collapse procedures*. The simplest one is the creation of an artificial pneumothorax. Gradually, however, as the utility of that procedure became more and more realized, other procedures were devised for the purpose of promoting an adequate collapse of the lung. Thus, ribs were removed from the chest wall in order to make the wall more yielding and therefore more likely to be pulled in by subsequent contraction of scar tissue. Also, operations were devised, based on the principle of interrupting the phrenic nerve so that the diaphragm on one side would become paralyzed and ascend readily into the thorax, thereby assisting in the collapse of the lung.

Tuberculosis is a disease characterized not only by the frequent occurrence of cavities within the lung but also by the development of empyema. In the latter instance, of course, the condition is again one of cavity although the cavity is pleural instead of pulmonary. Many of the principles, therefore, of collapse and compression which are useful for the obliteration of pulmonary cavities are likewise useful for the treatment of tuberculosis empyema.

As experience with collapse methods of treatment became more extensive, it was realized that such methods were applicable not only to cases in which there were demonstrable pulmonary cavities but also that many patients improved after such methods of treatment even when demonstrable cavities were not present. Now it is well known that the immobilization and shrinkage of the lung produced by methods of collapse therapy diminish the toxic absorption from the active lesions in the lung by diminishing the circulation of lymph, and also produce a chronic passive hyperemia of the lung. These two factors result in limitation and demarcation of the affected areas of lung tissue and also in the proliferation of connective tissue. An exudative process is, therefore, converted into a productive one. Moreover, collapse therapy also facilitates and increases the amount of expectoration which is the natural method of drainage of the debris from the cavities within the lung.

Since the development of the specific antibiotics, such as streptomycin, for the medical control of tuberculosis, the use of collapse procedures has largely been replaced by excisional procedures, whereby the diseased tissue is not compressed, but is removed completely from the body. In patients who cannot withstand major extirpative surgery for some reason or other, the collapse procedures may be helpful.

Artificial Pneumothorax. Formerly this procedure was widely used and was one of the most valuable adjunctal methods of therapy. With the advent of streptomycin, para-amino salicylic acid, and pneumoperitoneum the

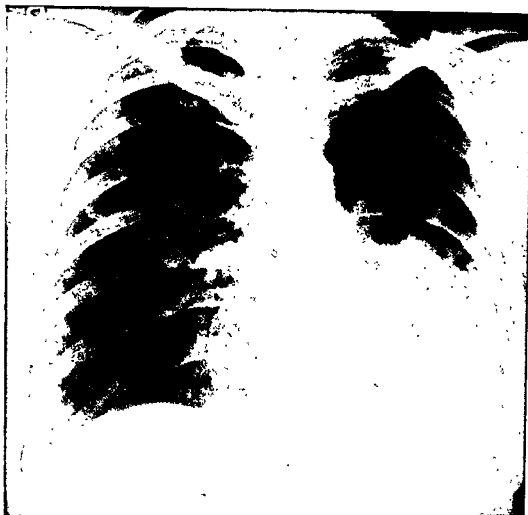

Fig. 20. Alveolar cell carcinoma. This 55-year-old woman complained of increasing dyspnea and the production of large amounts of clear sputum. The diagnosis was made by sputum cytology. Note the beginning involvement of the right upper lung by the process.

dular structure. The tumors often pursue a benign course for years, but Womack and Graham (1938) showed that many of them become malignant and produce regional and distant metastases. All of them, therefore, are to be regarded as potentially malignant. Often it is impossible to be sure from the microscopic appearance alone whether or not the tumor has become malignant, and mitotic figures are rarely seen.

The treatment of the so-called bronchial adenoma is surgical. While the tumor is still in a benign stage it can sometimes be handled by opening the bronchus, removing the growth, and closing the bronchus again. Usually, however, because of the presence of infection it is more advisable to perform a lobectomy. If, however, there is evidence of local invasion or involvement of regional lymph nodes pneumonectomy is to be preferred.

Alveolar Cell Carcinoma, Bronchiolar Carcinoma. The rare type of cancer of the lung, which is designated by one of these names, is distinguished from the common varieties by apparently arising in the pulmonary parenchyma instead of in a bronchus. It bears a close resemblance to the South African sheep disease known as "jagziekte." Also, there are many similarities to the cancer of the lung which occurs in mice. The prognosis is very bad in spite of radical surgery. Reports of cases will be found in articles by Delarue and Graham (21), Stephens and Shipman (22), and by Storey (23) (Fig. 20).

Fig. 22. Pulmonary resection for tuberculosis. This 36-year-old man had been treated for fibrocavitary tuberculosis of the left upper lobe for three years. Treatment included antituberculous drugs, left pneumothorax, and left phrenic nerve crush. Sputum was still positive at the time of left upper lobectomy. Left, shows lesion prior to surgery. Right, film one and one-half years after operation. Patient is sputum negative and clinically well.

performed. In those cases with unilateral multilobar cavitary disease or in those cases where stenosis of the main stem bronchus exists, it will be necessary to do a total pneumonectomy. Giant cavities which are notoriously hard to collapse by thoracoplasty are best treated by lobectomy (Fig. 22). Lesser degrees of involvement will be amenable to so-called segmental resections. One of the most common indications for pulmonary resection in tuberculosis is in that group which is loosely called "thoracoplasty failures." These are cases in which an apparently adequate thoracoplasty has failed to produce cavity closure and sputum conversion. Such cases are subjected to the removal of the lobe or the lung as required by the pathology (25). Tuberculomas are removed either by a simple "wedge" resection or by a segmental resection.

The results of excisional surgery are now sufficiently extensive and the follow-up of cases long enough to state unequivocally that resection in tuberculosis far surpasses any type of collapse therapy. Surgical removal of the diseased tissue allows earlier return to activity and a lower relapse rate. In properly selected operative cases, it is possible to achieve arrest of the disease in 85 to 90 per cent of the patients.

number of pneumothoraces has declined markedly.

Plombage. This procedure consists in the direct application of pressure exerted on the parietal pleura against a cavity in order to assist in its obliteration. Materials that have been used for this purpose are gauze packs, inflatable rubber bags, paraffin, lucite balls, and polyvinyl sponge. The chief dangers in the placement of any type of foreign material near tuberculous lung tissue are infection and migration of the plombe. The best results reported to date have been with the extraperiosteal placement of lucite spheres. It is probable that all types of plombage procedures will be discarded in favor of excision.

Extrapleural Thoracoplasty. The modern present-day operation of thoracoplasty has gone through a period of evolution, starting with operations for the collapse of cavities by the removal of ribs. Because of the extensive accumulation of experience with this operation, it is now possible to state rather dogmatically that the operation is not usually effective unless considerable portions of the upper ribs are removed. The modern operation is entirely extrapleural. It is divided into stages separated by intervals usually of at least two or three weeks and it is carried out through a posterior incision. One of the essential requisites that has been learned is that to be effective in collapsing the upper part of the lung, it is necessary that there should be a dropping downwards of the pulmonary apex. This cannot be expected to occur unless large segments amounting usually to practically the entire lengths of the first and second ribs are removed. If such an operation is performed, ordinarily it is not so necessary that very long segments of the lower ribs be removed, although it is customary in a case of complete unilateral thoracoplasty to remove the lower ribs from the corresponding transverse processes to at least the posterior axillary line and often to the anterior axillary line. It is customary also, in most cases, to begin the operation with the removal of the first two or first three ribs. This constitutes the first stage. Two or three weeks later, three or four more ribs are removed; and two or three weeks after that, the remaining ribs including the tenth and sometimes even a portion of the eleventh ribs are removed (Fig. 21). In other cases in which the tuberculosis is limited to the upper part of the lung, a total thoracoplasty is much less commonly performed than formerly because it is recognized now that removal of the upper three or five ribs is often sufficient to accomplish the desired result. This procedure leaves the function of the lower part of the lung relatively uninterrupted. Thoracoplasty is indicated less and less, and in the author's opinion will soon be a rarely used procedure.

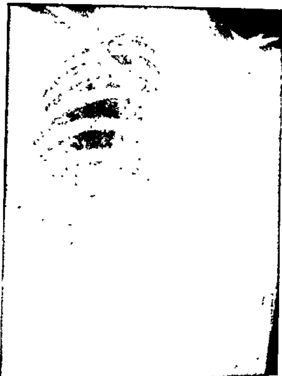

Fig. 21. Extrapleural thoracoplasty. This 19-year-old woman had a seven-rib, three-stage thoracoplasty on the left side for extensive cavitary disease of the left upper lobe. She remained well for five years but subsequently became sputum positive again, and required a left pneumonectomy before her disease was permanently controlled.

Pulmonary Resection in Tuberculosis. As mentioned previously, the tendency in general now is to do a total extirpation of the pulmonary disease whenever possible (24). The development of more refined technics and the protection afforded by the antibiotics, particularly streptomycin, has made possible the extirpation of infected pulmonary areas without either local or general dissemination of the disease. The extent of the disease will, of course, determine the type of resection to be

SURGERY OF CONGENITAL CARDIOVASCULAR DISEASE

Michael E. De Bakey, Denton A. Cooley,
George C. Morris, Jr., and E. Stanley Crawford*

INTRODUCTION TO SURGERY OF CARDIOVASCULAR DISEASE

Few areas in medicine have exhibited the phenomenal progress that has taken place in the field of cardiovascular surgery during the past few decades. Indeed, the advancements made during the past decade alone far surpass all previous efforts in this field of surgery. A number of recent developments in cardiovascular surgery constitute truly brilliant achievements reflecting vigorous effort and intensive investigation. One of the most striking features of this advancement, and undoubtedly an important factor underlying its attainment, has been the bold ingenuity and aggressive approach characterizing the surgical attack on certain cardiovascular problems, the gravity of which has long been recognized. Lesions which only a few years ago were considered hopeless are now amenable to curative surgical treatment. Of equal, if not of greater, significance is the fact that these intensive investigative endeavors have led to additional knowledge and better understanding of the underlying anatomic and physiologic disturbances of these diseases.

In the main, surgical treatment in cardiovascular disease is directed toward correction of the defect by mechanical means. This may be accomplished by one of several approaches, the choice depending upon the nature of the lesion. In some instances, for example, it is possible to remove the lesion with elimination of both anatomic and physiologic disturbances. This is exemplified by the procedures of division and suture of a patent ductus arteriosus, excision with end-to-end anastomosis of coarctation of the aorta, and resection with graft replacement of aneurysm of the aorta. In other instances, a more indirect approach must be employed, in which the

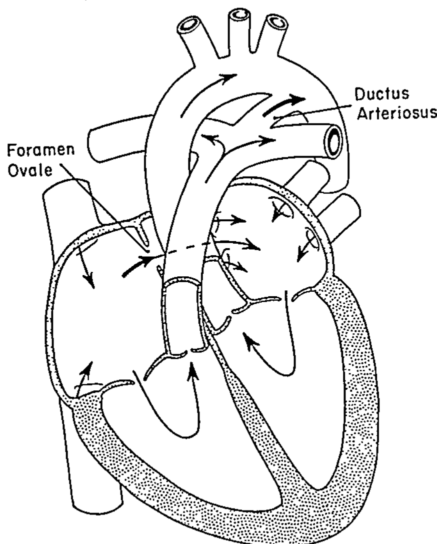

Fig. 1. Drawing of fetal circulation showing usual course of blood flow. Placental blood is shunted away from pulmonary circulation through the foramen ovale and the ductus arteriosus, both of which normally close after birth.

artery persists as the ductus arteriosus. Both the fourth and the sixth arches originate from the aortic sac, which connects with the bulbus cordis. Development of an aortic septum divides the common trunk into aorta and pulmonary artery. Ultimate fusion of this septum centrally with the advancing interventricular septum leads to final closure of the ventricular septum and separation of the heart into right and left sides.

Upon completion of development of the fetal heart, the circulation follows a definite pattern. Since oxygenation of fetal blood is provided by the maternal placenta, the fetal lungs are functionless until birth, when respirations commence and the lungs are inflated. Placental blood returning to the right side of the heart may bypass the pulmonary circulation through the foramen ovale or the ductus arteriosus Botalli (Fig. 1). Persistence of these structures, although not representing true cardiac anomalies, may lead to physiologic disturbance in the heart if spontaneous obliteration does not occur. Closure of the ductus arteriosus begins immediately after birth and the process is usually complete by the end of the second month. A patent foramen ovale is present at birth but is guarded by a valvelike arrangement of membranes, which permits blood to flow from the higher pressure right atrium to the left atrium. After birth, as this pressure relation-

operative procedure is designed to provide beneficial alteration of physiologic disturbances produced by the lesion. This is exemplified by the Blalock-Taussig operation for tetralogy of Fallot and the bypass grafting procedure for certain types of thrombo-obliterative disease of the aorta.

Although truly impressive progress has been made in this field of cardiovascular surgery, there still remains a host of diseases for which no satisfactory method of surgical treatment is yet available. The vigor and intense activity characterizing the investigative attack upon these conditions are highly gratifying and portend further advancement in this area of endeavor. It is manifestly impossible to discuss all phases of the subject, and primary consideration must be given to the more significant accomplishments and trends of development. For purposes of convenience the diseases included in this presentation have been classified into two broad categories according to their origin: congenital (Ch. 37), or acquired (Ch. 38).

Congenital malformations of the heart occur in many forms, either as a single anomaly or as a combination of anomalies. Since the basic and most important embryologic phenomena which ultimately lead to development of the heart and great vessels occur during the first six weeks in the intrauterine life of the embryo, many malformations are present long before birth. Such anomalies may be considered true cardiac malformations and thus represent a true developmental defect. On the other hand, certain normal structures in the embryonic heart which provide for the requirements of intrauterine life and the dependency upon placental circulation may persist after birth, such as a persistent patency of the ductus Botalli or foramen ovale (Fig. 1). Although these may lead to physiologic disturbance in extrauterine life and may not be actual congenital cardiovascular malformations, nevertheless, such anomalies must be considered along with the true congenital anomalies.

Accurate understanding of the morphologic anatomy and physiopathologic aspects of congenital malformations of the heart must be derived from a basic knowledge of embryologic and fetal circulation. By the third week of embryonic life the primitive cardiac tube has appeared near the cephalic end of the embryo. Growth of the tube occurs rapidly, producing convolutions and bulbous segments, one known as the bulboventricular loop and another a dilated segment which forms a common atrium from the left and right sinus venosus. The atrium lies above and behind the ventricles and is connected by a common atrioventricular canal. The anlage of the separate cardiac chambers is discernible by the fourth week. A muscular ridge appears in the floor of the bulboventricular canal and progressively extends centrally to form the muscular portion of the ventricular septum. By the fifth week, great progress in cardiac differentiation has occurred and the interatrial septum has been formed. During the next week, the primitive opening (ostium primum) at the inferior margin of the septum closes and the secondary opening (ostium secundum) appears and forms the foramen ovale. By the sixth week, the endocardial cushions developing in the region of the atrioventricular junction and converging centrally start the obliteration of the atrioventricular canal and also form the anlage of the mitral and tricuspid valves. The cushions meet the advancing muscular interventricular septum and fuse finally at a point which ultimately is known as the membranous portion of the interventricular septum. The endocardial cushions also fuse with the primitive interatrial septum and contribute to obliteration of the ostium primum. This completes the division of the heart into four chambers.

Simultaneous with the intracardiac development is rapid development of the vascular connections to the remainder of the embryo. The principal arterial connections of the heart are derived from a complex of primitive aortic arches, six in number. As the heart develops and moves caudally in the embryo, the aortic arch is derived from the fourth branchial arch and the pulmonary artery from the sixth (Fig. 2). Normally the sixth left branchial arch distal to the pulmonary

chambers, although the congestive effects are usually less rapid because of the compensatory forces which maintain cardiac function and delay onset of cardiac decompensation.

Method of Diagnosis. In diagnosis of congenital malformations of the heart, an accurate history is of utmost importance. Exact definition of the mode of onset of symptoms, date of appearance of symptoms, such as cyanosis and exertional dyspnea, and careful description of the disabling effects are often of vast importance in arriving at the final diagnosis. Careful physical examination, noting the presence of cyanosis, clubbing of the nails, location and nature of murmurs, and presence and character of pulses in all extremities, and so forth, is imperative in such cases. Laboratory studies including complete hemogram are useful, particularly since polycythemia accompanies most lesions associated with cyanosis.

Special diagnostic procedures of great importance have been developed in diagnosis of congenital cardiac defects; these include (a) roentgenography and fluoroscopy, (b) electrocardiography, (c) cardiac catheterization, and (d) angiocardiography and aortography.

ROENTGENOGRAPHY AND FLUOROSCOPY. Typical configurations of the cardiac silhouette by radiographic technic are useful in the diagnosis of congenital lesions of the heart and the great vessels. In the anteroposterior projection and in the right and left oblique and lateral views, specific enlargement of cardiac chambers and vessels may be evident. Fluoroscopy may be even more valuable than roentgenography since artifacts due due to poor position of the patient and other causes may be eliminated. Abnormal pulsations in the pulmonary vessels and changes in cardiac contour during systole and diastole may aid in identifying the defect. Diagnosis may be facilitated by filling the esophagus with radiopaque substance, such as iodized oil or barium paste, and demonstrating the encroachments of the cardiovascular structures on the esophagus. Typical abnormalities may be demonstrated by this means, including a right aortic arch, aortic arch anomalies, and various conditions producing left atrial enlargement. Erosion of ribs by dilated, tortuous intercostal arteries is a characteristic finding in coarctation of the aorta.

ELECTROCARDIOGRAPHY. The usefulness of electrocardiography in diagnosis of congenital cardiac defects has increased enormously in the past few years and some anomalies may be identified by this means alone. Complete electrocardiographic studies must include precordial and unipolar limb leads. Ventricular and atrial hypertrophy may be demonstrated and the degree of cardiac strain assayed. Condition disturbances and findings concerned with cardiac rhythm may be detected and may lead to an ultimate precise diagnosis. Usually interpretation of the finer points in electrocardiography must be made by a cardiologist thoroughly familiar with congenital cardiovascular disease.

CARDIAC CATHETERIZATION. Perhaps the most important recently developed specialized diagnostic procedure in cardiac diagnosis is catheterization of the heart (Fig. 3). Right heart catheterization is performed by inserting special woven catheters of small diameter into a peripheral vein, usually the left antecubital, and threading the catheter centrally into the heart. In infants, the catheter must be inserted through an external jugular or saphenous vein in the groin. General anesthesia with Trilene or another volatile agent is usually required for catheterization in infants and small children to provide relaxation and cooperation of the patient, but in large children and young adults deep sedation only is necessary. Under general anesthesia it is possible, in children, to demonstrate physiologic changes in cardiac dynamics during inhalation of room air or oxygen. During catheterization the position of the catheter tip is checked repeatedly with the fluoroscopic screen. Recently the use of the electrode tip catheter connected to the electrocardiograph has been useful in following the course of the catheter. Left-to-right shunts are identified and localized by detecting the presence of oxygenated blood in the right heart. Oxygen content of separate blood samples may be used for this purpose, but the Van Slyke technic is slow and complicated and is being replaced by more practical

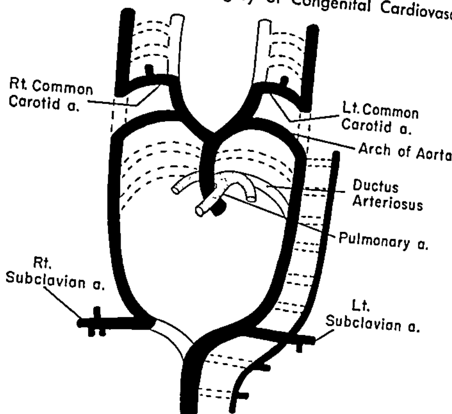

Fig. 2. Diagram showing developmental origin of the aorta, the major branches of the aortic arch, and the ductus arteriosus.

ship is changed, the valvelike foramen becomes obliterated or functionally closed. In about 10 per cent of individuals, a probe patency of the foramen ovale remains throughout life but is of no physiologic significance.

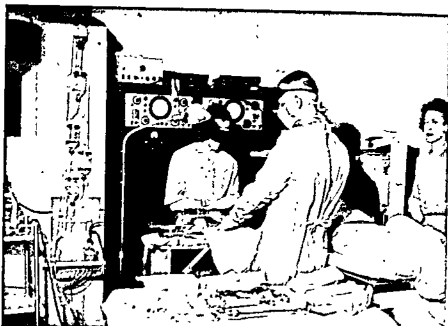
Physiologic Considerations. Congenital defects of the heart may produce a number of physiologic disturbances depending upon the nature of the lesion. For example, defects of the cardiac septa produce abnormal intracardiac shunts with blood shifting from a high-pressure to a low-pressure chamber. Shunts may be directed either from left to right or from right to left. Since pressures in the chambers of the left side of the heart are normally higher than in the corresponding chambers on the right side, an uncomplicated interatrial or interventricular septal defect leads to a so-called "left-to-right" shunt. Thus, blood of abnormally high oxygen content may be present in the right auricle, ventricle, or pulmonary artery. Defects with left-to-right shunts are not associated with cyanosis. If in addition to the septal defect another intracardiac anomaly exists, such as an obstructed tricuspid or pulmonary valve or underdeveloped right ventricle, the pressure in the chambers of the right side of the heart may be greater than the pressure in the corresponding chamber on the left, and a right-to-left shunt results. Under these circumstances, blood of low oxygen content is directed into the left atrium or ventricle, and when the blood gains access to the aorta and systemic arterial circulation, cyanosis results.

In another group of cardiac and great vessel anomalies, no vascular shunts exist and these lesions usually are manifested by the pressure effects and increased workload imposed upon the cardiac chambers. For example, valvular stenosis or atresia produces an obstruction to blood flow and increases the pressure and strain upon the chamber immediately proximal to the lesion. As the obstruction and intracavitary pressure increase, the effects may be transmitted to the lungs or liver, where congestion and edema may result. Underdevelopment of a cardiac chamber may lead to similar physiologic disturbance. Congenital valvular incompetence also increases the workload on the cardiac

and further useful diagnostic data are made available. Interpretation of the results of cardiac catheterization is sometimes difficult, and ultimate diagnosis may depend upon surgical exploration. Unquestionably these methods will be further developed and in the future other modifications in technics of cardiac catheterization will be introduced to improve diagnostic accuracy.

ANGIOCARDIOGRAPHY. Rapid injection of a radiopaque substance, usually an organic iodide solution, into the circulatory system provides a roentgenographic means of visualizing the chambers of the heart and great vessels (Fig. 4). A quantity, 1.0 ml. per kg. body weight of 70 per cent organic iodide solution (Urokon, Diodrast) is injected rapidly into a peripheral vein, using a large syringe either manually or mechanically operated. A special film changing device is used to expose films in rapid succession (usually six exposures per second is the maximum requirement) in order to follow the course of the solution throughout the heart, lungs, and aorta.

AORTOGRAPHY. Another technic of diagnostic importance in infants less than one year of age is retrograde aortography. In this technic, a small cannula is inserted in the left brachial artery and 5 to 15 ml. of 30 per cent iodized solution is injected (Fig. 5). The entire aortic arch may be visualized, and differential diagnosis of patent ductus arteriosus, truncus arteriosus, coarctation of the aorta, and other defects may be established. This technic is important in many instances, therefore, in excluding extracardiac lesions in the severely ill infant and providing information supporting the need for complete cardiac catheterization in establishing a diagnosis.



Classification. A number of classifications have been used for consideration of congenital cardiovascular defects. For the most part, these have been based primarily upon the presence or absence of cyanosis. With the growing emphasis placed upon physiologic and hemodynamic factors in congenital defects, a more useful classification would be based upon these vital factors. Thus, the following classification of the more common congenital cardiovascular defects is proposed:

I. Malformations not associated with a shunt
   A. Malformations of left side of heart
      1. Distal to mitral valve
         a. Coarctation of aorta
         b. Aortic vascular ring
         c. Aortic stenosis
         d. Endocardial fibroelastosis of left ventricle
         e. Anomalous origin of left coronary artery from pulmonary artery
      2. Proximal to mitral valve
         a. Congenital mitral stenosis
         b. Cor triatriatum
         c. Stenosis of pulmonary veins
   B. Malformations of right side of heart*
      1. Valvular or infundibular pulmonic stenosis
      2. Ebstein's malformation of tricuspid valve
      3. Underdevelopment of right ventricle
II. Malformations with a circulatory shunt
   A. Malformations with left-to-right shunt
      1. Atrial septal defect
      2. Ventricular septal defect
      3. Patent ductus arteriosus
      4. Aorticopulmonary septal defect
      5. Partial anomalous pulmonary venous drainage into right atrium
   B. Malformations with right-to-left shunt
      1. Transposition of great vessels
      2. Eisenmenger complex
      3. Tricuspid atresia
      4. Tetralogy of Fallot
      5. Pulmonary arteriovenous fistula
      6. Anomalous drainage of systemic vein into left atrium
   C. Malformations with combined shunts, predominantly left-to-right†
      1. True truncus arteriosus
      2. Single ventricle with increased pulmonary flow
      3. Total anomalous drainage of pulmonary veins into right atrium

The rapid and spectacular development of cardiovascular surgery has produced a significant effect upon the study of congenital heart disease. Lesions which just a few years ago were only of academic interest or considered to be rare medical curiosities now assume great importance. The incidence of many lesions now far surpasses previous estimates made during the presurgical era. Thus, it is important also to classify congenital defects on the basis of amenability to surgical repair or symptomatic relief.

* Right-to-left shunt may occur if foramen ovale is patent.

† Malformations with left-to-right shunt (Group A may with congestive heart failure manifest arterial unsaturation due to unsaturation of pulmonary venous blood and manifest a combined shunt).

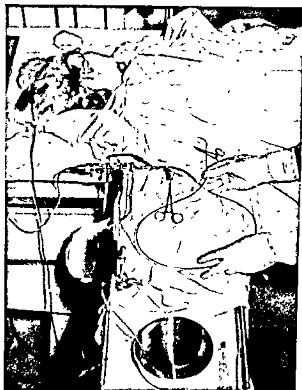


Fig. 3. Photographs of cardiac catheterization laboratory showing: above, the fluoroscopy table and electronic recording equipment used in catheterization, and, below left, patient on table with oximeter ear piece in place for estimation of peripheral arterial oxygen saturation. Cardiac catheter attached to strain gauge manometer and Couvette oximeter is ready for insertion in antecubital vein.

methods. The Couvette oximeter is extremely valuable for determination of oxygen saturations since a continuous recording of saturation may be obtained during gradual withdrawal of the catheter from pulmonary artery to vena cava. Thus, the point of the shunt may be determined with a high degree of accuracy.

Pressure measurements and continuous pressure tracings are important in recognizing valvular or infundibular subvalvular stenoses and in demonstrating valvular incompetence. Recent development of technics of left heart catheterization either by direct left atrial puncture or by left ventricular puncture has increased the accuracy in localizing right-to-left shunts by detection of blood of low oxygen saturation on the left side of the heart. Such technics are valuable in demonstrating the effects of congenital aortic or mitral stenosis but are not without potential danger of complications from intrapericardial hemorrhage.

The dye dilution curve is another technic being used in well-equipped diagnostic centers in demonstrating both left-to-right and right-to-left shunts by right heart catheterization. A small volume of Evans blue dye is injected into the chambers of the right heart and a recording is made of the appearance curve of the dye in the peripheral arterial system usually by ear lobe oximetry. Typical appearance curves may be recognized for right-to-left as opposed to left-to-right shunts

Expected Results of Surgical Treatment.

A. Lesions in which surgical methods are recom mended
   1. Good or excellent results
      a. Coarctation of the aorta
      b. Aortic vascular ring
      c. Aortic and subaortic stenosis
      d. Pulmonic valvular or infundibular stenosis
      e. Tetralogy of Fallot
      f. Tricuspid atresia
      g. Pulmonary arteriovenous fistula
      h. Ventricular septal defect
      i. Atrial septal defect
      j. Patent ductus arteriosus
      k. Anomalous drainage of pulmonary veins
      l. Sinus of Valsalva fistula
      m. Aorticopulmonary septal defect
      n. Cor triatriatum
   2. Fair or poor results
      a. Ebstein's disease
      b. Complete transposition of great vessels

B. Lesions in which surgery is not feasible
   a. Eisenmenger complex
   b. Truncus arteriosus
   c. Endocardial fibroelastosis

COARCTATION OF THE AORTA

Coarctation of the aorta is a congenital disease characterized by significant narrowing or complete obstruction of the aortic lumen usually involving the distal segment of the aortic arch but occasionally occurring in the descending thoracic or even the abdominal aorta. Its incidence according to postmortem studies is about 1:1,000 with reported figures ranging from 0.08 to 0.14 per cent. The etiology of the disease remains obscure, although various theories have been proposed to explain its development. Perhaps the most popular of these is the skodiac theory of Craig, which assumes extension of fibrosis into the aorta from faulty ductal closure. Other theories are based on faulty embryonic formation of the arch and "relative stagnation" of aortic arch blood flow during the period of fetal circulation. None of these theories, however, has proved entirely acceptable.

Because of the wide variations in the anatomic forms of coarctation that may be encountered, a number of different classifications have been proposed. Of these the most commonly used is that of Bonnet, who distinguished two types, the "infantile" and the "adult." In the former, the coarcted area lies proximal to the ductus arteriosus with a more diffuse constriction that may involve the aortic isthmus. In the latter, the coarctation lies immediately adjacent or distal to the insertion of the ductus and tends to be well localized. Although a number of other classifications have been proposed, the most satisfactory, according to clinical and surgical considerations, is that which is based upon two significant criteria: (1) the relation of the coarctation to the ductus arteriosus, i.e., preductile or postductile, and (2) the question of whether the ductus arteriosus is patent (Fig. 6). Coarctation of the aorta is associated with a patent ductus arteriosus in about 10 per cent of cases. In such instances, if the ductus is located proximal to

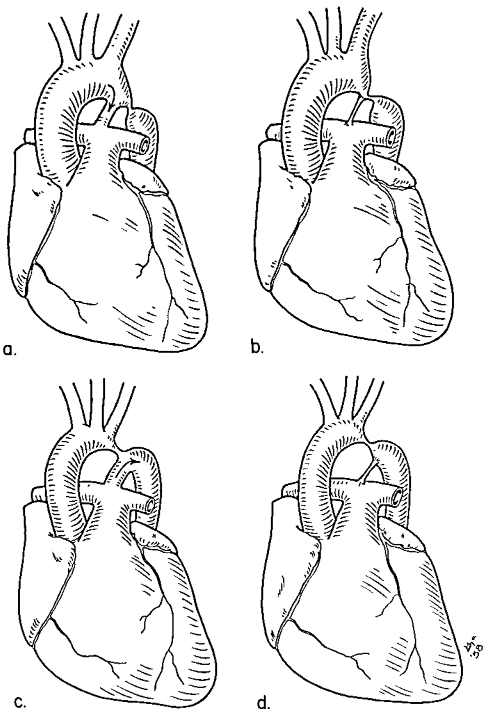

Fig. 6. Diagrammatic drawings illustrating classification of coarctation of aorta according to relation with the ductus arteriosus. Thus, the coarctation is postductile in a and b and preductile in c and d, and the ductus arteriosus is patent in a and c and closed in b and d.

the coarctation, blood flow is from the aorta to the pulmonary artery and a well-developed collateral circulation must exist at birth to sustain life (Fig. 6a). If the patent ductus is located distal to the coarctation, the direction of blood flow through the ductus is dependent upon the presence or absence of collateral circulation. In the presence of a poorly developed collateral system, blood flows from the pulmonary artery into the distal

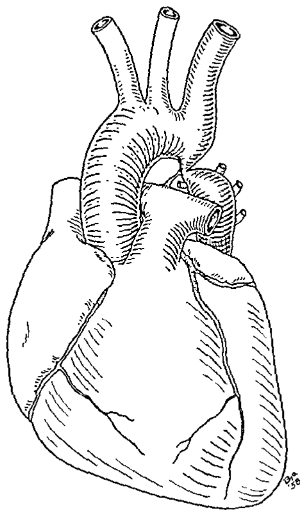

Fig. 7. Drawing illustrating the most commonly encountered clinical form of coarctation of the aorta.

aorta producing cyanosis in the lower half of the body (Fig. 6c). With a well-developed collateral system, blood flows from the aorta into the pulmonary artery.

In most cases encountered clinically, the coarctation is located close to and usually just distal to the aortic insertion of the ligamentum arteriosum (Fig. 7). Occasionally, however, the areas of narrowing may lie more proximally to involve the segment between the left common carotid and the left subclavian arteries. More rarely it may be located in the distal portion of the descending thoracic aorta and may even extend down to involve the upper segment of the abdominal aorta. Although in most cases the coarcted segment is fairly well localized and relatively short, in some the zone of narrowing may extend for a distance of several centimeters (Figs. 8, 9). Proximal to the point of greatest narrowing, the diameter of the aorta tapers gradually towards the stricture and then distally tends to dilate. In some cases this dilatation may assume actual aneurysmal formation. Although there may be complete obstruction of the lumen at the site of greatest narrowing, in most cases an opening measuring a few millimeters in diameter is present. Histologically, the structural changes in the aortic wall are most notable in the coarcted segment and are characterized proximally by medial thickening which tends to project into the lumen and by a fibrous and collagenous intimal proliferation which tends to be indurated and inflexible and poorly attached to the underlying media (Fig. 10). Occasionally, and particularly in older individuals, atheromatous plaques with or without calcification may be present. In the segment of aorta just distal to the stricture, the aortic wall may show focal changes to which the term "jet lesion" has been applied on the basis that they presumably result from the traumatic effects of the jetlike stream flowing through the narrowed lumen. This lesion is characterized by localized fibrous intimal thickening producing a corrugated appearance to the intimal surface with distortion and thinning of the media.

Other congenital anomalies involving the cardiovascular system are associated with coarctation in a significant proportion of cases. The relative incidence of these lesions varies with the type of cases from which the studies are made. Thus, in autopsy material and in patients dying within the first year of life, the incidence and severity of these lesions are high. Among patients surviving to adulthood, patent ductus arteriosus is one of the most common lesions encountered, occurring in about 15 per cent. Another relatively common associated anomaly is aortic valve deformity, particularly bicuspid valve with or without insufficiency or stenosis. Other less common anomalies include interventricular or interatrial septal defects, mitral valve deformity, pulmonary stenosis, and subendocardial fibroelastosis.

The development of collateral circulation in coarctation of the aorta has both physiologic and clinical significance since, from the former standpoint, it is the means by which

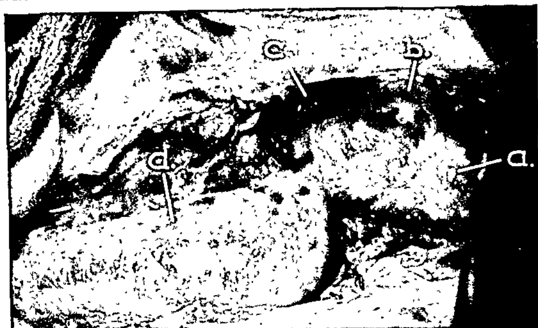

Fig. 8. Photograph made at operation showing characteristic gross appearance of usually encountered clinical form of coarctation; a, dilated left subclavian artery; b, aortic arch; c, ligated stump of obliterated ductus arteriosus; and d, descending thoracic aorta.

Fig. 9. Photograph made at operation showing somewhat elongated coarcted segment; a, left subclavian artery; b, transverse arch of aorta; c, ligated stump of obliterated ductus arteriosus; and d, descending thoracic aorta.

Fig. 10. obstruction to aortic circulation is overcome and, from the latter, it is of diagnostic value. The major source for these anastomotic channels is derived from the branches of the subclavian arteries, which include principally the thyrocervical trunk, the costocervical trunk, and internal mammary arteries (Fig. 11). Through their branches, including principally the inferior thyroid, superior intercostal, transverse cervical, transverse scapular and subscapular arteries, communications are made with the intercostal arteries, thus providing circulation from the aorta above to that below the level of the coarctation. In addition, the internal mammary artery, through its continuation in the abdominal wall as the superior epigastric artery and the communications of this vessel with the lumbar arteries and the inferior epigastric artery, provides circulation respectively to the abdominal aorta and the external iliac artery. By virtue of their function, these communicating arterial pathways become greatly dilated and tortuous and may produce conspicuous pulsations. Accordingly, the presence of these pulsations, which are readily palpable and often visible, especially about the shoulder girdle, in the axilla, or below the scapulas, provides a valuable diagnostic sign. As a consequence of this factor, too, the tortuous loops of the intercostal arteries gradually produce focal erosion of the lower margin of the ribs resulting in the characteristic notching observed in roentgenograms of the chest.

Clinical Manifestations. The clinical manifestations of coarctation are fairly characteristic, although symptoms, particularly early in life, may be minimal or absent. Indeed, in some patients, the condition may go unnoticed throughout childhood and early adult life during which growth and physical development may be quite normal. In many patients, symptoms may first appear after some excessive physical activity or intercurrent infection. The most common subjective manifestations include headaches, vertigo and dizziness, dyspnea, palpitation, increased fatigability, and epistaxis. Less frequently, the patients may complain of flushing and throbbing in the eyes, peculiar sensations in the head, pain in the trunk and arms, and occasionally of angina pectoris and intermittent claudication in the lower extremities.

On physical examination, the most characteristic findings are high blood pressure in the upper extremities and absent or low blood pressure in the lower extremities, palpable pulsations in the arteries over the back or front of the chest and particularly about the scapular or interscapular regions, excessive arterial pulsations at the root of the neck, and a systolic murmur heard best over the base of the heart and often transmitted to the interscapular region of the back. In most patients, there is moderate to severe elevation of systolic and to some extent of diastolic pressures in the upper extremities, but in some patients, particularly children and less frequently young adults, these pressures may be within a normal range or only slightly elevated. Under the latter circumstances the relative values obtained for the blood pressure in the upper and lower extremities are particularly significant. In normal individuals, the blood pressure in the legs is slightly higher than that in the arms, whereas in coarctation these values are characteristically reversed, and even in the presence of relatively normal pressures in the arms the pressure in the legs will be found well below that in the arms and is often unobtainable by the cuff sphygmomanometer. In this connection, the palpatory findings of arterial pulsations may be highly significant. In normal subjects,

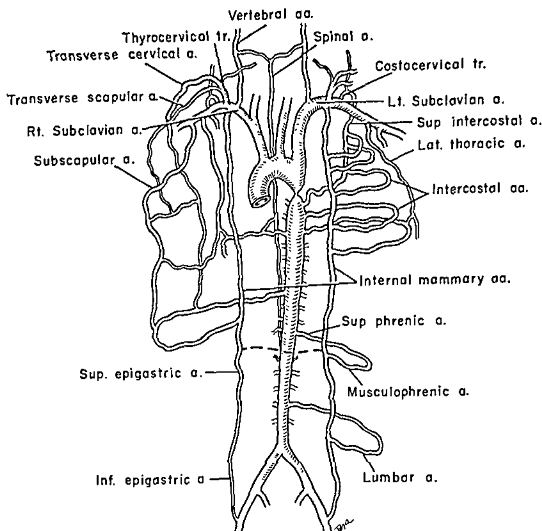

Fig. 11. Diagrammatic drawing showing collateral circulation in coarctation of the aorta.

for example, the femoral and pedal pulses, the dorsalis pedis and posterior tibial, are readily palpable, whereas in coarctation they are either greatly diminished or absent. On the other hand, arterial pulsations, which are normally not present in the chest and back, may be readily palpated in the presence of coarctation. They are usually found on the posterior wall of the chest just below and medial to the lower edges of the scapulas, along the anterolateral aspect of the chest, in intercostal spaces just below the breasts, in the axilla and axillary folds, and above and below the clavicles. Occasionally, pulsations may be noticed in the epigastrium and anterior abdominal wall.

Although murmurs are present in most patients with coarctation, they are quite variable both in character and location. The most frequent type of murmur is a precordial systolic bruit of mild to moderate intensity heard best over the base of the heart and transmitted to the interscapular regions usually on the left side. Diastolic murmurs may also occur and have been reported in about 20 per cent of cases. Their presence is particularly significant as they may indicate associated anomalies, such as patent ductus arteriosus, insufficient bicuspid aortic valve, endocarditis, or interseptal defect.

The most important laboratory studies are electrocardiography and roentgenography of the chest. In most cases, and especially in children, the electrocardiogram is normal. In

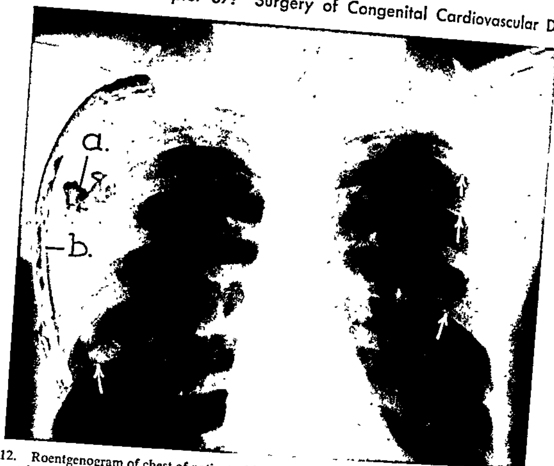

Fig. 12. Roentgenogram of chest of patient with coarctation of aorta treated surgically showing characteristic notching of inferior borders of ribs (indicated by arrows), lack of prominence of aortic knob, and slight left ventricular hypertrophy. a, excised segment of coarctation removed at operation; b, segment of left fifth rib removed at thoracotomy, showing areas of focal erosion along its inferior surface produced by enlarged tortuous intercostal artery resulting in roentgenographic appearance of rib notching.

about one third of the patients, and particularly in those beyond the third decade of life, evidence of left ventricular hypertrophy or strain is present. Its main significance lies in evaluating the status of the heart particularly in regard to associated anomalies and to its tolerance of the hypertension.

On roentgenographic examination of the chest the characteristic manifestations of coarctation are notching or scalloping of the ribs, lack of prominence of the aortic knob, and evidence of left ventricular hypertrophy (Fig. 12). In perhaps about 20 per cent of cases, however, and most frequently in infancy and early childhood, these findings are not demonstrable and little variation from normal may be observed in the chest roentgenogram. Rib notching, which usually appears after the age of 10 years, is the most characteristic finding and may be considered pathognomonic of the disease, although rarely it may be produced by neurologic and vascular lesions of the chest wall, such as neurofibromatosis of the intercostal nerves and arteriovenous fistulas. A significant radiologic sign, in some cases, consists in the presence of a double shadow in the region of the aortic knob, the upper component of which is produced by the dilated left subclavian artery and the lower part by the poststenotic segment of the descending thoracic aorta (Fig. 13). Although in the diagnostic study of most patients with coarctation angiocardiography is not necessary, it may be indicated and can provide useful information under certain unusual circumstances.

Prognosis. The serious nature of coarctation, if untreated, has been well demonstrated by a number of studies. Abbott, for example, found that death occurred before the age of 30 years in about half the patients and before the age of 40 years in about three fourths of the patients. Somewhat similar figures were obtained by Blackford. In the majority of

Fig. 13. Roentgenogram of patient with coarctation of aorta showing significant radiologic sign of double shadow in region of aortic knob: the upper component, a, is produced by dilated left subclavian artery and the lower part, b, by poststenotic segment of descending thoracic aorta. Characteristic rib notching and moderate left ventricular hypertrophy are also shown.

cases, death results from cardiovascular causes, such as heart failure, rupture of the aorta or heart, endocarditis and cerebral lesions. It is thus apparent that the disease is associated with high morbidity and decreased life expectancy, facts that emphasize the need for proper therapy.

Treatment. Surgical removal of the coarcted segment with restoration of aortic continuity by end-to-end anastomosis or by use of an aortic graft constitutes the most effective form of treatment of coarctation (Figs. 14, 15, 16). In general, it is considered preferable to delay operation until the patient is over six years of age. In younger patients, however, operation may be mandatory under certain urgent circumstances, such as heart failure or progressive cardiomegaly.

Results of surgical treatment have been increasingly gratifying. In the majority of cases, symptoms are relieved and the blood pressure in the extremities is restored toward normal levels. In uncomplicated cases operative mortality and morbidity rates are relatively low, being less than 5 per cent.

VASCULAR ANOMALIES PRODUCING TRACHEAL OR ESOPHAGEAL COMPRESSION (VASCULAR RINGS)

Abnormalities in development of the aortic arch system may lead to displacement, constriction, or compression of the trachea and esophagus. Such arterial anomalies in the thorax are common, often complex, and may occur in a number of forms. The most frequent types are the double aortic arch, right aortic arch with left ligamentum arteriosum, anomalous innominate artery, anomalous left common carotid artery, and aberrant subclavian artery.

Principal clinical features of vascular rings are usually related to tracheal or esophageal obstruction. Dysphagia (dysphagia lusoria) may or may not be present but is only produced by vascular rings which produce posterior compression of the esophagus. Disturbed swallowing may be manifested in several ways and may vary according to the type of food taken. For example, fluid may produce difficulties in a patient who swallows

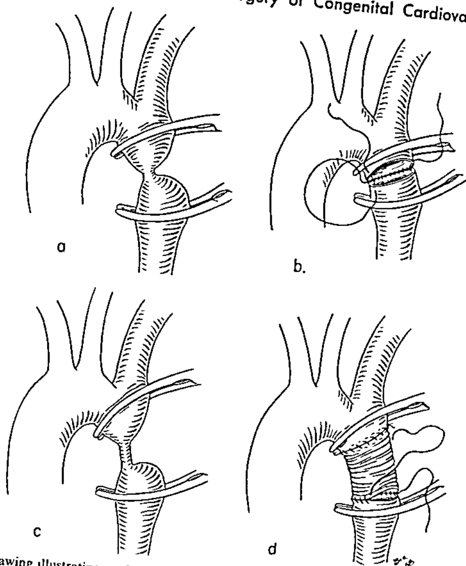

Fig. 14. Drawing illustrating methods of surgical treatment of coarctation of aorta: a, common form of coarctation in which end-to-end anastomosis, b, may be employed; c, longer form of coarcted area requiring use of graft, d, for replacement of excised segment.

semisolids normally. In some patients the reverse may be true. Nursing infants may even have regurgitation of milk and have peculiar gasping action.

Respiratory distress with stridor and inspiratory retraction of intercostal and supraclavicular tissues is characteristic of anterior compression of the trachea. These symptoms are frequently associated with double or bifid aortic arch and appear during infancy. Respiratory rate is usually increased and a noisy "crowing" respiration is audible even without a stethoscope. Respiratory symptoms are aggravated by ingestion of milk. Babies have a natural tendency to hyperextend the neck to obtain a free air passage. Infections of the lower respiratory tract may ensue, sometimes related to aspiration. A resulting bronchopneumonia may complicate an already serious condition. Death in infants is usually the result of respiratory embarrassment.

Roentgenographic examination is the most valuable diagnostic procedure available. Ordinary films may reveal pneumonitis (Fig. 17). Bronchograms show displacement and constriction of the lower trachea (Fig. 18). Lipiodol or barium esophogram may show posterior indentation of the esophagus at the same level. The combination of posterior encroachment upon the trachea and anterior constriction of the trachea are findings which for practical purposes are diagnostic of a vascular ring.

Surgical Treatment. Only those anomalies producing symptoms or evidence of impairment of tracheal or esophageal function deserve operative intervention. Largely because of the efforts of Gross, the technic of operation upon aortic arch anomalies has been greatly improved. The purpose of operation in every case is relief of tracheal and esophageal obstruction without sacrifice of major vital blood vessels. Although in some instances it is practical to divide an anomalous subclavian artery without restoration of circulatory continuity, carotid circulation should never be permanently interrupted (Fig. 19). In instances of double aortic arch, the arch which is present on the left side of the trachea is fortunately often the lesser of the two and division may be safely performed (Fig. 20). Under these circumstances, the left arch may be divided between the origins of the left common carotid artery and the left subclavian artery (Fig. 20). In some cases, a ligamentum arteriosum enters into the formation of the aortic arch and must be divided as part of the repair. A simple, uncomplicated retroesophageal right subclavian artery originating from a normal left descending thoracic aorta does not require surgical interruption. If symptoms (dysphagia lusoria) are present, the vessel should be divided.

CONGENITAL AORTIC AND SUBAORTIC STENOSIS

Stenosis of the aortic valve, like stenosis of the pulmonary valve, may involve the valve leaflets and commissures or may occur in a subvalvular position. In the latter instance, the lesion is referred to as subaortic stenosis and is usually a fibromuscular ridge or membrane in the left ventricular outflow tract. Whereas subaortic stenosis is always a congenital abnormality, valvular aortic stenosis may be either congenital or acquired.

In most instances, the symptoms during childhood are minimal, but if the stenosis is extreme, the patient may suffer from cerebral ischemia manifested by spells of syncope, sometimes accompanied by convulsions and sudden death. In newborn infants, a severe

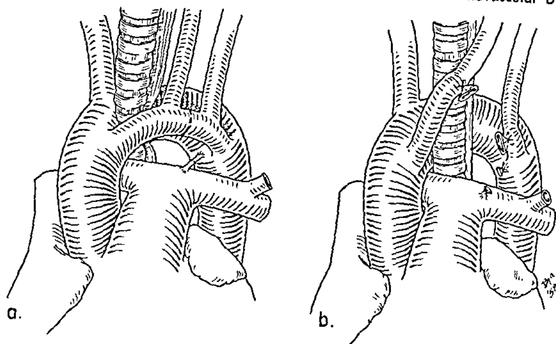

Fig. 20. Drawing showing complete vascular ring produced by bifid aorta. Relief of tracheal and esophageal obstruction is obtained by interruption of the lesser arch to left of trachea and release of the ring.

stenosis leads to pulmonary edema and dyspnea, and pulse pressure may be so reduced that peripheral pulses are not palpable.

Characteristic physical findings include the presence of cardiac enlargement and a harsh thrill and systolic murmur to the right of the sternum. Aortic closing sound may be present but is not loud. The murmur is transmitted readily to the suprasternal notch and may be audible in the axillary and brachial arteries. Pulse pressure is usually reduced unless some aortic incompetence is also present.

Aortic valvulotomy should be done for patients who have syncopal attacks or findings of left ventricular strain on electrocardiogram and progressive cardiac enlargement. Occasionally in small infants operation must be done as an emergency. At present the most widely accepted method of valvulotomy or subaortic resection is a transventricular approach to the valve using cardiac inflow occlusion and hypothermia or temporary cardiopulmonary bypass. Results of operation are generally satisfactory although mild aortic regurgitation may follow an extensive valvular dissection.

PULMONIC STENOSIS

Isolated or pure pulmonic stenosis with intact ventricular septum is a lesion in which obstruction to right ventricular outflow is the predominant physiologic disturbance. Two types of pulmonic obstruction are recognized, and both may be present in the same patient. In the commoner type, stenosis of the pulmonary valve is present and the valve is fused into a conical shape with a perforation at the apex (Fig. 21). In a much less frequent type, the obstruction occurs in a subvalvular position involving the infundibulum or conus region of the right ventricle (Fig. 22). In this position, a fibromuscular ring is located in the outflow tract of the ventricle, usually at the level of hypertrophied crista supraventricularis. A number of anatomic variations may occur, depending upon the level at which the infundibular obstruction is located. An infundibular chamber or so-called third ventricle may be produced in instances where the infundibular stenosis is several centimeters below the valve.

Cyanosis is typically absent in this defect, but perhaps in fewer than 50 per cent of cases a small septal defect is present, usually in the interatrial septum. If the pulmonary stenosis is severe, a right-to-left shunt occurs, producing cyanosis. Not uncommonly, therefore, even a slitlike patency of the foramen ovale may produce a significant right-to-left shunt and cyanosis. In this lesion, right ventricular

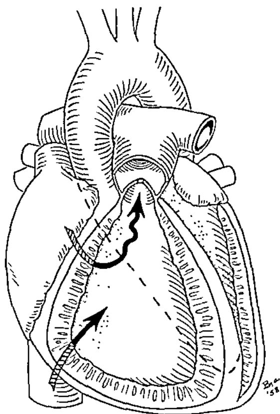

Fig. 21. Diagram showing isolated stenosis of pulmonary valve with intact ventricular septum. Poststenotic dilatation of the pulmonary artery is a characteristic finding in this anomaly.

strain and right sided failure are characteristic. Clinical findings usually include dyspnea on exertion which may be intense. Spells of paroxysmal dyspnea during infancy are frequent, and death may occur suddenly during such an episode. Syncopal attacks are not uncommon in older children. Cyanosis may or may not be present, depending upon the presence of an intracardiac shunt, but usually the cyanosis is not severe or accompanied by clubbing of the nails. So-called "peripheral" cyanosis may be evident indicating a reduced cardiac output and sluggish capillary flow. Squatting after exertion, which is common in patients with tetralogy of Fallot, is not typical in isolated pulmonic stenosis.

The characteristic physical finding is a harsh systolic murmur often accompanied by a palpable thrill along the left sternal border in the third intercostal space. The murmur is transmitted upward toward the left clavicle and no pulmonic second sound is audible. A substernal heaving pulsation signifies the presence of right ventricular hypertrophy. Extreme cardiac enlargement and hepatomegaly usually indicate the presence of secondary cardiac failure.

Roentgenograms reveal right ventricular enlargement. Dilatation of the main pulmonary artery segment is produced by hemodynamic factors produced by the turbulence in the blood stream distal to the stenotic valve (Fig. 23). This finding is useful in differentiating isolated pulmonary stenosis from tetralogy of Fallot and other defects in which the pulmonary artery is usually smaller than normal. Angiocardiography may be useful to demonstrate the anatomy of the outflow tract and in differentiating a valvular from infundibular stenosis.

Electrocardiograms show right ventricular preponderance, and in severely ill children or infants a strain pattern is present.

Cardiac catheterization is extremely useful and reveals an elevated right ventricular pressure often exceeding 200/0 mm. Hg. If an infundibular chamber is present, accompanied by both infundibular and valvular stenoses, an intermediate pressure zone may be detected in the outflow tract. In this chamber, a pressure lower than the pressure in the main chamber of the right ventricle is demonstrable and the pressure in the pulmonary artery is even lower, being 10 to 20/0 mm. Hg.

Prognosis in this lesion depends upon the pressure in the right ventricle. Right ventricular pressures less than 70 mm. Hg systolic are usually well tolerated. If the right ventricular pressure exceeds 80 to 100 mm. Hg, however, surgical treatment is indicated. In infants manifesting severe right ventricular failure, pulmonary valvulotomy must be done as an emergency procedure.

The first successful surgical attempts at pulmonary valvulotomy were made by Brock and Sellers of London, and the technic is often referred to as the "Brock Operation." In this procedure valvulotomes and dilators are passed through the right ventricular wall to incise and dilate the stenotic valve. A guillotine type valvulotome has more recently been used with better results than the instruments originally devised. Relief of symptoms

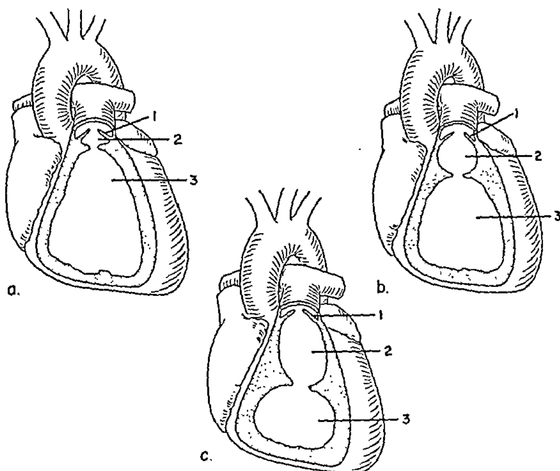

Fig. 22. *Diagrams showing types of subvalvular or infundibular pulmonic stenosis. The numbers 1, 2, and 3 identify the pulmonic valve, infundibular chamber, and right ventricular chamber. The infundibular chambers vary in size depending upon proximity of infundibular stenosis to pulmonic valve.*

is expected if the obstruction to right ventricular outflow is relieved.

During the past ten years numerous modifications of pulmonary valvulotomy and infundibular resection have been made. The most important were the application of open technics employing general body hypothermia or the pump oxygenator for temporary cardiopulmonary bypass. The latter is particularly useful if an infundibular stenosis or significant atrial or ventricular septal defect is present. In these cases, the pump oxygenator provides a means of total correction of the defect or defects with acceptable low risk.

TETRALOGY OF FALLOT

The combination of pulmonary stenosis, ventricular septal defect, and dextroposition of the aortic root produces a right-to-left shunt and a cyanotic state known as tetralogy of Fallot. This lesion assumes great importance, since it is the commonest type of "blue baby." The pathologic anatomy of this complex was first described by Peacock in 1866; later a detailed report of a series of cases by Fallot in 1888 clarified the syndrome which now bears his name.

Although in the past some disagreement existed regarding the criteria necessary for making this diagnosis, for the sake of uniformity only those patients with dextroposition or overriding of the aorta in combination with a ventricular defect and pulmonary stenosis or atresia should be included in this diagnosis (Fig. 24). The venous blood in tetralogy reaches the right ventricle and meets the obstruction in the outflow tract. The unoxygenated blood is shunted readily into the dextroposed aorta through the ventricular defect producing the cyanotic state. Usually these patients have no evidence of right ventricular strain or right sided failure. The right ventricle tends to hypertrophy under the

Fig. 23. Roentgenogram of chest in patient with isolated valvular pulmonic stenosis showing characteristic dilatation of main pulmonary artery.

strain of contraction against systemic pressure. The left atrium and ventricle receive a reduced quantity of blood and are usually underdeveloped. Intracavitary pressure in the right ventricle usually does not exceed aortic pressure since this ventricle has ready access to the aorta, which overrides the ventricular septum receiving part of the right ventricular output, the remainder entering the pulmonary artery, depending upon the degree of pulmonic stenosis present. Pulmonary circulation is greatly reduced and collateral vessels, provided predominantly by the bronchial arteries, may contribute significantly to pulmonary flow. The pulmonary stenosis usually involves the pulmonary artery and also the valve and the infundibulum of the right ventricle.

In this malformation, the outstanding features are intense cyanosis and clubbing of the extremities combined with a heart of normal size. The intensity of the cyanosis is highly variable, depending mostly upon the severity of pulmonary stenosis and the extent of dextroposition of the aorta. In severely incapacitated patients dyspnea is present even at rest, but in less severe lesions dyspnea and cyanosis are evident only following exertion.

Dyspnea usually limits the activities of the patient since not uncommonly an arterial oxygen saturation of 85 per cent at rest falls to 40 to 50 per cent with mild exertion. Squatting with fatigue is a typical habit among patients with tetralogy of Fallot. After extreme exhaustion, infant patients often assume the knee-chest position. Attacks of paroxysmal dyspnea are common in infants,

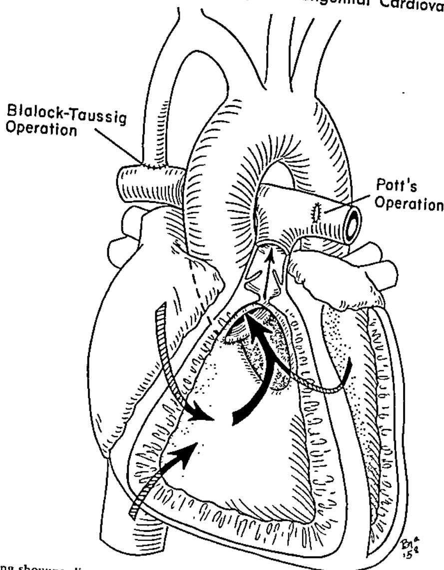

Fig. 24. Drawing showing diagrammatically the defects typical of tetralogy of Fallot which lead to a right-to-left intracardiac shunt and consequent pulmonary ischemia. Systemic pulmonary arterial anastomoses of Blalock-Taussig and Potts for relief of cyanosis are shown.

and such spells may be erroneously diagnosed as epilepsy since loss of consciousness and convulsions may occur.

The most significant and consistent laboratory finding is polycythemia. Red blood cell count may exceed 10 million and hematocrit may be 80 per cent or more.

Stunting of growth is common and many patients more than two years of age are undernourished. Onset of puberty is usually delayed.

Physical findings reveal striking cyanosis with plum colored mucous membranes and clubbed nails (Fig. 25). The heart is usually small or normal in size, although the enlarged right ventricle may produce convexity of the overlying chest wall. Heart action is usually forceful and a systolic murmur is heard to the left of the sternum. Intensity of this murmur depends upon the degree of pulmonic stenosis. In instances of severe pulmonary atresia, no pulmonic murmur is audible. Pulmonary second sound is reduced or absent. The aortic second sound, however, is usually louder than normal, and since the aortic root is large, the aortic sound may be confused with the pulmonic second sound.

Roentgenographic findings usually include a small heart, right ventricular hypertrophy, concave pulmonary conus, and decreased pulmonary vascularity. A right aortic arch occurs in more than 15 per cent of cases.

Fig. 25. Severe clubbing of fingernails and toenails in cyanotic boy aged 14 years with tetralogy of Fallot.

Fluoroscopy with barium filled esophagus is useful to delineate the course of the aortic arch. Angiocardiography reveals simultaneous filling of the aorta and pulmonary arteries confirming the presence of overriding aorta (Fig. 26). Cardiac catheterization shows increased right ventricular pressure which does not exceed systemic arterial pressure, and if the pulmonary artery can be entered, the pressure is low. Prognosis in tetralogy is fair and perhaps better than for most cyanotic conditions. Whereas most

and such spells may be erroneously diagnosed as epilepsy since loss of consciousness and convulsions may occur.

The most significant and consistent laboratory finding is polycythemia. Red blood cell count may exceed 10 million and hematocrit may be 80 per cent or more.

Stunting of growth is common and many patients more than two years of age are undernourished. Onset of puberty is usually delayed.

Physical findings reveal striking cyanosis with plum colored mucous membranes and clubbed nails (Fig. 25). The heart is usually small or normal in size, although the enlarged right ventricle may produce convexity of the overlying chest wall. Heart action is usually forceful and a systolic murmur is heard to the left of the sternum. Intensity of this murmur depends upon the degree of pulmonic stenosis. In instances of severe pulmonary atresia, no pulmonic murmur is audible. Pulmonary second sound is reduced or absent. The aortic second sound, however, is usually louder than normal, and since the aortic root is large, the aortic sound may be confused with the pulmonic second sound.

Roentgenographic findings usually include a small heart, right ventricular hypertrophy, concave pulmonary conus, and decreased pulmonary vascularity. A right aortic arch occurs in more than 15 per cent of cases.

Creation of a systemic to pulmonary shunt of the Blalock or Potts type increases pulmonary flow and relieves the cyanosis. Resort to surgical treatment is indicated whenever cyanosis is severe or incapacitating. Although results of anastomotic procedures are not as satisfactory as in tetralogy of Fallot, creation of an artificial ductus should be attempted in view of the poor prognosis of the anomaly if untreated. Direct surgical repair of the lesions in tricuspid atresia is not anatomically feasible.

PULMONARY ARTERIOVENOUS FISTULA

Among the rarer causes of cyanosis is pulmonary arteriovenous fistula. This lesion is considered by most to be congenital in origin and has definite hereditary characteristics. The pulmonary lesion may be only one manifestation of a hereditary hemorrhagic telangiectasia, the so-called Osler-Weber-Rendu disease. In more than 50 per cent of cases, the aneurysms are multiple in one or both lungs.

The lesions range from near microscopic size to several centimeters in diameter. Lesions tend to lie subpleurally, and pleural adhesions overlying the distended sac may develop. Disruption of adhesions by coughing or straining may produce bleeding and spontaneous hemothorax (Fig. 27). The fistulous communication usually involves more than one segmental artery and vein. The vessels are dilated and tortuous with aneurysmal dilatations adjacent to the fistulous communication.

The essential findings are cyanosis and clubbing of nails in the presence of a normal heart. Cyanosis appears at a later age than is customary with cyanotic types of congenital heart disease. Dyspnea is usually mild. Bleeding from the nose and pharynx is common and hemoptysis may be severe. Central nervous system involvement may occur because of paradoxical embolism or air embolism. Hemangiomata or telangiectases may be located elsewhere on the body indicating the generalized tendency of the disease process.

A soft, humming, continuous murmur may be audible over the involved pulmonary segment. Cardiac murmurs are absent and cardiac enlargement usually does not occur although multiple fistulas producing a large volume right-to-left shunt are present. Electrocardiogram shows no significant deviation from normal.

Roentgenographically, the arteriovenous fistula or aneurysm may be demonstrated as a cluster of tortuous vessels or well-defined aneurysm sac. Multiple fistulas may be noted. In some instances, the lungs are diffusely studded by multiple minute telangiectases. Angiocardiography may be the only means of demonstrating the lesions, particularly the minute, widely scattered hemangiomatous type.

Surgical resection of the involved segment or lobe may be justified in localized lesions of significant size producing cyanosis and polycythemia. Usually, however, total pneumonectomy should be avoided, since involvement of the remaining lung may be present and the lesions may be aggravated by the excessive resection. Simple ligation of a segmental pulmonary artery or vein is never curative because of the multiple communications present in each aneurysmal sac regardless of size of the lesion.

VENTRICULAR SEPTAL DEFECTS

Defects of the interventricular septum are perhaps the most common true congenital cardiac lesions occurring as isolated anomalies or in combination with valvular and other great vessel malformations. As an isolated anomaly the ventricular septal defect produces characteristic physiologic disturbance. Since pressure in the left ventricle is normally about four times that in the right, a significant left-to-right intracardiac shunt is produced depending upon the size and location of the defect and the resistance to flow in pulmonary arterioles and capillaries. Contrary to previous medical opinion, prognosis in ventricular defects is usually poor and estimates indicate that approximately 70 per cent of patients die of complications of congestive failure during the first year of life. In some patients, however, the defect causes little disability and is compatible with a relatively normal life. In still others, significant retardation of growth and development is noted. Obviously certain factors are respon-

other malformations causing cyanosis are incompatible with life for more than a few months, occasional patients with tetralogy of Fallot may live to adulthood. Of course, wide variation exists depending upon the severity of pulmonary stenosis and overriding of the aorta. Indeed, many infants expire from the effects of pulmonary ischemia and anoxemia before compensatory changes occur which would provide collateral pulmonary circulation.

Surgical treatment for tetralogy of Fallot was introduced in 1944 by Blalock and Taussig—an event which stirred the present enthusiasm for surgery of congenital heart disease. Recognizing the fact that infants with tetralogy not infrequently do well for the first few weeks of life while the ductus arteriosus is normally patent and deteriorate as the ductus spontaneously closes, these observers planned creation of an artificial patent ductus arteriosus. The principle of the Blalock-Taussig "blue-baby" operation is therefore based upon creation of an artificial ductus arteriosus which will permanently provide blood to the pulmonary circulation. In this procedure, a subclavian artery is divided and anastomosed end to side into the pulmonary artery (Fig. 24). Presence of a machinery type continuous murmur after operation is indicative of a satisfactory result. Several years after the Blalock-Taussig operation was devised, Potts introduced a technical modification of this procedure and anastomosed the side of the pulmonary artery to the side of the aorta, somewhat simplifying the operation (Fig. 24).

Brock in 1949 recommended a direct operative attack upon the pulmonary stenosis or infundibular obstruction. Enthusiasm for this procedure has waned, particularly with the recent advent of technics for open heart surgery.

Lillehei and co-workers now advocate total correction of the defects of tetralogy using a pump oxygenator for cardiopulmonary bypass. Repair of the ventricular septal defect and resection of the obstructing elements in the right ventricular outflow tract is performed using polyvinyl or synthetic prostheses if necessary to provide a complete plastic repair in the outflow tracts of right and left ventricles. At present, it is not possible to compare the results of total corrective operations with anastomotic procedures. In general, it may be stated, however, that anastomotic procedures of Blalock-Taussig or Potts are still indicated for infants and for patients with intense cyanosis and extreme aortic overriding. In other patients, complete repair of the defects is the procedure of choice.

TRICUSPID ATRESIA

In this anomaly, no communication exists between the right atrium and right ventricle. The foramen ovale must be widely patent or a gross atrial septal defect must be present in order for this anomaly to be compatible with life. If only a foramen ovale is present, the high pressure in the right atrium holds the foramen open. Usually in patients surviving infancy, a communication exists between the left ventricle and a diminutive right ventricle. Pulmonary stenosis with a narrow pulmonary arterial trunk is common with this defect and the combination of pulmonary ischemia and right-to-left vascular shunt at the atrial level produces a cyanotic state. The small size of the right ventricle in the presence of cyanosis provides the clue to diagnosis and differentiation from other cyanotic conditions.

Clinically, these patients are intensely cyanotic. Frequently, infants will become distressingly anoxemic as the ductus closes spontaneously and death may ensue if emergency measures and surgical treatment are not available. Murmurs may or may not be present, depending usually upon the patency of a ductus arteriosus. The quality of the second cardiac sound is usually single, since only the sound of closure of the enlarged aortic valve is audible.

Roentgenographically and fluoroscopically, an absence of the right ventricle and pulmonary conus distinguishes this from other cyanotic lesions which are associated with pulmonary ischemia.

The electrocardiogram shows left axis deviation, a finding in cyanotic patients which is always suggestive of tricuspid atresia and underdevelopment of the right ventricle. In small infants, however, the electrocardiogram may present a balanced axis.

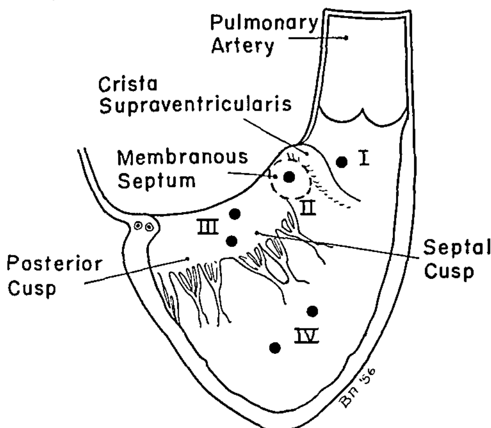

Fig 28. Diagram showing location of defects of the ventricular septum as viewed from the right ventricle. Approximately 85 per cent are in the membranous septum (Type II).

sible for this discrepancy. In the well-known *maladie de Roger*, for instance, in which the defect is relatively small and frequently located in the muscular portion of the septum, a harsh murmur is present, but the effects upon the cardiac function are mild and most patients are asymptomatic. In the past, this observation has led many to consider ventricular defect a relatively innocuous condition from the patient's standpoint. In general, large defects of the ventricular septum either of the membranous or muscular portion have a serious prognosis and surgical correction is necessary whenever it is clinically feasible.

Location of defects in the ventricular septum is important in the problems of diagnosis and treatment. The ventricular septum is composed of a small membranous portion and larger muscular portion. In addition, there is an inflow and outflow area separated by a crista supraventricularis (Fig. 28). Approximately 85 per cent of ventricular septal defects occur in the membranous septum. In this location, cardiac contraction has little tendency to close the defect during systole in contrast to those defects completely surrounded by myocardial tissue. Thus, the membranous defects, particularly those of large size, are associated with the largest volume of shunt and the poorest prognosis.

The murmur of ventricular septal defects may vary from a harsh systolic murmur of *maladie de Roger* to none at all. When the murmur is loud, it is located in the left third or fourth intercostal space and is frequently associated with a palpable thrill. Cyanosis is typically absent, but if pulmonary hypertension results and pulmonary vascular resistance is increased by hypertrophic and proliferative changes in pulmonary arterioles, cyanosis may subsequently appear, due to reversal of the shunt. The pulmonary valve closing sound is almost always accentuated, depending upon pulmonary arterial pressure. Pulse pressure is usually increased, especially in infants, before pulmonary hypertension

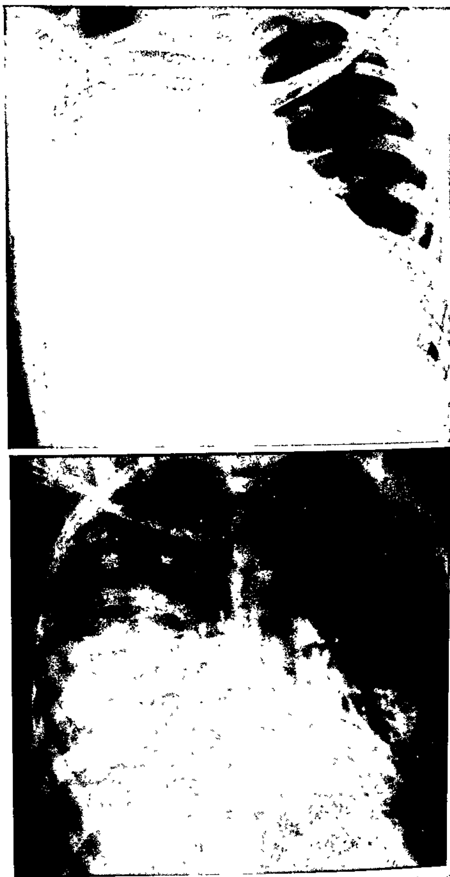

Fig. 27. Above, roentgenogram of chest in 24-year-old patient with spontaneous hemothorax. Below, diagnosis of pulmonary arteriovenous fistula was made by angiocardiography. Patient recovered from illness after decortication of lung and resection of right lower lobe. Note additional small pulmonary arteriovenous fistula in right upper lobe.

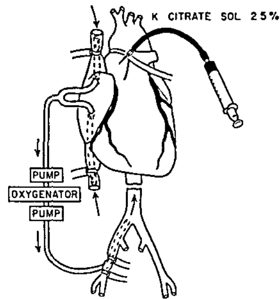

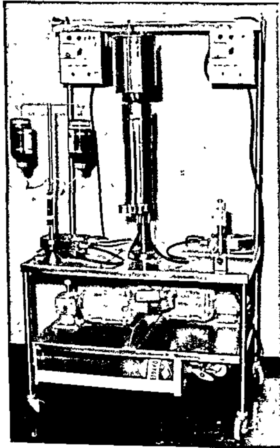

Fig. 30. Scheme of operation using a pump oxygenator for temporary cardiopulmonary bypass. Induced cardiac arrest using potassium citrate solution may be used to facilitate the repair.

present, indicating the presence of a right-to-left shunt. Such cases are usually unsuitable for attempted surgical correction.

Surgical Treatment. Recently methods of surgical correction of ventricular septal defects have been perfected which provide means of obtaining complete cure of the lesion. Development of the pump oxygenator as a *temporary cardiopulmonary* substitute has provided a satisfactory means of exposing ventricular defects for repair under direct vision (Figs. 30, 31). This significant development was the result of efforts by Gibbon, Dennis, Lillehei, Kirklin, and many others.

Patients selected for operation should have a significant left-to-right intracardiac shunt as manifested by left ventricular hypertrophy, cardiac enlargement, and increased pulmonary vascular markings. Optimum age for operation is between two and twelve years, although occasionally operation in small infants is required on an emergency basis. Op-

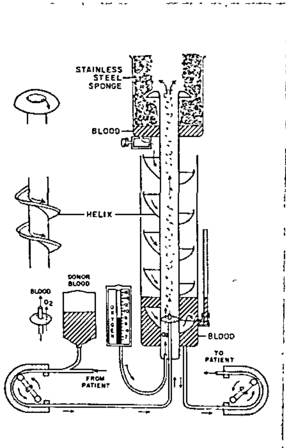

Fig. 31. Photograph and diagram showing pump oxygenator system which utilizes roller pumps and stainless steel oxygenator.

Fig. 29. Roentgenogram of chest in seven-year-old patient with ventricular septal defect showing cardiac enlargement and prominence of pulmonary vascular markings.

develops. Progressive cardiac enlargement is an early warning sign in the asymptomatic patient that cardiac failure is impending. If pulmonary hypertension is extreme, a Graham Steell diastolic murmur of pulmonary valvular incompetence may be audible.

Roentgenograms of the chest show left ventricular enlargement, a prominent pulmonary conus, increased pulmonary vascular markings, and frequently left atrial enlargement (Fig. 29). Fluoroscopy is useful to demonstrate the increased pulmonary flow. In small infants, differentiation between a large patent ductus arteriosus and ventricular septal defect may be made by retrograde aortography (Fig. 5). An injection of 6–10 ml. of 30 per cent Diodrast in the left brachial artery permits visualization of the entire aortic arch. If the contrast medium is visible in the pulmonary vessels, the presence of a ductus arteriosus is confirmed but the possibility of a ventricular defect is not necessarily excluded.

The electrocardiogram reveals left ventricular hypertrophy. If pulmonary hypertension develops, right ventricular hypertrophy occurs. Frequently combined left and right ventricular hypertrophy is demonstrated by electrocardiogram.

In the typical case, cardiac catheterization reveals oxygenated blood in the right ventricle and unmixed venous blood in the right atrium; the pressure in the right ventricle and pulmonary artery is usually elevated but with a small defect may be normal. When the pulmonary and systemic arterial pressures are roughly equal and the oxygen saturation of right ventricular blood only slightly exceeds right atrial saturation, peripheral arterial oxygen unsaturation may be

encountered congenital cardiac defects of young adults. During fetal life, defects of the interatrial septum cause no physiologic disturbance; the blood is directed from right to left in the normal manner. After birth, however, when left atrial pressure exceeds the pressure in the right atrium, the flow reverses. A left-to-right shunt produces a pulmonary flow greater than systemic and consequently an increased burden upon the right ventricle.

Under ordinary circumstances, there is no cyanosis. Mottling of the skin is a frequent finding in young children particularly and may be confused with true cyanosis, but this may be differentiated by the normal color of lips and nail beds. The so-called gracile habitus or thin, weak, small-boned appearance, supposedly characteristic of patients with atrial defects, is by no means constant. The patient with a large incapacitating defect may have a normal growth pattern.

The thorax over the precordium may be deformed, the prominence being due primarily to a dilated and hypertrophied right ventricle. A systolic murmur is usually audible along the left sternal border and is produced in the outflow tract of the hypertrophied ventricle or in the dilated pulmonary artery. The defect itself produces no murmur unless it is associated with an anomaly in the mitral or tricuspid valves. At birth, a murmur is usually absent, and even when it becomes audible, considerable variation may be noted in its location and intensity. The pulmonary valve closing sound is accentuated, and in the presence of right bundle branch block, the sound is widely split.

Roentgenographically cardiac enlargement, principally right ventricular, is evident with prominence of the pulmonary conus and pulmonary vascular shadows. In large atrial defects fluoroscopy may reveal the so-called "hilar dance" produced by the pulsating pulmonary arteries. Electrocardiography indicates right ventricular hypertrophy and often right bundle branch block.

Cardiac catheterization reveals the presence of oxygenated blood in the right atrium. In infants and children pulmonary arterial pressure is often normal, but in the adult the pressure increases and may subsequently equal systemic arterial pressure.

With increasing age right ventricular hypertrophy advances and many patients develop severe pulmonary hypertension. Although this defect may be compatible with a relatively normal infancy and childhood, frequently during early adulthood incapacitating symptoms appear. In general, therefore, cases should be selected for surgery at an early age when cardiac reserve is greater and risk of operation less.

The usual atrial septal defect is located in the upper portion of the septum and represents a failure of the septum secundum to close the ostium secundum or foramen ovale (Fig. 33). If the septum secundum does not develop completely, a true septal defect of clinical significance occurs. In many instances, the septum secundum develops normally, yet a slitlike opening of the foramen ovale persists after birth. Such a lesion may be present throughout life and produce no disturbance in cardiac physiology. Defects located in the lower portion of the atrial septum result from failure in closure of the ostium primum or atrioventricular canal. Because these defects are frequently associated with developmental failures in the embryologic endocardial cushions, a cleft may be present in the mitral or tricuspid valves. An ostium primum defect associated with cleft mitral valve may be associated with mitral regurgitation. Under these conditions left ventricular hypertrophy may be present, adding to the volume of left-to-right atrial shunt and more severe physiologic disturbance. In cases of complete atrioventricularis communis or persistent atrioventricular canal, mitral and tricuspid incompetence may be present as well as interatrial and interventricular shunts. These defects, which are often associated with mongolism, lead to early congestive failure and death during infancy or the first few years of life.

Operation for atrial defect should be recommended whenever manifestations of cardiac enlargement, failure in physical development, or increasing pulmonary hypertension become evident. With recent development of effective and safe methods of surgical closure, procrastination in submitting such patients to diagnostic study and operation is no longer justified.

Surgical Treatment. Selection of patients with atrial septal defect for operation is based

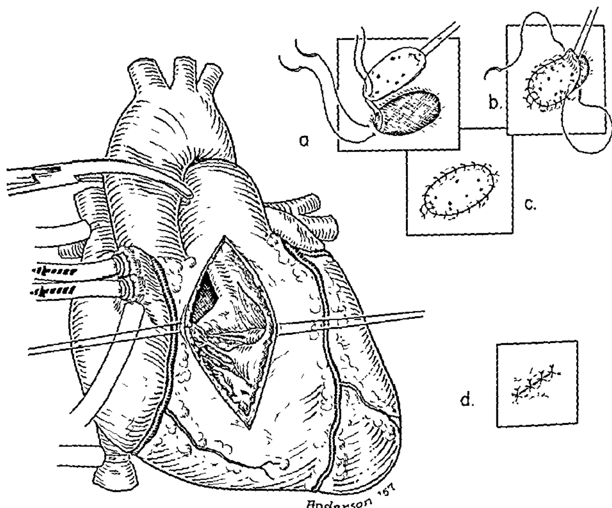

Fig. 32. Drawing showing technic of repair of membranous ventricular septal defect using temporary cardiopulmonary bypass. The defect may be repaired using a patch of synthetic material or by a direct suture technic.

eration should not be advised in the presence of a significant right-to-left shunt through a ventricular defect, of clubbing of nails with severe cyanosis, or of right ventricular hypertrophy and a small left ventricle. In such patients, risk of surgery is high and survivors can expect little if any benefit.

During bypass the right ventricle is incised widely to expose the defect (Fig. 32). Complete cardiac standstill induced by potassium citrate solution or acetyl choline injected into the coronary circulation is used by some surgeons to obtain a quiet and bloodless surgical field inside the heart. Others prefer using intermittent occlusion of the ascending aorta to control coronary flow and coronary sinus return during bypass, and results are equally satisfactory. Although small defects may be sutured directly, for larger defects a polyvinyl sponge patch or tampon over the defect insures complete closure without excessive tension on the suture lines. After the ventriculotomy is repaired and air is eliminated from the cardiac chambers, the bypass is discontinued and cardiac action resumes. In some instances, a transatrial approach to the ventricular defect is preferable, and since it preserves right ventricular integrity, postoperative recovery may be easier. After operation, pulmonary arterial and right ventricular pressures are reduced and cardiac enlargement gradually disappears. In properly selected cases, the mortality from operation is approximately 10 per cent and should improve with advances in diagnostic technic and increased experience.

ATRIAL SEPTAL DEFECTS

Defects of the atrial septum are not uncommon and, in fact, are the most frequently

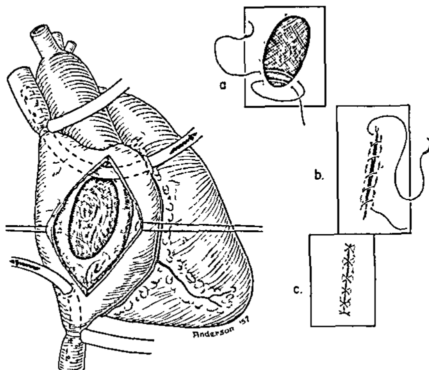

Fig. 34. Drawing showing method of repair of septum secundum type of atrial defect using temporary cardiopulmonary bypass. Direct suture of the defect without use of an occluding patch gives satisfactory results.

tient in an iced tub. At temperatures of approximately 30° C., vena caval return and cardiac inflow interruption are possible for periods of six to eight minutes during which the defect is exposed and repaired. Addition of coronary perfusion during the period of inflow occlusion reduces the danger of cardiac arrhythmia in the cold heart. Because of the limitations on time imposed by this technic and the inability to close ostium primum defects safely, this method also is gradually being discarded by most surgeons.

Cardiopulmonary bypass offers the most satisfactory means of repair for atrial septal defects permitting accurate and satisfactory repair of all types with the possible exception of some extensive types of complete atrioventricularis communis. Defects of the septum secundum type are usually repaired by direct suture and do not require a patch of foreign material for closure (Fig. 34). For ostium primum or low defects a compressed Ivalon patch is usually employed to avoid distortion and tension on the inferior rim of the opening in which the atrioventricular conduction bundle is located since total heart block may result (Fig. 35). Clefts in the mitral and tricuspid valves may be repaired at the time of repair of the septal opening. Results of operation are usually excellent (Fig. 36). Under most circumstances a mortality rate of less than 5 per cent is expected unless patients with severe pulmonary hypertension or advanced cardiac failure are included, in which case the risk of operation is increased.

PATENT DUCTUS ARTERIOSUS

The ductus arteriosus is a vascular communication between the pulmonary artery near its bifurcation and the aorta just beyond and opposite the origin of the left subclavian artery (Fig. 37). Its embryologic development has been discussed in the preceding sections. Normally patent during intrauterine life, the ductus serves an essential function in fetal circulation by permitting the the shunting of most of the blood from the pulmonary to the systemic circulation, owing to the fact that during this period the unexpanded lungs are functionless and the pulmonary pressure is relatively high. Following

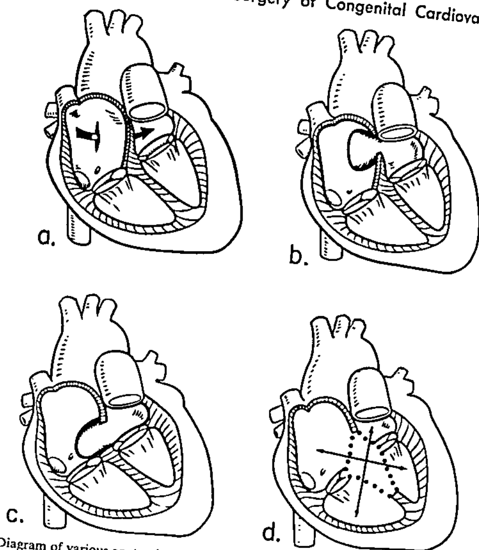

Fig. 33. Diagram of various anatomic types of atrial septal defect showing: a, patent foramen ovale; b, septum secundum defect; c, ostium primum defect; and d, an atrioventricularis communis or atrioventricular canal.

upon the same principle used in selection of patients with ventricular defect. The presence of a large left-to-right shunt with mild or moderate increase in pulmonary vascular resistance is the best indication for operation. The optimum age for operation is five to fifteen years. In some atrial defects, particularly the ostium primum and atrioventricularis communis, severe cardiac disturbance may be present during infancy and early childhood and operation must be performed early.

A number of technics were used in the past to close atrial defects by closed technics, i.e., without actually opening the heart. Atrioseptopexy (Bailey) and circumclusion (Sondergaard, Crafoord, and Björk) were typical of these methods in which the walls of the dilated right atrium were brought into the repair. Other modifications of these technics were used but are gradually being discarded in favor of open technics. An ingenious semiopen method was used in which a rubber funnel was sutured to the side of the right atrium (Gross). Upon opening the atrium the atrial well filled with blood and repair of the defect was accomplished in the depths of the pool of atrial blood. Recently more satisfactory methods of repair have been devised in which the heart is opened for repair under direct vision using general body hypothermia or temporary cardiopulmonary bypass and a pump oxygenator. By the former technic body temperature is reduced artificially under general anesthesia by cooling blankets or by immersion of the pa-

birth, however, the lungs expand and assume function, and blood flow through the lungs becomes necessary for oxygenation. The shunting of blood from the pulmonary bed through the ductus arteriosus then becomes unnecessary as well as undesirable. Although this vessel is normally patent at birth, it soon undergoes obliteration after birth and in most individuals is completely closed within a few weeks to a few months. In some instances, however, closure of the ductus may be delayed for as long as six months to two years. Its failure to close beyond this period constitutes an abnormality and may produce serious disturbances.

In this connection, persistent patency of the ductus may be associated with other congenital cardiac abnormalities, such as complete pulmonary atresia, coarctation, truncus arteriosus, and transposition of the great vessels. Its failure to close under some of these circumstances represents a different problem since it may thus serve an essential function in maintaining life by providing blood flow to the lungs. Reference to its association with these conditions is made elsewhere and this section is devoted to its occurrence as an isolated abnormality.

Although various theories have been proposed to explain the mechanism by which normal closure of the ductus takes place, none is entirely satisfactory. According to some observers, normal closure of the ductus represents an inherent tendency through certain basic characteristics of its tissue. This may be effected through a reflex mechanism,

patient has reached adult life, although on close questioning many of these patients recall their inability to keep up with their playmates during childhood. Less commonly, manifestations of frank cardiac failure occur.

Physical findings in this condition are usually so characteristic that the diagnosis can often be made on this basis alone. The most striking finding, which may be considered pathognomonic, is the presence of a continuous "machinery" murmur. It is usually heard best in the second or third interspace just left of the sternal border and has a harsh, rasping, rumbling quality. Continuous throughout both systole and diastole, the murmur is greatly accentuated during systole, and this element of the murmur may be transmitted widely over the precordium and into the neck, axilla, or back. In many cases, a thrill, similar in location and quality to the murmur, may be elicited. In some instances and particularly those with a high pulmonary pressure, the typical continuous murmur may not be present and only a systolic murmur may be heard.

Characteristically, the heart tends to be normal in size or only slightly enlarged. The blood pressure may be entirely normal but more often tends to show an increased pulse pressure with a slightly decreased diastolic pressure which may become more pronounced on exercise, particularly in cases with a large ductus.

Laboratory findings including electrocardiographic studies are usually within normal limits. Occasionally, in patients with beginning cardiac embarrassment, the electrocardiogram may show left axis deviation. Roentgenographic examination of the chest may show little or no abnormality, particularly if the ductus is small. In most cases, however, certain characteristic features may be recognized. The transverse dimension of the heart tends to be slightly to moderately increased and the pulmonary artery shadow along the left sternal border may be somewhat more prominent than normal (Fig. 38). The pulmonary vascular markings, particularly in the hilar regions, may be accentuated. Fluoroscopy may reveal more conspicuous pulsation of the pulmonary artery, and in some cases with a large shunt, a "hilar dance" produced by the increased amplitude of pulsations in pulmonary arteries may be observed.

The diagnosis of patent ductus arteriosus is not difficult in the great majority of cases and can be made on the basis of the characteristic manifestations, particularly the auscultatory findings described above. The major difficulty in diagnosis arises in the occasional cases in which the characteristic continuous murmur is not present. Under these circumstances further studies, including angiocardiography and cardiac catheterization, may be necessary to determine the correct diagnosis.

Treatment. Surgical closure or obliteration of the ductus constitutes effective treatment. This may be accomplished by simple ligation, but division and suture is the preferred method (Fig. 39). The risk of operation in uncomplicated cases is minimal, with an operative mortality of less than 2 per cent. In light of the potential hazards of this condition and the minimal risk of operation, operative treatment is recommended in all cases whether or not symptoms are present, except in the asymptomatic individual beyond the sixth decade of life. Unless symptoms occur, it is preferable to delay operation in infants until the child has reached the age of three or four years. In the presence of subacute bacterial endocarditis, preliminary penicillin therapy should be employed and operation performed about six months later if an effective response is obtained; if not, early operative treatment is indicated.

Under certain circumstances operative closure of the ductus may be inadvisable. These include particularly those associated with severe degrees of pulmonary hypertension with reversal of flow through the ductus or with other noncorrectable cardiac malformations in which the ductus is serving as a compensatory mechanism. With the use of open heart surgery by means of the artificial heart lung apparatus, some of these abnormalities associated with patent ductus are now amenable to operative treatment. In the presence, however, of a pulmonary artery pressure that approximates or exceeds systemic pressure, operation is probably inadvisable.

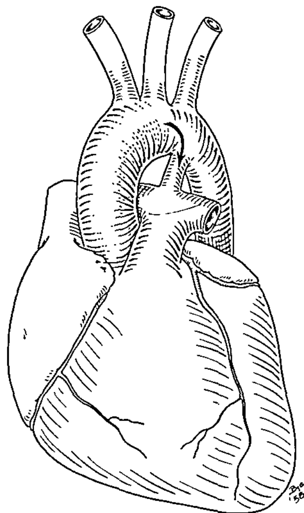

Fig. 37. Drawing showing anatomic relationship of patent ductus arteriosus.

possibly by way of the vagus nerve or by certain chemical constituents of the blood, particularly oxygen. Still another theory is based upon changes in anatomic relationship of the mediastinal structures which take place following birth and expansion of the lungs. While the role of these and perhaps other factors in initiating closure of the ductus is not entirely clear, its actual obliteration apparently results from certain characteristic morphologic changes which take place in the vessel consisting essentially in proliferation and thickening of the intima and media.

Persistent patency of the ductus arteriosus beyond the first year or two of life produces certain physiologic disturbances characteristic of an arteriovenous fistula. As indicated above, during fetal life the gradient of pressure in the pulmonary and systemic circulation permits blood to be shunted from the former to the latter circuits. Following birth, however, a reversal in this gradient of pressure takes place with an increase in aortic pressure and a decrease in pulmonary artery pressure. As a consequence, blood flow through the patent ductus is also reversed and is directed from the aorta to the pulmonary artery. The volume of flow through this abnormal channel is variable, depending upon the size of the ductus and the pressure gradients in the two circuits. The amount of blood which may be shunted in this manner has been studied by a number of observers who have found that it may range from about 2 to almost 20 liters per minute. According to these investigations, the volume of blood thus shunted may represent from 45 to 70 per cent of the total left ventricular output. Obviously, the major consequence of this abnormal blood flow from the systemic to the pulmonic circuits is to impose an increased workload upon both ventricles.

Although this physiologic disturbance in circulation may be well tolerated in some individuals, particularly in the presence of a relatively small shunt, in most cases it is associated with certain disturbances and complications that may have serious import. These include particularly retardation in growth and development owing to diminished peripheral blood flow, cardiac embarrassment, or failure as a result of the increased workload on the heart, and infection usually with *Streptococcus viridans* with the production of subacute bacterial endocarditis.

Clinical Considerations. For undetermined reasons, this malformation occurs somewhat more frequently in females than in males, the respective ratio being about two or three to one. Symptoms produced by the lesion are variable depending upon the size of the ductus, the amount of blood shunted through it, and the occurrence of complications. In some cases no significant manifestations occur and the patient may lead a normal existence well into an advanced age. More often, however, there develop mild to moderate degrees of cardiac disturbances manifested by dyspnea, palpitation, and tachycardia, especially following excessive exercise. Easy fatigability and poor exercise tolerance may become apparent only after the

Fig. 40. Diagram showing types of anomalous drainage of pulmonary veins: a, partial anomaly of the right pulmonary vein is present, emptying into right atrium. In b and c are shown the commonest types of total anomalous drainage of pulmonary veins.

Fig. 38. Roentgenogram of chest in patient with patent ductus arteriosus showing characteristic features of slight increase in transverse dimensions of heart, increased prominence of pulmonary artery shadow along left sternal border and somewhat accentuated pulmonary vascular markings.

ANOMALOUS DRAINAGE OF PULMONARY VEINS

Drainage of pulmonary venous blood into the right atrium or into the systemic veins produces a left-to-right vascular shunt with physiologic effects similar to atrial septal defect. Indeed, in most instances, anomalous pulmonary venous drainage and atrial septal defect occur concomitantly. Although at one time considered to be rare, Brody's review of 106 collected cases in 1942 focused attention upon this anomaly; and recently such anomalies have proved to be common abnormalities. The type of lesion may vary in many respects depending upon whether partial or total anomalous pulmonary drainage is present and upon the location of entry of the abnormal communication (Fig. 40).

Partial anomalous drainage usually occurs from the right lung in which the connection is into the superior vena cava, right atrium, or inferior vena cava. Partial anomalous venous drainage from the left lung is less common than right pulmonary anomalies. In right sided anomalies drainage into the superior vena caval system by a trunk leading to the left innominate vein is the predominant type. In many instances, anomalous drainage may occur at more than one point. Differential diagnosis between partial transposition of anomalous veins and an interatrial septal defect may be difficult even with the use of cardiac catheterization because in both situations oxygenated blood is present in the right auricle, right ventricle, and pulmonary artery. In most instances of partial anomalous pulmonary venous drainage, the volume of left-to-right shunt is less than in the average atrial septal defect. Usually the volume of left-to-right shunt does not exceed

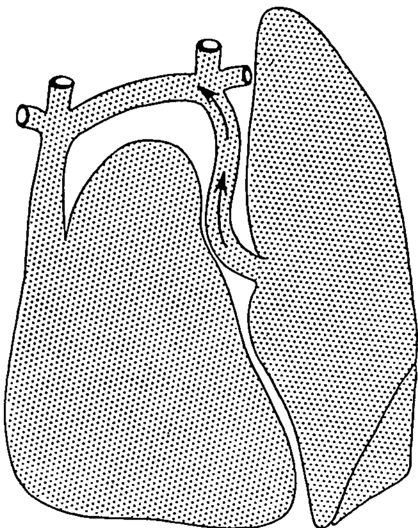

Fig. 41. (Cont.) Diagrammatic representation of x-ray on facing page.

lesion is incompatible with life. In most instances this communication is a patent foramen ovale or septum secundum type of atrial defect. Prognosis in most instances is poor and death usually occurs during the first few months of life unless surgical correction is undertaken. Cyanosis may occur with total anomalous venous drainage since mixed venous and arterial blood must gain access to the left atrium via an atrial septal defect. In some patients, therefore, and particularly in those with a large atrial communication, cyanosis may be severe. In general, however, the larger the atrial defect the better the prognosis for survival.

Surgical treatment of anomalous pulmonary venous return may not be necessary if only a single segmental pulmonary vein empties anomalously, such as is common with the right upper lobe draining into the superior vena cava. When the volume of drainage is large and an entire lobe or more drains anomalously, indications for surgical correction are the same as for atrial defects. At present partial anomalous pulmonary drainage is relatively simple to repair during cardiopulmonary bypass by open cardiac technics. In most instances the anomaly is repaired by transposing the septum during repair of the associated patent foramen or atrial septal defect. In instances in which the left lung drains separately into the left in-

50 per cent of total pulmonary flow, whereas shunts of 70 to 85 per cent are not uncommon with atrial septal defects. When the partial drainage is into the left innominate vein, the presence of blood of high oxygen saturation in this vessel may confirm the diagnosis at the time of cardiac catheterization.

Partial anomalous pulmonary venous drainage may be associated with an excellent prognosis depending upon the volume of shunt produced. If a significant shunt exists, the same clinical symptoms and findings are present as for atrial septal defect. Cyanosis is not characteristically a feature of this anomaly. Total anomalous drainage may exist in several anatomic types. In the most common type the pulmonary veins enter a common venous trunk which empties into the superior vena caval system via the left innominate vein (Fig. 41). Drainage may occur directly into the right atrium as a separate posterior opening or may join the coronary sinus and empty with coronary venous blood into the coronary sinus ostium. In a rare type of drainage the pulmonary venous trunk enters the inferior vena caval system usually connecting with the hepatic vein. In all cases of total anomalous venous drainage, an intracardiac communication between right and left sides must be present, otherwise the

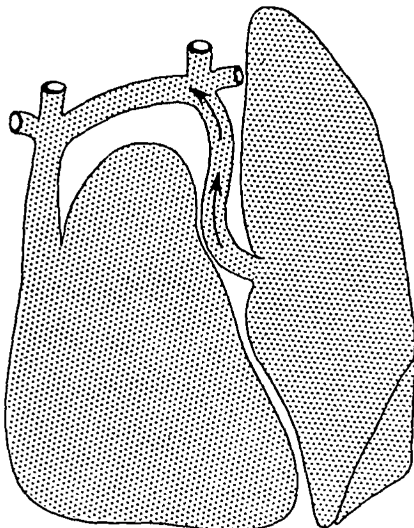

Fig. 41. (Cont.) Diagrammatic representation of x-ray on facing page.

lesion is incompatible with life. In most instances this communication is a patent foramen ovale or septum secundum type of atrial defect. Prognosis in most instances is poor and death usually occurs during the first few months of life unless surgical correction is undertaken. Cyanosis may occur with total anomalous venous drainage since mixed venous and arterial blood must gain access to the left atrium via an atrial septal defect. In some patients, therefore, and particularly in those with a large atrial communication, cyanosis may be severe. In general, however, the larger the atrial defect the better the prognosis for survival.

Surgical treatment of anomalous pulmonary venous return may not be necessary if only a single segmental pulmonary vein empties anomalously, such as is common with the right upper lobe draining into the superior vena cava. When the volume of drainage is large and an entire lobe or more drains anomalously, indications for surgical correction are the same as for atrial defects. At present partial anomalous pulmonary drainage is relatively simple to repair during cardiopulmonary bypass by open cardiac technics. In most instances the anomaly is repaired by transposing the septum during repair of the associated patent foramen or atrial septal defect. In instances in which the left lung drains separately into the left in-

Common pulmonary venous trunk* is ligated in superior mediastinum after anastomosis is completed.

nominate vein, this connection may be divided and the vein anastomosed directly into the left auricular appendage without using cardiopulmonary bypass (Fig. 42).

Surgical correction of total anomalous pulmonary venous drainage must be done, using temporary cardiopulmonary bypass. Depending upon the type of anomaly this may be accomplished by repositioning the atrial septum toward the right in order to permit entry of the veins into the left atrium. In the most common form of total anomaly the common venous trunk entering the superior vena cava is ligated and an anastomosis between the retrocardiac vessel and the left atrium must be done. Several successful cases of this difficult type of repair have recently been reported, indicating that virtually all cases of anomalous pulmonary venous drainage are now amenable to surgical correction.

SINUS OF VALSALVA FISTULA

Rupture of an aneurysm of the sinus of Valsalva at the root of the aorta is a rare cardiac lesion which may lead to development of a fistulous communication between the aorta and a cardiac cavity. Usually the rupture occurs into the right ventricle or right atrium, producing a left-to-right circulatory shunt. Not all aneurysms of the sinus rupture. They may persist as more or less silent lesions. The aneurysm itself represents a congenital defect in the aortic annulus and its sinuses of Valsalva, but rupture usually does not occur until after the first few years of life. At the site of the aneurysm the aortic media does not contribute to the wall of the sinus, and the sinus wall is formed by surrounding tissues, usually the right atrium or right ventricle. These tissues are incapable of withstanding aortic pressure and subsequently an aneurysm is formed.

Sinus of Valsalva fistula produces striking physical findings, being associated with aortic insufficiency and a circulatory shunt. Thus, a loud systolic and diastolic murmur of almost machinery quality is audible along the left sternal border. This finding, together with a widened pulse pressure, makes this condition easily mistaken for patent ductus arteriosus. Other conditions from which the lesion must be differentiated are anomalous communication of a coronary artery with coronary vein, coronary sinus, or atrial cavity.

Cardiac enlargement usually occurs and ultimately left ventricular failure ensues. Diagnosis may be made by retrograde aortography, and cardiac catheterization is useful to locate the position of the fistulous opening.

Surgical treatment has been reported in a small number of patients in whom open cardiac technics were used for temporary cardiopulmonary bypass. Right ventriculotomy or atriotomy is used to expose the intracardiac fistulous opening for repair. Sometimes after repair of the fistula aortic regurgitation persists.

AORTICOPULMONARY SEPTAL DEFECT

A congenital defect of the aortic septum producing free communication between the ascending aorta and adjacent main pulmonary artery is a rare anomaly often producing serious physiologic disturbance and a massive left-to-right shunt. Several descriptive terms have been suggested for this lesion, including aorticopulmonary septal defect, aorticopulmonary fistula, and aortic window or fenestration. Until recently clinical diagnosis was not possible, but with developments in angiography, aortography, cardiac catheterization, and dye dilution studies the diagnosis may be made with some accuracy. Usually the expected continuous murmur is not present and only a systolic murmur with accentuated pulmonary second sound is heard.

Surgical repair of the lesion without cardiopulmonary bypass is hazardous and death from hemorrhage is a serious threat. Recently the complete repair of aorticopulmonary septal defect with cardiopulmonary bypass has been successful and is now considered the method of choice in such lesions.

COR TRIATRIATUM

In this rare anomaly the left atrium is divided by a septum into two chambers. One or more openings must exist in the septum in order for the patient to survive. In patients with a large communication, no symptoms may be manifest and the lesion is an incidental finding at autopsy. If the opening is sufficiently small to produce significant obstruction to pulmonary outflow, a clinical picture similar to mitral stenosis may be produced. When a patent foramen ovale is also present, a right-to-left shunt is produced and cyanosis may result.

The most logical embryologic explanation of this anomaly is that it represents a failure of the embryologic common pulmonary vein to incorporate normally into the posterior aspect of the left atrium. The third chamber is nothing more than a dilated common pulmonary vein. Surgical treatment has been made possible by the technics of open heart surgery including both general body hypothermia and temporary cardiopulmonary bypass with pump oxygenator.

EBSTEIN'S DISEASE

This anomaly consists of a downward eccentric displacement of the tricuspid valve into the right ventricle. The anterior leaflet

of the tricuspid valve is usually normally placed and the septal leaflet is attached to the ventricular septum in an anomalous manner. The septal leaflet may be functionless but in many instances forms an obstructive flap to outflow of the right ventricle. The posterior leaflet arises below the annulus usually having no connection with the atrioventricular ring. Considerable variation usually exists in the number and position of papillary muscles and chordae tendinae.

As a result of the downward displacement of the valve, a portion of the right ventricle becomes a functional part of the right atrium. A patent foramen ovale is common, and because of the increased right atrial pressure produced by tricuspid incompetence, a right-to-left shunt and cyanosis result. Dyspnea, cardiac enlargement, and signs of right sided failure are common in this malformation. Although some patients live into adulthood, prognosis is usually poor and sudden death is frequent.

Surgical treatment has been attempted by Kirklin and associates with some success. Closure of an interatrial communication may relieve cyanosis. Relief of outflow obstruction in the right ventricle by revising the septal leaflet of the tricuspid valve may enhance right ventricular propulsion and relieve cardiac failure to some degree. Nevertheless, results are still somewhat equivocal and because of the complex nature of the lesion indications for operation are controversial.

COMPLETE TRANSPOSITION OF THE GREAT VESSELS

In this anomaly the aorta arises directly from the right ventricle and the pulmonary artery from the left. Various theories have been advanced for the cause of this developmental abnormality which indicate that improper rotation and torsion of the aortic septum and great vessels result in failure to fuse properly with the upper margin of the ventricular septum. This condition leads to a severely cyanotic state since unoxygenated venous blood entering the right ventricle is pumped directly into the aorta. Oxygenated blood from the pulmonary veins enters the left atrium, after which it enters the left ventricle and is returned to the pulmonary circulation via the pulmonary arteries (Fig. 43). In order for this lesion to be compatible with life even for a short time, some communication between the systemic and pulmonary circuits must be present to permit interchange of oxygenated and unoxygenated blood. Three possible communications are a patent foramen ovale, a patent ductus arteriosus, or a ventricular septal defect. The foramen ovale and ductus arteriosus are normally patent before birth but have a tendency to close after birth, leading to increased cyanosis. A ventricular septal defect is a more effective type of shunt in these patients for relief of cyanosis, since it has no tendency to close spontaneously. The majority of patients with uncomplicated transposition usually have a combination of two or even all three of these associated defects.

Prognosis in complete transposition of the great vessels is poor. Lillehei and Varco reported only 4 per cent of patients in collected series were alive at seven years of age and 78 per cent of the group died during the first year of life. Cyanosis may or may not be present at birth but becomes evident and intense shortly thereafter, particularly if the cardiac septa are intact. If an adequate interchange of blood between the two sides of the heart is present, it is remarkable how normal the infant may appear except when crying. Sooner or later in complete transposition the cyanosis usually becomes intense. Underdevelopment and malnutrition are almost inevitable if the patient survives the first six months of life. Long, thin fingers with almost flail interphalangeal joints are typical and severe clubbing of the nails is common.

Physical examination usually reveals cardiac enlargement. Murmurs are variable and not diagnostic since they may reflect changes in intracavitary pressure, valvular defects, and varying direction of shunts. Cardiac failure usually is present in varying degree, manifested by hepatomegaly and distended pulsatile neck veins. Death is usually caused by anoxemia or cardiac failure. Cerebral infarctions and abscesses are an occasional cause of death.

Roentgenographic examination reveals cardiac enlargement of both right and left ventricles with a waistlike narrowing at the base due to the alignment of ascending aorta

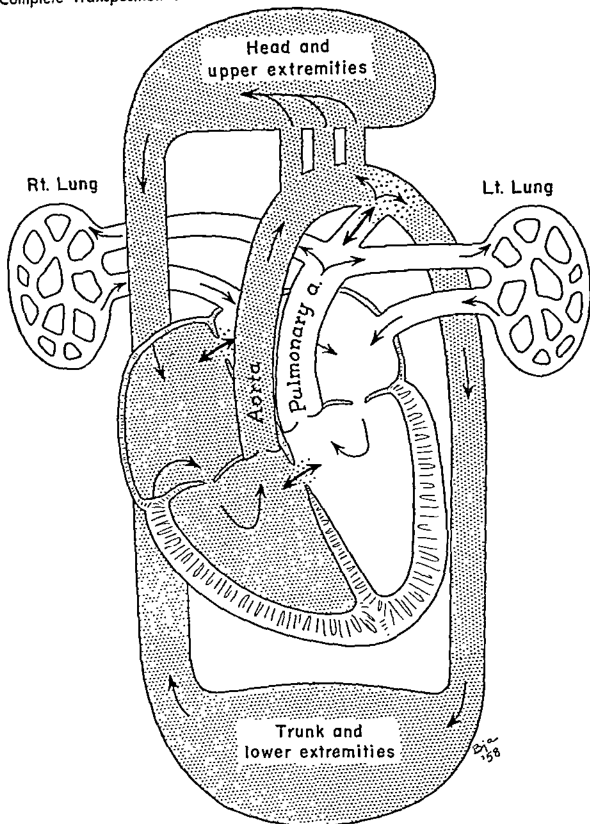

Fig. 43. Diagram showing course of circulation in complete transposition of great vessels. Since the aorta arises directly from the right ventricle, unoxygenated blood gains ready access to the systemic arterial system.

Fig. 44. Roentgenograms of chest in patient with complete transposition of great vessels. Above, an anteroposterior film shows the narrow superior mediastinum, vascular lung fields, and cardiac enlargement; below, an angiocardiogram in lateral position reveals anterior position of aorta arising from the right ventricle.

and pulmonary artery in the anteroposterior projection. Usually pulmonary vascular markings are accentuated. Angiocardiography in the lateral view shows a characteristic anterior position of the ascending aorta arising from the right ventricle (Fig. 44). Electrocardiograms show right ventricular hypertrophy usually with right axis deviation, but since the left ventricle may also be hypertrophied a normal electrical axis may be present.

Surgical repair of complete transposition of great vessels continues to challenge cardiac surgeons. Blalock and Hanlon reported creation of an interatrial septal defect to provide an intracardiac communication. This technic may be accomplished by closed cardiac technics and is still considered to be the simplest and possibly most effective of the palliative procedures. Others including Varco and Lillehei, and Baffes have tried transposition of venous inflow to compensate for the anomalous origin of the aorta and pulmonary artery. Although palliation with improvement in cyanosis has resulted in some instances of partial correction by transfer of venous inflow, results have not been particularly encouraging and operative mortality is high. An ideal operation which would totally correct the anomaly could theoretically be done by changing the origin of the arterial outflow or by transposing venous inflow. Recently the pump oxygenator has been used with attempts at repair, using both of these technics, but to date not a single survivor of total correction of complete transposition of the great vessels has been reported.

EISENMENGER COMPLEX

In this anomaly a dextroposed aorta which partially overrides the ventricular septum is associated with a high ventricular septal defect. Thus in some respects the anomaly resembles tetralogy of Fallot, but pulmonary stenosis is not present. Pressure in the two ventricles is similar and accordingly pressure in the pulmonary artery is elevated. The direction of flow through the ventricular defect depends upon the relative resistance in the pulmonary and systemic circuits. Sclerotic and obliterative changes in the pulmonary arterioles lead to a severely elevated pulmonary resistance, and a right-to-left shunt occurs at the ventricular level, ultimately producing cyanosis.

Cyanosis is usually absent in infancy and childhood. The subsequent development of cyanosis during adolescence is frequently diagnostic of Eisenmenger complex. Clubbing of the fingers and toes is relatively slight, since the degree of anoxemia is minor compared to other cyanotic heart diseases. Hemoptysis occurs in advanced cases. Cardiac findings are variable, but right ventricular hypertrophy is always present. A systolic murmur may be present and an accentuated pulmonary second sound is typical. Increased pulmonary pressure may lead to a functional incompetence of the pulmonary valve manifested by a Graham Steell murmur. Although hilar pulmonary vessels are large roentgenographically, peripherally the lungs may appear ischemic, due to the reduced arteriolar flow.

Surgical treatment of this lesion in its advanced stages is not possible because the pulmonary vascular resistance prevents repair of the ventricular defect. The interventricular defect serves as a safety valve releasing blood in the right ventricle into the aorta, thus preventing right side congestive failure. Drugs for reducing pulmonary hypertension will probably be developed and symptomatic relief may result, but at present oxygen inhalations are the only effective method of providing relief of symptoms.

TRUNCUS ARTERIOSUS

This anomaly is characterized by the presence of a single great vessel of large caliber which receives all of the blood from both ventricles. Blood is directed from the truncus to the systemic and pulmonary circulations. Pulmonary circulation may be derived from the trunk directly or from collateral channels developed from bronchial arteries. Coronary arteries arise from the base of the common trunk which, after giving off vessels to supply the lungs, continues as the aorta to the systemic arterial system. Since the truncus arises from both ventricles, it overrides the ventricular septum. A ventricular septal defect is therefore an integral part of the malformation. The malformation causes cardiac enlargement and hypertrophy of both

ventricles. Pulmonary hypertension is frequently a sequela to this defect.

Satisfactory surgical treatment of this lesion in its true form is not possible at present. Because of lack of sufficient cuspal tissue in the aortic and pulmonic valves, creation of separate valves and main vessels does not appear to be feasible.

ENDOCARDIAL FIBROELASTOSIS

Thickening of the mural endocardium by elastic and collagenous connective tissue characterizes the primary pathologic derangement of endocardial fibroelastosis. The left ventricle is most commonly involved, although a similar process has been described in all cardiac chambers. The etiology remains uncertain although numerous causative factors have been suspected.

On the basis of its appearance two types of endocardial fibroelastosis of the left ventricle may be distinguished: the contracted type and the dilated type. The final result is a thickened endocardium limiting expansion and contraction of the left ventricle. Progressive impairment in pulmonary venous drainage produces effects on the pulmonary circulation and right ventricle similar to those of mitral stenosis. Survival beyond early childhood is uncommon.

There is no satisfactory treatment for this condition.

SURGERY OF ACQUIRED CARDIOVASCULAR DISEASE

MICHAEL E. DE BAKEY, DENTON A. COOLEY,

GEORGE C. MORRIS, JR., AND E. STANLEY CRAWFORD*

WOUNDS OF THE HEART

Wounds of the heart have attracted interest since the beginning of civilization. In the ninth century B.C., Homer described vividly the movement of the human heart transmitted through a spear: "The hero Idomeneus smote him in the midst of the breast with the spear. . . . And he fell with a crash, and the lance fixed in his heart, that, still beating, shook the butt end of the spear." The ancients considered wounds of the heart necessarily fatal, a concept that predominated until the end of the last century. Important isolated advances, however, had been made before that time. In 1761 Morgagni pointed out the danger of compression of the heart due to hemorrhage into the pericardium and thus originated the concept of pericardial tamponade. Larrey, Napoleon's surgeon, is credited with performing the first successful pericardicentesis in 1829.

Types. PENETRATING WOUNDS. These are the most frequently encountered cardiac wounds among civilian patients who do not die immediately. They are made by knives, icepicks, and other sharp instruments. The site of entry most commonly is the left parasternal region in the precordial portions of the second through the seventh ribs. Because of its vulnerable anterior position, the right ventricle is injured more than twice as often as the left ventricle (Fig. 1). Less frequently injured are the atria and the intrapericardial portions of the great vessels. The predominance of penetrating over perforating injuries has also been observed in military surgery. In 2,811 chest casualties of the Korean conflict treated at Tokyo Army Hospital, 117 had injuries of the heart and mediastinum. In the latter group, 90 per cent were penetrating wounds usually caused by shell fragments.

PERFORATING WOUNDS. These are characteristically produced by bullets. Usually there are two or more perforations in one or more cardiac chambers. Generally, cardiac wounds inflicted by large caliber firearms are immediately fatal, but patients with wounds caused by smaller caliber weapons sometimes live long enough to permit transportation to emergency centers. Gunshot wounds may enter the heart from any direction.

CLOSED INJURIES OF THE HEART. Types of closed cardiac injury include: 1. direct contusion from forces exerted against the wall of the chest or spine; 2. tearing injuries associated with the suspensory anatomy of the heart; 3. concussion producing multiple

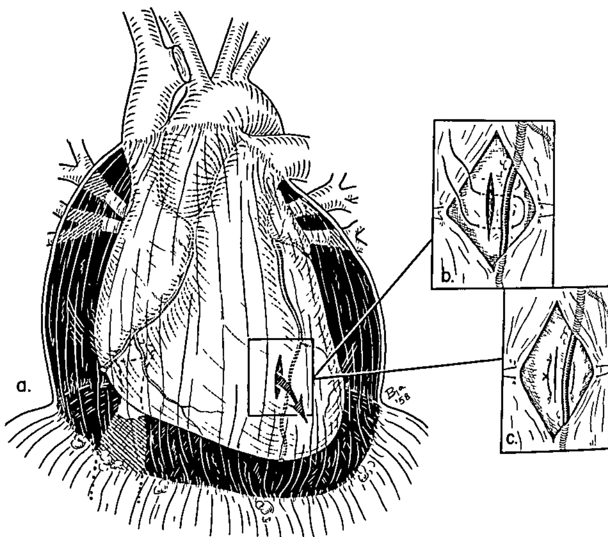

Fig. 1. a, schematic drawing of the heart and pericardium showing the effect of cardiac tamponade. Increased intrapericardial pressure compresses the venae cavae and pulmonary veins impeding venous return of blood to the heart. b, method of suture repair of wound adjacent to anterior descending branch of left coronary artery. c, tied horizontal mattress suture closes ventricular wound but does not impair blood flow through the coronary artery.

minute hemorrhages and often alterations in the autonomic control of the heart; 4. intracavitary pressure changes within the heart due to compression of distant parts, such as the abdomen and extremities; 5. subintimal coronary hemorrhages usually associated with atheromatous plaques and resulting in reduction of the lumen of the coronaries; and 6. secondary myocardial changes associated with shock, hemorrhage, and stress. In spite of Beck's prophetic writings on cardiac contusion in 1935, there remains general lack of awareness of this common injury among physicians. Indeed, in most hospital record libraries, this diagnosis is infrequently recorded. The most common cause of such injuries is the automobile steering wheel. In our experience, significant electrocardiographic changes almost invariably are demonstrable in patients with steering wheel injuries associated with external evidence of precordial contusion when serial tracings are performed. These electrocardiographic alterations may vary from minor T-wave depression to a picture of severe myocardial infarction. The changes may persist for weeks or months, and in an occasional patient exertional angina persists indefinitely. Usually, cardiac injuries from blunt force cause only myocardial contusion and recovery is uneventful. The medicolegal implications of such injuries, however, will undoubtedly become a significant problem. Such injuries may rupture the pericardium, myocardium,

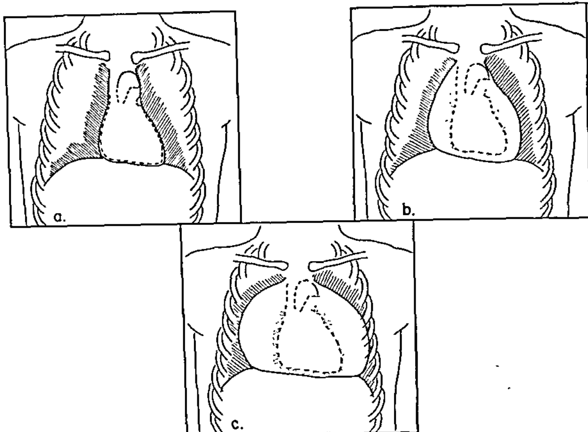

Fig. 2. Schematic drawing of cardiac silhouette in: a, normal condition; b, acute cardiac tamponade; and c, chronic pericardial effusion. The inelastic fibrous pericardium does not allow the massive pericardial enlargement in acute tamponade common with chronic effusion or delayed tamponade.

cardiac septa, or valves. Delayed hemopericardium may produce cardiac tamponade. Constrictive pericarditis may present a late complication. An unusual type of closed cardiac trauma is exemplified by the recent report of a man caught in a sand cave-in and buried only to the level of the waist. He died instantly and post-mortem findings included laceration of the interventricular septum and papillary muscles of both ventricles.

Clinical Considerations. Successful therapy of cardiac wounds depends on timely diagnosis. Few surgical emergencies require such prompt clinical evaluation. In such emergencies, sometimes successful treatment will depend on a diagnosis derived from a single glance at a moribund patient with a precordial wound. The diagnosis, however, is often not obvious and sometimes can be made only if the examiner is constantly aware of this possibility. Important also is a thorough understanding of the hemodynamic alterations associated with cardiac wounds. The lethal factors, in order of frequency, are pericardial tamponade, exsanguinating hemorrhage, and intrinsic cardiac damage. The physiologic derangement of cardiac tamponade results from collection of blood in the relatively inelastic pericardium, producing interference with return of blood from the venae cavae and pulmonary veins (Fig. 2). The critical level of pericardial pressure, as determined in our laboratory, is 20 cm. of saline. If such pressure is even slightly increased in the experimental animal, venous pressure and pericardial pressures become equalized, arterial pressure rapidly falls, and cardiac action ceases. These studies in reverse demonstrate the resuscitative effect of pericardicentesis in cardiac tamponade and strikingly reveal that as little as 5 to 10 ml. of aspirant has immediate influence upon recovery of circulation.

Beck proposed the diagnostic triad of the

quiet heart, increased venous pressure, and hypotension. Other classic signs of pericardial tamponade include a narrow pulse pressure, dusky cyanosis, and a decreased pulse rate. Roentgenograms provide less diagnostic information in acute tamponade than in the chronic form, since the relatively inelastic pericardium does not immediately become greatly distended. In chronic or delayed tamponade, an enormous cardiac silhouette is frequently demonstrated roentgenographically, and several liters of bloody fluid can often be aspirated (Fig. 2). In an occasional doubtful case of acute tamponade, fluoroscopy may be of value.

If the opening in the pericardium is adequate for the egress of blood, no tamponade will occur and clinical signs will be those of hemorrhagic shock. In addition, occasionally there is a picture of deranged pulmonary function due to massive hemothorax or pneumothorax. Rarely, valvular and septal ruptures are immediately evident. In most instances such intracardiac derangements become apparent several days after injury with the appearance of murmurs or cardiac failure. Blunt trauma to the heart may produce direct myocardial damage from contusion or from ischemia associated with damage to the coronary artery. In such cases, there may be no signs of tamponade and hemorrhage, and hypotension may be the only presenting sign. Often the heart tones may have a "tick tick" quality due to epicardial and pericardial injury. Shock from cardiac contusion is less favorably responsive to intravenous administration of fluids and vasopressor agents. Electrocardiographic alterations may vary from minor T-wave depression to those of massive myocardial infarction.

Treatment. The first successful suture of a human cardiac wound was performed by Rehn in 1896. Within 10 years after this pioneering achievement, it was possible to collect 124 cases of cardiorrhaphy with recovery in 40 per cent of the patients. Until the past decade emergency cardiorrhaphy was generally considered the treatment of choice in cardiac wounds, and in this country a number of surgeons accumulated wide experience with this method of treatment. The operative mortality rate, however, remained high, ranging from 30 per cent to more than 50 per cent. Although pericardicentesis had been employed previously, the rationale of this method combined with replacement of blood and other fluids as definitive treatment in cardiac injuries was first recommended by Blalock and Ravitch in 1943. Since then, several reports of such management have indicated a mortality rate below that of cardiorrhaphy. Obviously, not all cardiac wounds are amenable to conservative management, and cardiorrhaphy may be necessary for survival. If the best of previous clinical experience is to be applied to the individual patient, keen surgical judgment must be exercised in the choice of conservative versus operative management or the combination of these modalities.

Emergency treatment of cardiac injuries is based upon prompt relief of pericardial tamponade. When the pericardial pressure reaches 20 cm. of saline or more, aspiration of as little as 5 to 10 ml. has an immediate influence upon recovery of circulation. Commonly, pericardicentesis is necessary only once, because patients with penetrating injuries who survive long enough to reach a hospital usually have small wounds. These tend to become sealed by clots with the aid of pericardial tamponade. Pericardial aspiration may be performed repeatedly if signs of recurring tamponade appear. Blood lost by aspiration is replaced by transfusion, and occasionally continuous autotransfusion of aspirated blood may be lifesaving while preparations for cardiorrhaphy are being made. Incoagulable blood from pericardicentesis is assumed to have come from the pericardial sac, whereas if a coagulum forms, the blood may have been withdrawn from a cardiac chamber. The paraxyphoid route for aspiration is preferable to precordial interspace approaches because coronary injury is less likely.

In previous years intravenous administration of blood and other fluids was thought to be contraindicated since they elevate venous pressure and tend to increase the constricting force of intrapericardial fluid pressure. It has been repeatedly demonstrated experimentally and clinically that intravenous administration of fluids tends to increase arterial pressure. Vasopressor agents also have a favorable in-

fluence on arterial pressure in the presence of pericardial tamponade.

One must always be prepared to perform cardiorrhaphy since a significant number of patients will continue to bleed profusely. An incision in the left anterior fourth or fifth interspace permits rapid entrance into the chest with adequate exposure. Torrential hemorrhage may be controlled with a finger or sponge over the wound, but the friable myocardium may be further torn if a finger is placed through the defect. In wounds adjacent to the anterior descending branch of the left coronary artery, an on-end mattress suture may preserve the vessel. The pericardium should be left open or closed loosely to avoid delayed collections of pericardial fluid. It must be pointed out that, in at least two centers where large numbers of penetrating injuries of the heart are treated, primary surgical repair is still favored over initial conservative management.

Closed injuries of the heart with contusion are treated essentially the same as is myocardial infarction. The period of bed rest is properly governed by the time necessary for the electrocardiographic changes to return to normal.

Periodic observation of all patients with cardiac injury is essential. Delayed effusion and chronic tamponade may develop months after the initial injury. Traumatic intracardiac shunts and valvular injuries may not be evident for days after the injury. Such intracardiac defects are now amenable to definitive open repair using cardiopulmonary bypass. Some retained foreign bodies within the heart or pericardium must be removed.

CHRONIC CONSTRICTIVE PERICARDITIS

Chronic constrictive pericarditis is a disease involving thickening and contraction of the pericardium or epicardium with the hemodynamic alterations associated with an imprisoned and restricted heart. The principal circulatory defect is limitation of diastolic filling of the ventricles. Common eponyms are Pick's disease and syndrome of Delorme. Lower was the first to describe constrictive pericarditis as a pathologic entity, in 1669. It was not until 1895, however, that Weill predicted surgical cure when he stated, "It will one day come within the province of surgery to deliver the heart from the shell which strangles it." Several years later Delorme, on the basis of careful observations made on cadavers, recommended operative treatment by lysis and excision of the adherent pericardium, but his proposal at that time was not favorably received. Rehn reported the first successful pericardiectomy in 1913. At the time of Churchill's report in 1929, representing the first surgical success in the United States, 37 cases of pericardiectomy had been published. The slow acceptance of pericardiectomy for constrictive pericarditis was, in part, a result of some confusion in the pathologic anatomy and physiology of the lesion. Brauer advocated an operation that consisted of resection of the precordial portions of the ribs and sternum in the belief that the heart was immobilized by fibrous scars attached to the anterior chest wall. Schmieden's report of seven surgically treated patients in 1926 and Churchill's thoughtful analysis of the problem published a few years later firmly established pericardiectomy as the technic of choice.

Pathologic Features. Although tuberculosis can be established pathologically in less than one third of cases, it is considered to be etiologic in the majority, since symptomatic manifestations of the disease follow the stage of typically tuberculous healing when dense fibrous scar tissue with contraction oppresses the heart. Hence, tubercles and the organism itself have frequently long disappeared from the pericardium. Thickening of the pericardium is pronounced and may reach several centimeters. The parietal pericardium most commonly produces the constricting envelope about the heart, although occasionally the epicardium alone may be the restricting factor. Frequently the pericardial space is obliterated. Adhesions between the parietal and the visceral layers of pericardium do not cause significant interference with cardiac action. Such adhesions frequently follow rheumatic fever, which seldom, if ever, produces constrictive pericarditis.

Trauma with resulting hemopericardium and fibrous organization occasionally produces this condition. Constricting pleuritis may develop in a similar fashion with associated constrictive pericarditis. In this com-

Fig. 3. a, posteroanterior and b, lateral roentgenograms in a case of constrictive pericarditis. Calcification in the pericardium is present in more than 50 per cent of cases. It is noteworthy that there is no cardiac enlargement nor evidence of pulmonary congestion.

bination, pulmonary decortication may be as vital to surgical success as pericardiectomy. Other rare causes are cholesterol pericarditis and specific infections with staphylococcus and actinomycosis bovis.

Significant calcification is radiologically obvious in only about 50 per cent of cases, although tomograms will reveal at least slight calcification in most. A solid wall of calcium occasionally surrounds the entire heart, producing a striking roentgenographic picture (Fig. 3).

In chronic cases atrophy of the heart may occur, and it demands early operation. This atrophy is both histologic and gross and is not entirely reversible after pericardiectomy.

Physiologic Alterations. The principal circulatory defect in constrictive pericarditis is limitation in diastolic filling of the ventricles. This results in diminution in stroke volume and usually decreases cardiac output per minute even though compensatory tachycardia may be present. An elevated end diastolic pressure is characteristic, owing to lack of distensibility of the right ventricle. The resulting increase in right atrial pressure produces an increased venous pressure which ranges from 150 to 410 mm. H_2O. It is extremely unusual for a pressure gradient to exist between the superior or inferior vena cava and the right atrium. Accordingly, constriction of the caval orifices producing signs and symptoms of chronic constrictive pericarditis is unusual.

Spontaneous variations in venous pressure, which may be observed, are not usually related to alteration in cardiac output but rather to fluctuations in blood volume. Lyons has shown that intravenous administration of fluids to these patients may elevate venous pressure by 130 to 160 mm. H_2O, while phlebotomy may induce a decrease of 30 to 60 mm. H_2O.

Clinical Manifestations. The diagnosis of chronic constrictive pericarditis should be considered whenever a patient presents a picture suggesting congestive heart failure without the usual causes. Peripheral edema, ascites, hepatomegaly, and increased venous pressure are apparent, but pulmonary congestion, orthopnea, murmurs, and cardiac enlargement remain conspicuously absent. The characteristic features of chronic constrictive pericarditis include: 1. increased venous pressure; 2. edema, ascites, and pleural effusion; 3. quiet heart with normal or reduced blood pressure, normal sounds, and a paradoxical pulse; 4. electrocardiographic changes

including low voltage QRS and alterations of T waves; and 5. roentgenographic evidence of pericardial calcification.

The typical patient is seen in the third decade of life although the ages of patients range from 6 to 60 years. Venous distention with elevated venous pressure is always present. In more than 90 per cent of patients, hepatomegaly, peripheral edema, ascites, and tachycardia are also present. In more than 80 per cent, diminution in heart sounds, decreased blood pressure with paradoxical pulse, and pleural effusion are noted. Exertional dyspnea and cyanosis are common findings. All patients exhibit decreased cardiac pulsation on fluoroscopy. Kymograms show absence of diastolic thrust in the cardiac silhouette. Significant calcification is present in about half of these patients.

Cardiac catheterization is seldom necessary to complete the diagnosis. When performed, the elevated caval pressures equal right atrial pressure with no gradient. Myocardial fibrosis and endocardial fibrosis cannot be differentiated from chronic constrictive pericarditis by catheterization studies. Atrial fibrillation is present in nearly 25 per cent and is usually associated with chronic disease and myocardial atrophy.

Frequent mistaken diagnoses include congestive heart failure, cirrhosis, hepatitis, idiopathic polyserositis, and nephrosis. Congestive failure may be excluded by the findings of dry pulmonary fields and a small, quiet heart without murmurs. Although hepatic function is frequently impaired in patients with constrictive pericarditis, the presence of cervical venous distention should readily distinguish the condition from cirrhosis and hepatitis as well as polyserositis and nephrosis.

Treatment. Pericardiectomy for chronic constrictive pericarditis elicits one of the most dramatic surgical cures in the field of medicine. Diuresis usually begins in the immediate postoperative period. The chronically ill, water-logged patient with an abdomen distended by ascitic fluid usually gains a normal appearance within several weeks.

Digitalis in the preoperative preparation of these patients is usually contraindicated since it may further decrease cardiac output. A period of bed rest, restriction of salt and fluids, a high protein diet, and mercurial diuretics may aid in the attainment of an optimum condition for operation. Paracentesis for massive ascites may simplify anesthetization and pulmonary ventilation in the early postoperative period. The presence of tuberculosis activity in the pericardium indicates drug therapy but should not long defer surgical treatment.

Excellent exposure for decortication of both ventricles may be obtained through a bilateral anterior fourth or fifth interspace incision which transects the sternum (Fig. 4). Previous surgical failures were due in part to inadequate exposure through small left parasternal or interspace incisions. Complete decortication of the ventricles should be the surgical aim; further resection over the atria and intrapericardial portions of the great vessels is not essential and may add to the risk of operation. The left ventricle should be freed first to avoid sudden transference of peripheral congestion to the pulmonary bed. A cleavage plane usually can be developed over the epicardium and carefully advanced with sharp and blunt dissection (Fig. 4). Occasionally it is necessary to remove the epicardium as well. To safeguard the anterior descending branch of the left coronary artery, a small strip of adherent pericardium may be left along the path of this vessel.

Gratifying response to pericardiectomy can be expected in more than 80 per cent of patients. The two most common causes of operative failure are inadequate pericardial resection, and irreversible myocardial fibrosis and atrophy. The increased incidence of auricular fibrillation, myocardial fibrosis and atrophy with long duration of the syndrome of chronic constrictive pericarditis bespeaks the urgency of early diagnosis and surgical treatment.

MITRAL VALVULAR DISEASE

More than fifty years ago Brunton and later Samways suggested that since mitral stenosis was in essence a mechanical obstruction to circulation it should be amenable to surgical relief. In 1923 Cutler and Levine reported the first actual clinical attempts to relieve mitral stenosis by valvulotomy which met with no success. In the next few years others made unsuccessful attempts, and the

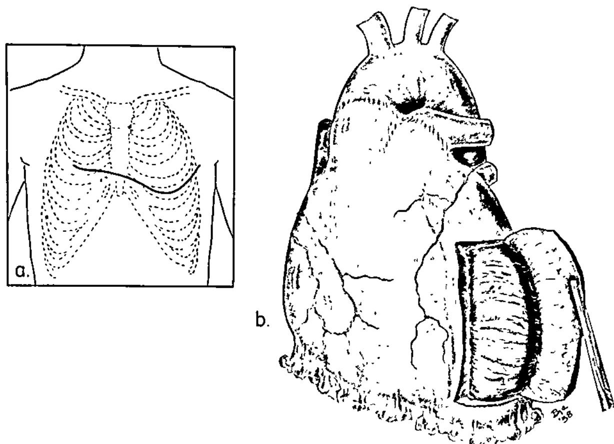

Fig. 4. a, line drawing showing modern incision for pericardiectomy. Such a sternal transecting bilateral interspace incision affords excellent exposure. b, tone drawing illustrating the initial dissection in pericardiectomy. The left ventricle should be freed first to prevent acute pulmonary vascular congestion. Note the bulging myocardium in the resected area.

problem was not attacked clinically again until the efforts of Smith, Bailey, Harken, and Brock soon after World War II. Since that time, surgical treatment of mitral stenosis has been developed and perfected by experience in literally thousands of operations. More recently operations for mitral regurgitation have been proposed and used in a relatively small number of patients with less satisfactory but nevertheless encouraging results.

Acute rheumatic fever and valvulitis is the usual etiologic factor in production of mitral stenosis or mitral incompetence. The initial rheumatic valvulitis occurs along the margin of the leaflets. If the cusps remain separate and only the margins are affected, the final result is permanent thickening and distortion of the edges of the cusps which are of no functional importance. Fusion of the cusps at the commissures of the valve where chordae tendinae insert leads to stenosis of the valve, interfering with mobility of the valve in opening and closing during the cardiac cycle. Thus, fusion and contraction of the chordae tendinae are just as much a part of the pathologic condition known as mitral stenosis as obstruction of the valve orifice. Calcification frequently occurs in rheumatic mitral valvulitis. Little is known definitely, however, why in some patients rheumatic inflammation leads to mitral stenosis while in others mitral regurgitation may be produced. In regurgitant lesions the circumference of the annulus may increase, interfering with apposition of the leaflets during systole. Several causes for mitral incompetence are recognized. Destruction of valve leaflets may result and is common when bacterial endocarditis is superimposed on the rheumatic process. Rupture of chordae tendinae or papillary muscle may occur and produces a serious degree of mitral incompetence, which is often rapidly fatal. It is remarkable, however, how severe the valvular involvement from rheumatic inflamma-

tion may become, with either stenosis or incompetence, before symptoms of congestive failure ensue. If the myocardium is not itself seriously involved, the heart has a remarkable capacity to compensate for involvement of the mitral valve. Such patients in many instances may have relief of symptoms by correction of the valvular dysfunction. On the other hand, rheumatic myocarditis in association with mitral valvulitis may lead to early congestive heart failure and death. In severe rheumatic myocarditis, the left atrium may be greatly distended to aneurysmal proportions. So-called giant atrium is usually associated with some degree of mitral regurgitation. For the purposes of this text the clinical and surgical aspects of mitral stenosis and insufficiency will be considered separately insofar as possible. Obviously patients may have degrees of both, but such complicated problems are outside the scope of this presentation.

MITRAL STENOSIS

So-called "pure" mitral stenosis produces typical symptoms. Dyspnea on exertion is the most prominent feature and is brought on by walking 50 to 100 yards or climbing a flight of stairs. Although fatigue at the end of a day may be described by the patient, this symptom is more commonly the complaint of patients with mitral regurgitation. In such cases, shortness of breath may be extreme and brief episodes of pulmonary edema may occur following exercise. Pulmonary hypertension results from the increased left atrial and pulmonary venous pressure. Pulmonary hypertension may lead to hemoptysis, a symptom characteristic of severe mitral stenosis. Extent of the hemoptysis varies from mild streaking of sputum to frank hemorrhage, sometimes leading to exsanguination or suffocation. Paroxysmal nocturnal dyspnea and orthopnea are also common. In far advanced pulmonary hypertension, functional pulmonic valvular insufficiency occurs. Subsequently, functional tricuspid insufficiency and signs of right ventricular failure ensue. Cyanosis occurs late in the disease and may be caused by a combination of pulmonary congestion, reduced cardiac output, and increased peripheral venous pressure. Peripheral embolism occurs more commonly in patients with mitral stenosis than with mitral insufficiency since in the former lesion severe stasis of blood in the left auricle leads to thrombosis. The clots tend to occur in the auricular appendage. Auricular fibrillation, which is a frequent finding in mitral stenosis, predisposes to auricular thrombosis. Moreover, the fibrillation which leads to frequent rapid changes in ventricular rhythm may dislodge a thrombus. The embolus may travel to the cerebral vessels where it may produce serious neurologic symptoms, hemiplegia, and death. Other vital areas of lodgment may be the aortic bifurcation, visceral vessels, or vessels of the extremities. In most instances, prompt surgical removal of the embolus (embolectomy) is indicated.

Mitral stenosis is characterized by a rumbling diastolic murmur at the apex with a crescendo presystolic murmur. An accentuated pulmonary second sound is audible. A Graham Steell murmur of functional pulmonic insufficiency may also be present. If auricular fibrillation occurs, the presystolic murmur may disappear.

Roentgenographically, a typical configuration of the heart in mitral stenosis shows right ventricular enlargement, dilated pulmonary artery, and left atrial appendage (Fig. 5). The left ventricle and aortic knob are inconspicuous. The left atrium is enlarged and encroaches on the esophagus posteriorly, but the chamber is not typically dilated as occurs in mitral regurgitation. Lungs may show chronic passive congestion and hemosiderosis. The electrocardiogram shows right ventricular and atrial hypertrophy with increased P waves.

Operative Treatment. Technics of operation in use for mitral stenosis all stress the importance of control or prevention of mitral regurgitation after valvulotomy by accurate control of extent and direction of the valvular dissection. In most of the earlier attempts valvulotomy was accomplished blindly, usually by introducing a valvulotome into the left ventricle in order to punch out, sometimes at random, a piece of the stenotic valve. In instances in which this purpose was accomplished, severe and frequently fatal mitral insufficiency was produced. It is now well recognized that valvulotomy must be done by division of only the point of fusion of the

problem was not attacked clinically again until the efforts of Smith, Bailey, Harken, and Brock soon after World War II. Since that time, surgical treatment of mitral stenosis has been developed and perfected by experience in literally thousands of operations. More recently operations for mitral regurgitation have been proposed and used in a relatively small number of patients with less satisfactory but nevertheless encouraging results.

Acute rheumatic fever and valvulitis is the usual etiologic factor in production of mitral stenosis or mitral incompetence. The initial rheumatic valvulitis occurs along the margin of the leaflets. If the cusps remain separate and only the margins are affected, the final result is permanent thickening and distortion of the edges of the cusps which are of no functional importance. Fusion of the cusps at the commissures of the valve where chordae tendinae insert leads to stenosis of the valve, interfering with mobility of the valve in opening and closing during the cardiac cycle. Thus, fusion and contraction of the chordae tendinae are just as much a part of the pathologic condition known as mitral stenosis as obstruction of the valve orifice. Calcification frequently occurs in rheumatic mitral valvulitis. Little is known definitely, however, why in some patients rheumatic inflammation leads to mitral stenosis while in others mitral regurgitation may be produced. In regurgitant lesions the circumference of the annulus may increase, interfering with apposition of the leaflets during systole. Several causes for mitral incompetence are recognized. Destruction of valve leaflets may result and is common when bacterial endocarditis is superimposed on the rheumatic process. Rupture of chordae tendinae or papillary muscle may occur and produces a serious degree of mitral incompetence, which is often rapidly fatal. It is remarkable, however, how severe the valvular involvement from rheumatic inflamma-

tion may become, with either stenosis or incompetence, before symptoms of congestive failure ensue. If the myocardium is not itself seriously involved, the heart has a remarkable capacity to compensate for involvement of the mitral valve. Such patients in many instances may have relief of symptoms by correction of the valvular dysfunction. On the other hand, rheumatic myocarditis in association with mitral valvulitis may lead to early congestive heart failure and death. In severe rheumatic myocarditis, the left atrium may be greatly distended to aneurysmal proportions. So-called giant atrium is usually associated with some degree of mitral regurgitation. For the purposes of this text the clinical and surgical aspects of mitral stenosis and insufficiency will be considered separately insofar as possible. Obviously patients may have degrees of both, but such complicated problems are outside the scope of this presentation.

MITRAL STENOSIS

It is now well recognized that valvulotomy must be done by division of only the point of fusion of the

Fig. 5. Roentgenograms of chest in patient with pure mitral stenosis. So-called "mitralized" cardiac configuration consists of right ventricular hypertrophy, prominent pulmonary conus, distended left auricular appendage, and inconspicuous aortic knob. In lateral view, characteristic indentation of the esophagus by dilated left atrium is shown.

Fig. 6. Drawing showing the importance of the anterior mitral leaflet as a baffle in the outflow tract of the left ventricle preventing mitral regurgitation. Preservation of integrity of this leaflet is vital to successful commissurotomy.

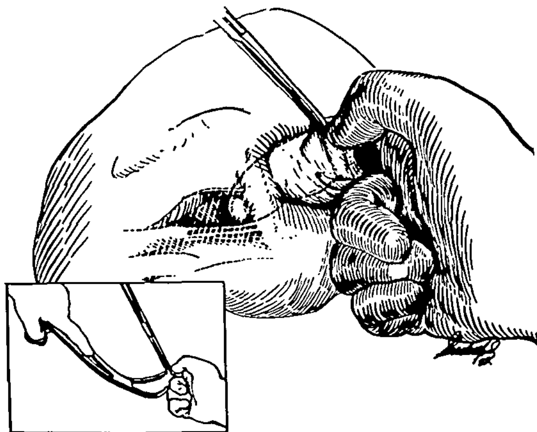

Fig. 7. Drawing showing usual technic of mitral commissurotomy approaching the valve through the left auricular appendage for digital dissection of the fused commissures.

valve leaflets. The anteromedial leaflet is vital to the efficiency of the left ventricle, serving as a baffle to the left ventricular outflow tract assisted to a lesser degree by the posteromedial leaflet in preventing reflux into the left atrium (Fig. 6). In order to protect these leaflets and at the same time increase the size of the orifice, the valvular division is made at the point of fusion of the leaflets known as the *commissures*. By this technic maximum relief of the stenosis is obtained without disturbing the competence of the valve.

Most surgeons approach the valve through the left auricular appendage using a purse-string suture around the base of the appendage for control of hemorrhage. Dissection of fused commissures can often be accomplished by digital manipulation with the right index finger (Fig. 7). In particularly difficult cases the valve must be opened with a cutting instrument, and a wide variety of valvulotomes, scissors, and dilators are available for this purpose.

Prevention of embolization during the procedure is of prime importance, particularly in patients with auricular fibrillation. Atrial thrombosis occurs frequently in patients with mitral stenosis due to stasis of blood in the left atrium. Fibrillation adds to the stagnation of blood in the atrium and peripheral embolism may occur. Prevention of these complications during operation may be difficult, but various steps may be used to reduce the incidence. If the appendage is filled with thrombus, the thrombus may be flushed out of the heart by releasing a gush of blood from the distended atrium. It may be possible to approach the valve through an opening made in a pulmonary vein if necessary and thus avoid disturbance of the clot in the appendage. During intracardiac manipulation temporary occlusion of carotid circulation for periods less than 60 seconds may prevent cerebral embolism. In all instances the patients are examined carefully postoperatively to locate any peripheral embolism. Prompt

embolectomy under these circumstances may be lifesaving.

Recently new technics have been used in patients with mitral stenosis with good results. Bailey has advocated an approach to the valve through a right thoracotomy. In this technic the exploring finger is introduced into the left atrium at a point of junction of the right pulmonary veins with the heart. Actually this approach has proved particularly useful for exposure of the mitral valve for an open repair or valvulotomy. Using the pump oxygenator for temporary cardiopulmonary bypass, the left atrium is opened widely on the right side. The location of the mitral valve is such that an accurate and complete visualization is possible only from this direction. Valvulotomy may be accomplished by incision at the commissures and dilatation under direct vision. This technic is useful in patients with unsatisfactory valvulotomy by the closed technic or when mitral stenosis recurs after previous successful valvulotomy.

MITRAL INSUFFICIENCY

Typical symptoms of mitral regurgitation are somewhat different from those of mitral stenosis. They include fatigue and generalized weakness more than simple exertional dyspnea. Chronic congestive failure may be present, although patients may continue relatively asymptomatic even if the heart and left ventricle are greatly enlarged. Ultimately, signs of right ventricular failure appear, including hepatomegaly, splenomegaly, peripheral edema, and ascites.

Roentgenograms usually show a remarkably enlarged heart with evidence of pulmonary congestion. The left ventricle and atrium are hypertrophied and distended and the left atrium tends to be greatly dilated, causing an extensive displacement of the esophagus posteriorly. Electrocardiograms show predominant left ventricular hypertrophy but also right ventricular.

In spite of intensive interest in surgical treatment of mitral regurgitation, until very recently the results have been unsatisfactory. Attempts to obturate the mitral orifice during systole by baffles, pericardial slings, synthetic prostheses, and other ingenious devices were mostly failures. Attempts to reduce the circumference of the mitral annulus or repair an incompetent commissure by insertion of sutures through the heart or passage of circumferential sutures about the annulus have provided temporary relief in some patients, but the long-term results of all of these procedures will probably be disappointing.

Recently the pump oxygenator for temporary cardiopulmonary bypass has been used for repair of the incompetent mitral valve under direct vision with encouraging results. Exposure of the valve permits accurate placement of sutures to the exact point of regurgitation. This method of valvulorrhaphy provides hope of relief in severely disabled patients. Unfortunately, these technics will probably be unsatisfactory in patients with extensive valvular calcification or ruptured papillary muscle as the cause of the mitral insufficiency.

AORTIC VALVULAR DISEASE

AORTIC STENOSIS

The fundamental defect in aortic stenosis is mechanical obstruction of the outflow tract of the left ventricle. As a consequence of this increased outflow resistance, a high left ventricular pressure is produced proximally and a low aortic pressure distally. This physiologic derangement produces the deleterious combination of increased ventricular work with reduced coronary perfusion pressure. A further physiologic disadvantage to the heart results from the prolonged systolic ejection period since coronary flow takes place principally during the diastolic phase of the cardiac cycle. Finally, the poststenotic jet stream may produce a Venturi or vacuum effect at the coronary ostia, further reducing coronary perfusion.

Even the normal aortic orifice has considerably less cross sectional area than the aorta. In aortic stenosis, as the effective cross sectional area decreases, the resistance to left ventricular expulsion increases, not in a simple linear fashion but by the exponential third or fourth power. Hence, a critical diameter can be reached, beyond which compensation collapses. With such unfavorable factors, it is indeed remarkable that the critical valve opening may be as little as 10 per cent of normal. The fundamental compensatory mechanism in aortic stenosis is con-

centric hypertrophy of the left ventricle without increase in chamber volume.

Appreciation of this delicate physiologic balance in aortic stenosis readily explains the nearly universal clinical impression that the onset of certain signs and symptoms of decompensation indicates a terminal stage of the disease. The frequency of sudden death in these patients is also not difficult to understand, even in those patients who have had no symptomatic manifestations of aortic stenosis. In light of these various considerations, it is possible that the diagnosis of aortic stenosis in itself may become the only necessary indication for operation.

Pathology. CONGENITAL AORTIC STENOSIS. Two types of congenital aortic stenosis occur: aortic valvular stenosis and subaortic stenosis. Valvular stenosis may appear as an inverted cone or megaphone without evidence of commissures or with commissural fusion. One or more valve cusps may be hypoplastic. Although bicuspid aortic valves may occur without stenosis, they are more commonly associated with stenosis. It is difficult to evaluate the incidence of true developmental aortic stenosis as opposed to commissural fusion and valvular derangement due to inflammatory processes early in life.

The valve cusps may be thickened or bulbous, resembling those of the embryo before the definite stage of cusp formation is seen. There may be considerable increase in hyaline connective tissue with scattered mucinous degeneration of loose connective tissue, perhaps representing fetal mesenchymal tissue due to developmental arrest. If the child survives, to reach adulthood, the deformity of congenital valvular stenosis may progress with deposition of platelet thrombi and calcium until the structure is buried in nodular calcified plaques obscuring the original congenital nature. Undoubtedly a significant number of valvular deformities, classified as acquired aortic stenosis, are congenital in their inception.

Subaortic valvular stenosis results from incomplete involution of the embryonic bulbus cordis with persistence of the demarcating fibrous ridge normally occurring at the junction of the bulbus cordis and the original ventricle. The position of this embryologic fibrous ring coincides with the stenotic area observed in most cases.

Coexistent congenital defects associated with aortic stenosis are not unusual. Some of the more frequent concomitant derangements are coarctation, patent ductus, aortic atresia, and endocardial fibroelastosis.

The relative incidence of valvular versus subvalvular congenital aortic stenosis is difficult to assess. In an analysis of 1,000 autopsies of congenital heart disease, Abbott found 11 cases of aortic valvular stenosis and 18 of subaortic stenosis. In the authors' open transaortic operation series, there were seven subvalvular, seven valvular, and one combined. However, an undetermined number of patients with congenital valvular aortic stenosis may be concealed in the acquired group.

ACQUIRED AORTIC STENOSIS. Characteristically acquired aortic stenosis is, in effect, calcific aortic stenosis and is most commonly caused by rheumatic fever. Indeed, in one large clinical series over half the patients had combined aortic and mitral stenosis, thus suggesting the etiologic significance of rheumatic fever. As has been previously pointed out, however, many cases of congenital valvular stenosis lose their identity in the acquired group with the deposition of calcium. In addition, congenital bicuspid valves without stenosis may develop calcific aortic stenosis. Acquired calcific aortic stenosis primarily due to atherosclerosis is probably rare and certainly not as common as previously considered. Although bacterial endocarditis constitutes an ever present threat in both congenital and acquired aortic stenosis, it is a rare cause of stenosis. Primary cardiac tumors have also been reported as rare causes.

The high degree of calcification associated with aortic stenosis compared with stenotic lesions of other valves is believed to be related to abnormal mechanical stresses of the deformed valve in a high pressure area. The extreme degree of grotesque deformity of the aortic valve commonly seen in calcific stenosis cannot be overemphasized and has considerable surgical significance in the technic and results of valvulotomy. It is commonly difficult to demonstrate even vaguely the previous cusps and commissures; and with their gross distortion by calcific verrucae, it is sur-

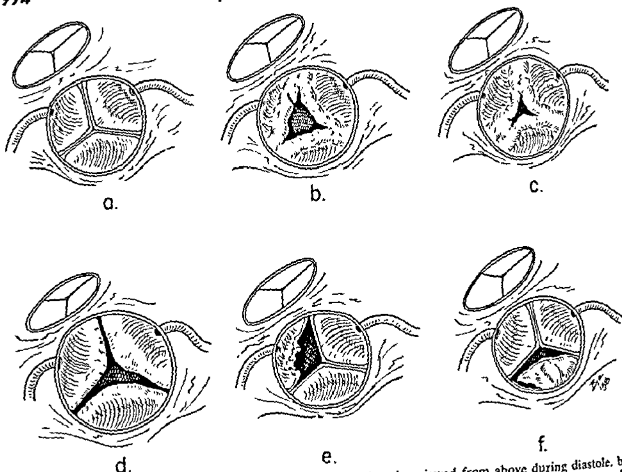

Fig. 8. a, drawing showing appearance of normal aortic valve viewed from above during diastole. b, rheumatic aortic insufficiency with some stenosis. c, rheumatic stenosis with slight insufficiency. In such acquired calcific stenosis the valve cusps are often grotesquely deformed. d, syphilitic aortic insufficiency caused by dilatation of the annulus fibrosus. e, aortic valvular insufficiency caused by bacterial endocarditis. f, aortic valvular insufficiency resulting from a traumatic commissural tear of one leaflet.

prising that any valvular function remains (Figs. 8, 9).

Clinical Considerations. The physiologic changes resulting from acquired aortic stenosis develop long before the onset of symptoms. This frequent dormant period without symptoms has been responsible for the false clinical impression that aortic stenosis is a relatively benign condition. Sudden death is not unusual and may even occur in asymptomatic patients. In general, however, there appears to be a correlation between the severity of symptoms and stenosis. Although tight stenosis does occur without symptoms, eventual subjective evidence of the disease is the rule. The usual progress is late development of exertional dyspnea, fatigability, paroxysmal nocturnal dyspnea, orthopnea, and syncope. Vertigo and syncope result from cerebral anoxia. Angina is usually a late symptom occurring in over 50 per cent of patients and denotes a grave prognosis without surgical intervention.

The physical signs are characteristic. Cardiac enlargement with a forceful apex beat stands in marked contrast to the diminished peripheral pulse. A systolic thrill is palpable over the precordium which radiates into the neck. The harsh systolic murmur can be heard loudest over the right second intercostal space and is well transmitted along the course of the great vessels into the neck. This murmur is often heard posteriorly in the interscapular region. An aortic second sound is usually present, though it may be diminished or absent.

If the systolic murmur is transmitted to the apex, confusion may arise with mitral insufficiency. More troublesome, however, is the frequent occurrence of an Austin Flint murmur caused by transmission of a diastolic murmur to the apex when a degree of relative

Fig. 9. Photograph showing characteristic gross features of calcific aortic stenosis with extensive deformity of valve.

aortic insufficiency coexists. In a significant number of patients with rheumatic aortic stenosis, mitral stenosis may be a combined lesion. The classical rumbling quality with presystolic accentuation usually allows differentiation of the mitral stenotic murmur. Although relative aortic insufficiency is not uncommon in acquired aortic stenosis, the latter is characteristically the predominant derangement. When demonstrable, a plateau pulse suggests aortic stenosis. Blood pressure may be diminished but is often relatively normal.

Congenital aortic stenosis, particularly subaortic, often exists for years before symptoms arise, and the recognition of heart disease may be dependent on routine examination for other reasons. Differentiation of valvular from subvalvular stenosis on the basis of physical findings is extremely difficult, if not impossible. Previous attempts to delineate the two types by the presence of a normal aortic second sound have proven completely unreliable.

Roentgenographic examination of the chest may reveal left ventricular enlargement, but the expansion in the cardiac silhouette is rather subtle, since it is due to concentric hypertrophy without dilatation. The right anterior oblique view best reveals left ventricular enlargement. Poststenotic dilatation of the ascending aorta may be evident and is most marked in the congenital group. Fluoroscopy demonstrates a significant contrast between forceful ventricular systole and relative decrease in aortic pulsation. Demonstrable calcification is rare in children but frequent in adults.

Electrocardiography is particularly useful in aortic stenosis. Usually a pattern of left ventricular hypertrophy is present with left ventricular strain. In rheumatic aortic stenosis, coexistent right axis deviation usually signifies associated mitral stenosis. Electrocardiograms are helpful in appraising cases of congenital aortic stenosis, since symptoms are often difficult to evaluate in children.

When clinical evaluation fails to give a firm

diagnosis, three special studies may be useful, namely, pulse tracings, angiocardiography, and left heart catheterization. In aortic stenosis, a delay in the upstroke of the pulse wave appears, usually interrupted by an anacrotic notch. In the angiocardiogram, the area of poststenotic dilatation may be delineated, differentiating valvular and subvalvular stenosis. Left heart catheterization is a somewhat more formidable procedure than right heart catheterization. Pressure tracings from the left ventricle reveal extremely high pressures with an abrupt reduction as the tip of the catheter passes through the stenotic area. Differentiation between valvular and subvalvular stenosis may be obtained with left heart catheterization.

Surgical Management. Selection of patients for aortic valvulotomy may ultimately become only the problem of diagnosis. It now appears that with the increasing safety allowed by the open transaortic approach, aortic stenosis may be the only necessary indication for operation. At the present time, operation should be deferred in those patients who are asymptomatic, without roentgenographic evidence of cardiac enlargement, and who show no electrocardiographic evidence of significant left ventricular hypertrophy or strain. This is because in both congenital and acquired aortic stenosis a long latent period often persists for 10 or more years. In contrast, a very tight congenital valvular stenosis may be incompatible with early life unless a patent ductus or foramen ovale allows temporary survival. Under these circumstances, valvulotomy may be necessary in the first few days after birth. Certainly the development of cardiac decompensation or atrial fibrillation never should be allowed in patients who are carefully followed, since such deterioration has grave prognostic implications. Once symptoms or signs of left heart strain develop, the period between onset and death is relatively short and averages about one or two years.

Historically two men stand out in their early pioneering efforts to treat aortic stenosis. Tuffier in 1913 performed a successful aortic valvulotomy digitally through the invaginated wall of the aorta itself. The next year Carrell published a paper showing that open transaortic valvular procedures with inflow occlusion were safe, provided the period of circulatory arrest did not exceed 2.5 minutes. It is interesting that Tuffier assisted Carrell in some of these surgical procedures on dogs. Surgical interest then waned until 1947 when Smithy, who was himself a victim of aortic stenosis, revived clinical interest and urged the application of experimental methods to clinical use in the surgical treatment of the diseased valve. Since then a number of different methods and technics have been developed for this purpose, including both closed transventricular and transaortic approaches, as well as the open or direct approach using hypothermia or the artificial heart-lung apparatus. The recent application of cardiopulmonary bypass, using the artificial heart-lung apparatus to the open transaortic approach, has distinct advantages. With a pump oxygenator there is no severe time limitation during the open portion of the procedure. Danger of ventricular fibrillation is lessened, and should it occur, defibrillation is easier.

In the technical performance of aortic valvulotomy the important principle of the limited objective should be followed. This is because only a small increase in cross sectional area suffices to permit relief of the aortic stenosis and because, if strenuous efforts are made to reconstitute an anatomically normal valve opening, there is grave danger of producing intolerable aortic insufficiency. In the case of subvalvular stenosis great care must be exercised to avoid injury to the aortic cusp of the mitral valve, which is in direct relation to one third of the circumference of the stenotic area.

In the immediate period after operation prophylactic antibiotic therapy seems essential because of the frequency of subacute bacterial endocarditis at this time. The results of open transaortic valvulotomy employing cardiopulmonary bypass are now good and will continue to improve as more experience is gained with this direct approach. In our series of 30 cases in which this method of treatment was employed, there were no operative deaths in those with the congenital form of the disease. The operative risk in patients with the acquired form of the disease has been found to be somewhat higher, owing to the related coronary insufficiency.

AORTIC INSUFFICIENCY

Aortic insufficiency constitutes a condition in which blood ejected into the aorta is allowed to regurgitate into the left ventricle because of aortic valvular incompetence. The similarities in the effects of aortic stenosis and aortic insufficiency are noteworthy. Both produce dyspnea, orthopnea, angina, syncope, excessive left ventricular work, decreased net cardiac output, and left sided failure with essentially the same frequency. Also similar are inadequacies of coronary, cerebral, and peripheral circulation. The ominous threat of sudden death is common to both valvular lesions. The hemodynamics in these two lesions are, of course, quite dissimilar.

Reflux of blood into the left ventricle increases ventricular and diastolic pressure. As a direct result, inflow of blood from the left atrium is impeded with consequent pulmonary vascular congestion. Compensation is effected by an increased stroke volume through left ventricular hypertrophy and dilatation. Secondary compensation also results from the elastic reservoir function of the thoracic aorta, which expands markedly during systole and then passively contracts during diastole. In spite of the increased cardiac work demanded, the heart receives diminished coronary perfusion. This is because coronary perfusion takes place principally during diastole and diastolic aortic pressure in open aortic insufficiency is usually very low.

Pathology. William Harvey in 1628 presented the first clear description of valvular function when he wrote, "The several valves of the heart are so arranged that the blood once received into the ventricles shall never regurgitate and once forced into the pulmonary artery and aorta shall not flow back upon the ventricles." The earliest descriptions of aortic insufficiency which appeared many years later by Cowper, Vieussens, Morgagni, and Hodkin were of mixed lesions including both stenosis and insufficiency. Corrigan first presented the clinical picture of pure aortic insufficiency, and subsequently his contemporary, James Hope, proved experimentally the origin of the second heart sound and the murmur of aortic insufficiency. It was also Hope, not Corrigan, who first described the water-hammer pulse.

Effective antibiotic therapy during the past 15 years has produced a significant reduction in the incidence of syphilitic aortic insufficiency. In a recent analysis of 100 cases of aortic insufficiency, the etiology was rheumatic in 83, syphilitic in 12, congenital in 4, and traumatic in 1 (Segal, Harvey, and Hufnagel). In a series of 2,000 cases of rheumatic fever in young people with long term study, the incidence of aortic insufficiency was 6.5 per cent (Bland and Wheeler). The lesion appeared twice as frequently in males. Although aortic stenosis or combined aortic stenosis and insufficiency represent the more characteristic rheumatic affliction of the aortic valve, pure rheumatic aortic insufficiency is not uncommon. Rheumatic fever may produce pure aortic insufficiency in two ways. First, the aortic annulus fibrosus may be stretched so that the valve cusps, even when undamaged, fail to approximate during diastole; or second and more often, rheumatic fever may cause agglutination of the cusps to the aortic wall, and thus produce apparent widening of the commissural spaces simulating dilatation of the annulus. In advanced stages of the disease, the coronary ostia may become enclosed in cystlike spaces.

Syphilis characteristically produces a generalized dilatation of the aortic annulus fibrosus. Widening of the commissures between the valve cusps prevents coaptation during diastole (Fig. 8). The valve cusps may remain relatively normal although atrophy and distortion sometimes occur. Associated syphilitic aneurysms of the aortic arch are quite common.

Varied congenital abnormalities of the aortic valve may be associated with aortic regurgitation. Usually bicuspid deformities exhibit concomitant aortic stenosis. Aortic insufficiency may also result from subacute bacterial endocarditis, which rarely involves a normal aortic valve but frequently attacks congenitally deformed valves or valves altered by the effects of rheumatic fever. Fenestrations of the valvular cusps may be congenital or acquired and may produce valvular incompetence. Aortic insufficiency occasionally develops as a complication in Marfan's syndrome.

Closed trauma can produce rupture of one or more valve cusps or rupture of the sinus of

Valsalva (Fig. 8). Rupture of the sinus of Valsalva usually results from congenital weakness or subacute bacterial endocarditis. A communication may be thus produced between the aorta and the right atrium or ventricle.

Clinical Considerations. Aortic regurgitation creates a distinctive clinical picture. A blowing or musical early diastolic murmur is usually heard over the right second interspace and is transmitted toward the apex of the heart along the left sternal border. The late mid-diastolic murmur heard at the apex, familiarly known as the Austin Flint murmur, may be mistaken for the diastolic murmur of mitral stenosis. A quite variable systolic aortic murmur frequently occurs. The heart is grossly enlarged with downward and outward displacement of the apex beat, which is particularly forceful. The peripheral vascular signs are characteristic and include the violent collapsing or water-hammer pulse, widened pulse pressure with elevated systolic and greatly reduced diastolic pressure, and demonstrable capillary pulse. Fluoroscopy of the chest shows a rocking motion of an enlarged heart and significant systolic expansion of the aorta. The electrocardiogram typically reveals evidence of hypertrophy and left ventricular strain. Ballistocardiographic tracings are diagnostic.

The age at which symptomatic manifestations of aortic insufficiency develop depends largely on the etiology. In rheumatic fever, there is usually a 10-year latent period after significant aortic insufficiency has evolved, and symptoms arise typically in the third or fourth decade. Symptoms in syphilitic cases usually become manifest in the fifth or sixth decade and the progression is more rapid than in those following rheumatic fever. Compensatory mechanisms have less opportunity in traumatic aortic valvular insufficiency and death commonly occurs within a year.

When symptoms do begin, easy fatigability, palpitations, and exertional dyspnea are the first to be noted. Later symptoms are those of congestive failure and angina from coronary insufficiency. Syncope may follow periods of cerebral vascular insufficiency. Sudden death is not uncommon.

Surgical Treatment. Surgical approaches to aortic valvular insufficiency have been circuitous until recently, when the advent of temporary cardiopulmonary bypass made open definitive repair possible. The Hufnagel ball-valve plastic prosthesis offered a degree of improvement to some patients, but because of anatomic and physiologic factors, it was necessary to insert the valve in the descending thoracic aorta and thus the regurgitation was only partially ameliorated (Fig. 10). Complications, such as false aneurysm and embolic phenomenon, were not infrequent. Circumclusion technics have not been very satisfactory because the constricting suture or band frequently cuts through the aorta or rides up on the coronary arteries, producing coronary occlusion. The search for an ideal valvular prosthesis which may be inserted proximal to the ostia of the coronary arteries continues, but many observers doubt that the solution to the problem of aortic insufficiency lies in this approach.

Open plastic repair of the valve during cardiopulmonary bypass with a pump oxygenator appears most promising. The type of repair must of necessity bear technical adaptation to the pathologic deformity. Several principles of repair are now under clinical evaluation. The annulus fibrosus may be incised and its circumferential diameter decreased by suture repair. Portions of the posterior noncoronary area of the proximal aorta can be excised and the aorta repaired, bringing the valve cusps into apposition. Mattress sutures placed in the annulus at the valve commissures have proven successful in some instances. Another approach which has been clinically successful converts the valve into the bicuspid type by suturing two cusps together and then adding cusp area, if needed, by suturing prosthetic pledgets to the cusp edges.

TUMORS OF THE HEART

Neoplasms of the heart are relatively rare, although involvement of the pericardium by malignant tumors arising in adjacent structures is rather common. Among tumors of the heart itself, unfortunately, at least 95 per cent are metastatic. The most common primary tumors producing cardiac metastases include bronchogenic carcinoma, melanoma, lymphosarcoma, and other sarcomas. Direct embolic dissemination through the coronary ar-

The rings which hold the aorta over the valve have inner teeth which prevent ischemic necrosis of the incorporated segment of aorta. b, drawing showing the location of the Hufnagel valve. Since coronary filling takes place during diastole, the valve cannot be placed in the ascending aortic arch. The aortic arch, therefore, remains a regurgitant segment.

teries represents the most common mode of metastasis. Spread to the heart may also occur along lymphatic channels. Usually cardiac metastases are asymptomatic and are brought to light as an interesting post-mortem finding. When symptoms do occur, the diagnosis generally is obvious, but treatment at best consists of palliative radiation. Metastatic cardiac tumors are primarily pathologic curiosities, since the ultimate outcome is not significantly affected by cardiac metastasis but is determined by the primary tumor. Metastatic cardiac tumors most commonly involve the right side of the heart.

In contrast to metastatic tumors, primary tumors of the heart are of real surgical interest. They may be conveniently divided into intracavitary and mural types. Intracavitary tumors are almost exclusively benign myxomas whereas among mural tumors, sarcomas of various cell types predominate.

PRIMARY TUMORS

1. **Intracavitary Type.** From a surgical standpoint it is fortunate that 50 per cent of the primary tumors of the heart are benign myxomas. Since almost all other primary tumors involve the heart essentially as mural growths, myxoma is for practical considerations the principal intracavitary tumor. Characteristically, myxomas arise from the region of the fossa ovalis of the atrial septum on a narrow pedicle. The point of attachment to the septum is generally 1 cm. or less in diameter. The left atrium is involved in about 75 per cent and the right atrium in the remainder. Their size varies from those that are so small as to be asymptomatic, and are diag-

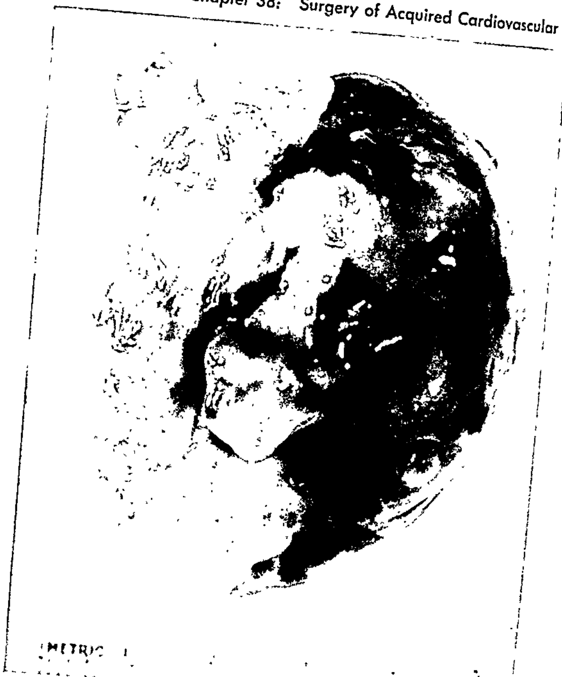

Fig. 11. Photograph of a myxoma removed during cardiopulmonary bypass with open atriotomy. Note the small segment of interauricular septum attached to the short pedicle. Intracavitary myxomas characteristically arise from the interauricular septum near the fossa ovalis.

nosed accidentally, to lesions 6 to 8 cm. in diameter that almost completely fill an already enlarged atrium. Myxomas are now generally conceded to represent a true neoplasm, although formerly some pathologists considered their origin to be from organization of atrial thrombi. Grossly, they may be smooth and round or polypoid and occasionally villous (Fig. 11). Cut surface appearance varies from white and gray to pink and red.

Microscopically, myxomas present a rather poorly cellular stroma containing occasional multinuclear and stellate cells with a thin surface covering of endocardium (Fig. 12). Occasional areas of calcification and hemosiderin deposition may be observed.

The clinical picture of a myxoma arising in the left atrium is similar to that of mitral stenosis with several characteristic and differentiating features resulting from the action

Fig. 12. Photomicrograph (× 200) of myxoma arising in the left atrium from the fossa ovalis. The tumor is covered by endothelium and the loose stroma is mucoid and well vascularized.

of the tumor itself as an obturator (Fig. 13). These important features due to the ball-valve effect of the tumor on the mitral orifice include: (1) dramatic alterations in symptoms and murmurs associated with positional changes; (2) relatively rapid onset with accelerated progression of symptoms; and (3) conspicuously minimal response to medical therapy. A fourth differentiating feature is absence of a history of rheumatic fever.

Tumors arising in the right atrium mimic tricuspid valvular disease or chronic constrictive pericarditis. One unusual case of a patient whom Hanlon successfully treated by cardiopulmonary bypass had an associated atrial septal defect. The patient was intensely cyanotic because of impingement of the tumor on the tricuspid valve, which accentuated the right-to-left shunt.

Catheterization of the heart uniformly shows evidence of obstruction to atrial outflow and increased pulmonary capillary pressure with left atrial tumors. Definite diagnosis of intracavitary myxoma can be obtained in nearly every instance by angiocardiography. An atrial filling defect is demonstrable, and often the point of attachment to the atrial septal wall is clearly visualized. Mural thrombi and tumors, since they tend to be laminar, do not ordinarily produce filling defects. Unfortunately, until physicians become accustomed to excluding myxoma when considering the diagnosis of mitral stenosis, the first hint of the true diagnosis will commonly arise when the commissurotomy finger encounters the tumor.

Successful removal of an intracavitary myxoma offers one of the most gratifying ex-

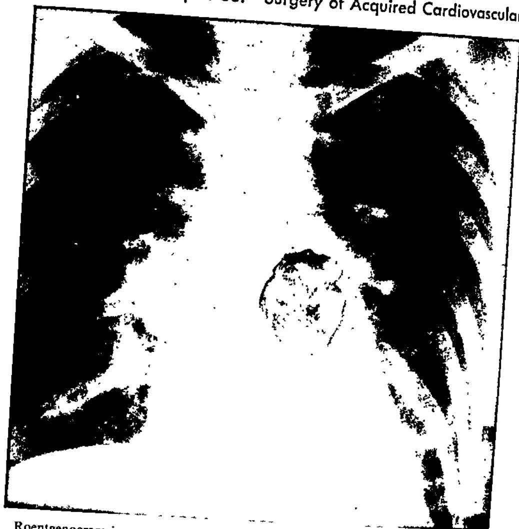

Fig. 13. Roentgenogram in a case of intracavitary myxoma of the left atrium. The x-ray findings are indistinguishable from those of mitral stenosis. The superimposed tumor has a smooth lobulated appearance.

periences in the scope of surgery. Removal through an open atrium during cardiopulmonary bypass using the artificial heart-lung apparatus is a relatively simple technical procedure. Should air embolism into the coronary vessels occur or ventricular fibrillation develop, the pump oxygenator offers a much better means than hypothermia of overcoming this complication. Although we have approached myxomas in the left atrium directly through the left side of the atrial wall, there is reason to believe it may be preferable to use the right sided approach through the right wall of the left atrium or through the septum of the right atrium. Such approaches would minimize the dangers of air embolism incident to open operations on the left side of the heart. Should a myxoma first become evident in the course of an anticipated mitral commissurotomy, it is best to terminate the operation and make plans for open atriotomy employing cardiopulmonary bypass. The literature is replete with reports of unsuccessful impromptu attempts at removal. Because of the frequency of sudden death associated with mitral or tricuspid occlusion or embolization of the tumor, surgical treatment should be instituted as soon as possible.

2. **Mural Type.** The second most common primary cardiac tumor is the sarcoma. Many isolated cases have been reported of various cell types including myxosarcoma, leiomyosarcoma, fibrosarcoma, rhabdomyosarcoma, malignant mesothelioma, lymphosarcoma, and various angiosarcomas. Other less frequent types are benign and include rhabdomyomas, hamartomas, dermoids, teratomas, fibromas, and lipomas. The presenting symp-

toms and signs are protean and are determined largely by the location and type of the lesion. Hemopericardium is common. Alteration of the cardiac silhouette by the tumor may be noted in the roentgenogram or at fluoroscopy. Electrocardiographic alterations may be produced by sterile pericarditis with bloody effusion or may result from conduction changes due to encroachment of the tumor. Although the outlook for curative surgical intervention is hardly as favorable as in benign intracavitary myxomas, even the sarcomas may be amenable to cure. Scannell reported a fibrosarcoma of the right atrium successfully removed as a wedge excision through a closed operative approach. It is even possible, through an open operation with cardiopulmonary bypass, to excise portions of the ventricular wall and repair the myocardial defect with plastic prosthetic material.

PERICARDIAL TUMORS

Pericardial tumors logically should be considered with tumors of the heart because of their clinical and pathologic association. Excluding cysts, primary pericardial tumors are even more uncommon than cardiac neoplasms. In a review of 413 primary neoplasms, Mahaim found 329 of the heart and 84 of the pericardium.

The various cellular types are those that might be anticipated from a structure composed of fibrous connective tissue, blood vessels, lymphatics, fat, and nerves with a covering on both surfaces of mesothelium. Hence, most primary malignant lesions of the pericardium are fibrosarcomas, various angiosarcomas, lymphosarcomas, liposarcomas, neurogenic sarcomas, and mesotheliomas. Malignant mesothelioma represents the most common type and may produce polyarthritis, as has been observed in their pleural counterpart.

The benign tumors follow a similar morphologic pattern. Some of the most commonly encountered varieties include fibroma, hemangioma, lipoma, neurofibroma, dermoid, and teratoma.

The first manifestations of pericardial tumors may be the same as those of pericardial effusion. Frequently, sterile pericarditis is produced and this causes pain in the chest and electrocardiographic alterations. In most instances the effusion is bloody. The accumulation of fluid may greatly enlarge the cardiac silhouette. In such instances, a picture of chronic tamponade may elicit findings consistent with chronic constrictive pericarditis. The latter may also result from a sheath of tumor encasing the heart. When the pericardial effusion is more rapid, cardiac tamponade may represent the first clinical manifestations of the tumor. Pericardial aspiration may prove not only therapeutic but diagnostic when the fluid is submitted for pathologic examination. Frequently benign tumors first become evident on routine roentgenography of the chest.

The success of surgical treatment is determined largely by the extent and type of the tumor. Most benign pericardial tumors can be excised without difficulty. The first such success was reported in 1930 by Keller and Callender when they removed a neurofibroma arising on the pericardial pleura. Twelve years later, Beck removed a cystic intrapericardial teratoma. In the years since these pioneering operations, there have been many successful surgical extirpations of almost every type of benign tumor encountered in the pericardium. In occasional fortuitous circumstances, malignant pericardial tumors may be encountered at an early stage and completely excised.

PERICARDIAL CYSTS

Pericardial cyst is a distinct clinical and pathologic entity. The term should be reserved for those thin walled sacs containing watery fluid. Frequently used synonyms include pericardial celomic cysts, spring-water cysts, and pleurodiaphragmatic cysts. Their thin, translucent walls are lined with flattened mesothelial cells. They vary in size from small masses, which are detected at the time of thoracotomy performed for some other reason, to unilocular cysts containing more than a liter of clear fluid. These cysts appear most commonly at the cardiophrenic angles with a predilection for the right side. Malignant degeneration has never been reported. They are of developmental origin and grow either as embryonic lacunae that fail to coalesce with the pericardium or as pinched-off rem-

nants of diverticulumlike structures that normally appear in the development of the pericardium.

Pericardial cysts rarely produce symptoms and are generally first revealed on routine roentgenography of the chest. They are ordinarily found forming a bulge on the cardiac silhouette, usually in one cardiophrenic angle. On fluoroscopy, the contour of these cysts may change with movement of the heart or the patient.

Treatment consists in excision. The basis for thoracotomy is the same as for exploration of any intrathoracic mass. Usually the cyst can be readily dissected from the pericardium without rupture.

CORONARY ARTERY DISEASE

More than a half century has elapsed since the first surgical attack in the form of sympathectomy was made by Jonnesco in a case of angina pectoris. During this period and particularly in recent years, intensive experimental and clinical investigations have been directed toward this problem, and while these studies have enriched the literature and have added to greater knowledge and better understanding of the various aspects of coronary artery disease, the surgical approach remains inconclusive and controversial. There are several reasons for this disputed and uncertain status of the surgical treatment of coronary artery disease. For one thing, the natural course of the disease may be highly variable in different patients and even in the same patient at different periods and may be greatly influenced by many factors both intrinsic and extrinsic as well as by medical therapy. For another, precise and accurate evaluation of the clinical results of surgical therapy has been extremely difficult owing to the many variables involved and the inability to provide a properly controlled study.

The underlying pathologic lesion in coronary artery disease is atherosclerosis, which ultimately leads to narrowing and occlusion of the lumen by progressive intimal thickening, intimal hemorrhage, or superimposed thrombosis. As a consequence of this pathologic process, coronary arterial circulation is reduced to a variable degree, depending upon the extent and nature of the lesion and the extent to which intercoronary collateral vessel formation takes place. Serious disturbances occur when the latter compensatory mechanism fails to meet the ischemic effects of the former process of coronary artery occlusion, thus producing one or more of the following effects: 1. angina pectoris; 2. myocardial infarction and damage, fibrosis, congestive failure, aneurysm formation, or rupture; and 3. mechanism failure. Ultimately these disturbances lead to a variable degree of disability, invalidism, and death.

Surgical treatment of coronary artery disease is directed toward relief of these adverse effects of coronary artery insufficiency. The various methods which have been advocated for this purpose may be classified as follows: 1. denervation of the heart for the relief of angina pectoris; 2. improvement of arterial circulation to the myocardium; and 3. decreasing metabolic demands on coronary circulation by thyroidectomy.

Historically, interruption of cardiosensory and motor pathways represents the first method of surgical attack upon coronary artery disease, the procedure having been suggested originally by François Franck in 1899 and successfully performed by Jonnesco in 1916. Since then extensive experimental and clinical investigations have provided a better understanding of the underlying anatomic and physiologic principles of this method of attack. It has been shown that the sensory nerve endings of the heart and aorta are present in the heart muscle, endocardium, and epicardium and in the adventitia of the coronary arteries. The neurons to these sensory endings converge in the periarterial plexus of the coronary arteries, traverse the superficial and deep cardiac plexuses, and course in the middle and inferior cardiac nerves which join the corresponding cervical ganglia of the sympathetic chain. Practically all of these outbound fibers then descend to the upper thoracic ganglia and finally reach their cells in the spinal ganglia by passing through the white rami communicantes into the central portions of the first thoracic and upper four or five intercostal nerves. The vasomotor efferent or accelerator impulses to the heart and coronary arteries differ from the sensory, and their actions and pathways are not as well understood. These pathways involve both vagal and sympathetic nerves.

but the exact mechanism of their action in producing vasoconstriction and vasodilation has been difficult to determine.

In general, three methods of denervation of the heart have been employed clinically. These include: 1. cervicothoracic ganglionectomy; 2. posterior rhizotomy; and 3. paravertebral chemical (alcohol) block of the upper four or five sympathetic ganglia. The advantage of the first two procedures lies in the fact that they provide a more accurate and permanent interruption of cardiosensory nerves, but they have the disadvantage of requiring a major operation and accordingly are associated with a higher operative mortality, about 8 to 10 per cent. Good results in terms of relief of pain, increase of work capacity, and improvement of general condition have been reported in about 70 to 75 per cent of cases following all these methods, but there is no good evidence that survival expectancy is increased.

The procedure of total thyroidectomy for the treatment of coronary insufficiency is now of historical interest only, since this objective may be accomplished by the use of radioactive iodine and possesses the obvious advantage of being associated with much less risk to the patient. The induction of hypothyroidism in euthyroid patients by means of radioactive iodine has now been employed in a large number of patients with severe and intractable angina pectoris, and good results have been reported in about 75 per cent of cases. Final evaluation of this method of therapy in terms of work capacity and longevity remains to be determined.

The various surgical methods directed toward improvement of the circulation of the myocardium may be classified into two broad categories, namely, direct and indirect approaches. The former is aimed at increasing arterial inflow through the coronary arteries by removal of the stenotic lesion or by anastomosis of a systemic artery to the coronary arteries distal to the occlusion. The latter is designed to increase extrinsic coronary collateral circulation by one of several methods, including the grafting of various vascular structures (such as the pericardium, omentum, pectoral muscle, intercostal muscle, lung, and intestines) to the myocardium, implantation of a systemic artery (such as the internal mammary artery) into the wall of the ventricle, ligation of the coronary sinus, and ligation of the internal mammary artery.

Extensive experimental, physiologic, and morphologic studies have been done in an effort to assess the value of these procedures. In general, the experimental designs of most of these studies have employed one or more of the following criteria of benefit: 1. reduction in the amount of myocardial damage or in mortality rate in the group of animals having the experimental "protective" operation as compared with the controls following occlusion of a test artery, such as ligation of the left anterior descending coronary artery; 2. increase in retrograde coronary backflow in the experimentally treated animals as compared with the controls; and 3. gross and histologic evidence of new vessel formation following the experimental procedure.

Many of these procedures have been applied clinically with reports of successful results according to the advocates of the various types of operations. For the most part these results have been evaluated on the basis of symptomatic improvement and increased work or exercise capacity, using the patient as his own control. The operative mortality for the simpler procedures has been relatively low, about 3 to 6 per cent.

Efforts to assess the relative value of these various methods of surgical treatment of coronary artery disease are fraught with many difficulties. The remarkable similarity in the clinical results following these widely varying surgical methods and approaches, as reported by their respective advocates, is particularly striking. This would suggest that they all possess some common factor or mechanism other than improvement in coronary circulation. The major difficulty in their critical evaluation lies in the lack of properly controlled clinical investigations. Until these provisions are made and rigid criteria of benefit are employed, their value will remain controversial. There is sufficient reason to believe, however, that further investigations along these lines, directed toward surgical relief of coronary obstruction, are fully justified.

ANEURYSMS OF THE AORTA

The term, aneurysm, derived from the Greek word "aneurynein" meaning "to widen

or dilate," signifies a hollow tumor or sac directly connected with the lumen of an artery and filled with liquid or coagulated blood or both. Aneurysms may be classified in several ways according to the nature and cause of the lesion. Pathologically, for example, they may be divided into two types: the true aneurysm, in which one or all of the mural layers of the parent artery enter into the composition of the sac; and the false aneurysm, in which the sac is formed by perivascular connective tissue usually following the development of a pulsating hematoma as a result of disruption of the wall of the artery by trauma or infection. Morphologically, they may be divided into three types: sacciform, fusiform, and dissecting. The sacciform aneurysm, as the name implies, has a pouchlike appearance with a relatively narrow neck constituting the orifice from the side of the parent artery to which the larger sac is connected (Figs. 14, 22). Fusiform aneurysms tend to be more spindle-shaped and to involve the entire circumference of the parent artery (Figs. 14, 24, 28). Dissecting aneurysms are of intramural origin and, owing to their distinctive features, are discussed separately. Aneurysms may also be classified according to their cause into congenital and acquired types. The former are relatively uncommon and usually are associated with other congenital anomalies, such as patent ductus arteriosus and coarctation. The latter, by far the more common, are due to arteriosclerosis, trauma, or infection.

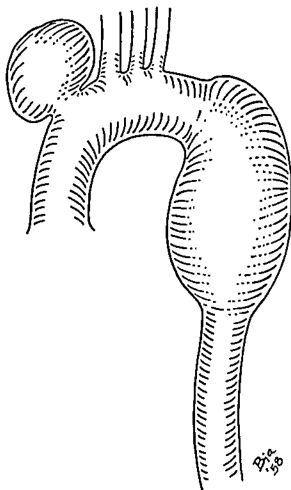

Fig. 14. Diagrammatic drawing illustrating sacciform type of aneurysm arising from ascending aorta and fusiform type of aneurysm involving descending thoracic aorta.

The relative frequency of aneurysms of the aorta has been variously reported according to statistics derived from hospital admissions and necropsy studies. Earlier reports suggested figures ranging from 1 to 2 per cent of all autopsies, but more recent studies indicate that this incidence is somewhat higher. At the Charity Hospital in New Orleans, Matas found that among 81,242 admissions there were 106 aortic aneurysms, an incidence of 0.13 per cent. Earlier reports also indicate a much greater frequency of thoracic than of abdominal aneurysm, the ratio being about 3:1 or 4:1. More recently, however, there is reason to believe that this incidence is changing, probably as a result of the diminishing occurrence of syphilis, which is a common cause of aneurysms of the thoracic aorta. This is well illustrated by the recent studies of Maniglia and Gregory, who found that the ratio of arteriosclerotic to syphilitic aneurysms has increased from 1:8 during the period 1906 to 1931 to 2.5:1 during the period 1949 to 1951. These observations gain further support from our own experience with resected cases of aneurysm of the aorta. In this series of over 650 cases, the thoracic aorta was involved in only about 23 per cent while the remainder were located in the abdominal aorta. Moreover, in the former group, syphilis was considered to be the causative factor in only about half the cases and arteriosclerosis in about one third, whereas among the greater number of aneurysms of the abdominal aorta, arteriosclerosis was the predominant etiologic agent, its incidence being about 96 per cent. It is thus apparent

that in resected cases, at least, arteriosclerosis is now the primary and major cause of aortic aneurysms.

The disease occurs most commonly in the fifth, sixth, and seventh decades of life and predominantly in males. The ratio of males to females in our experience is about 9:1.

Pathogenesis and Pathology. The essential factor in the pathogenesis of aneurysms is damage to the medial elastic coat of the vessel, only the outer adventitious layer remaining to withstand the repeated force of systolic impact. Once this medial disruptive process has occurred, whether it results from trauma, infection, or atherosclerosis, progressive dilatation ensues at the weakened area and pressure is exerted on surrounding tissues. Nature's efforts to counteract this pathologic process apparently take two directions. One consists in development of fibrous tissue presumably produced by chronic irritative hyperplasia in the perianeurysmal tissues. The other consists in deposition of laminas of thrombi on the inner surface of the aneurysm in an effort to maintain normal size of the lumen. Both of these processes, along with extrinsic support from adjacent structures, tend to retard progress of the lesion. In most

Fig. 15. Lateral roentgenogram of patient with syphilitic fusiform aneurysm of descending thoracic aorta showing erosion of vertebrae.

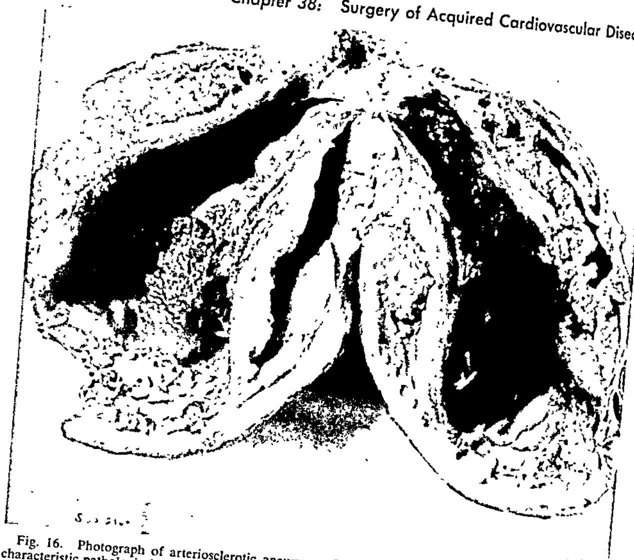

Fig. 16. Photograph of arteriosclerotic aneurysm of abdominal aorta after sagittal section showing characteristic pathologic features including particularly evidence of liquefaction necrosis in laminated clot around lumen.

instances, however, these efforts are unable to cope with the continuous pounding effect of the systolic force so strikingly exemplified in some aneurysms, particularly those of syphilitic origin, by the gradual erosion of adjacent osseous structures (Fig. 15). For one thing, fibrous tissue is an inadequate replacement of elastic tissue for this purpose, progressively becoming thinner and weaker in the face of the unrelenting force of the systolic pressure. For another, the normal process of organization does not usually occur in the laminated thrombus within the aneurysmal sac. Instead, ischemic liquefaction necrosis takes place, usually in the more peripheral portions of the clot immediately adjacent to the outer fibrous tissue wall (Fig. 16). These two factors combine to produce further weakness of the aneurysmal sac, resulting in progressive enlargement and leading ultimately to rupture of the aneurysm. Depending upon the type and location of the lesion, rupture may occur into the mediastinum, pleural, pericardial, or peritoneal cavities, retroperitoneal area, or into adjacent viscera, such as the esophagus, bronchus, gastrointestinal tract, and vena cava.

Although the underlying pathogenic factor, i.e., destruction of the aortica elastica, is the same for most aortic aneurysms, there are certain characteristic anatomic and pathologic features depending upon the nature, location, and cause of the aneurysm. Those of syphilitic origin, for example, tend to involve the thoracic aorta, particularly about the arch, and to be sacciform in character (Fig. 22). Less often, the syphilitic process may be more diffuse with the production of a fusi-

form aneurysm. Arteriosclerosis may also lead to aneurysmal formation in the thoracic aorta, but these lesions are more likely to produce diffuse dilatations of the aorta rather than sacciform aneurysms and to be located in the descending thoracic aorta (Figs. 24, 28). Of interest in this connection is the fact that, whereas in the past aneurysms of the thoracic aorta were considered to be predominantly of syphilitic origin, there are reasons to believe that in recent years this incidence is diminishing with increasing frequency of arteriosclerosis as the cause of these aneurysms. Analysis of our experience with approximately 150 cases of aneurysms of the thoracic aorta treated by resection reveals the incidence of these different types to be as follows: somewhat less than half the cases were of syphilitic origin; about 35 per cent were arteriosclerotic; about 7 per cent were traumatic; and the remainder were congenital, mycotic, or of undetermined origin.

Aneurysms involving the abdominal aorta are predominantly of arteriosclerotic origin. In our own series of approximately 500 cases, arteriosclerosis was considered to be the underlying cause in about 95 per cent. Characteristically, these aneurysms are fusiform, arise just below the origin of the renal arteries, and usually extend distally to involve the bifurcation (Fig. 17). Gross and microscopic evidence of the characteristic arteriosclerotic degenerative mural process is readily demonstrable on section (Fig. 16). Calcific and atheromatous changes are present in the dilated peripheral wall with a laminated thrombus on the inner surface. Immediately adjacent to the peripheral wall of the aneurysm, the laminated thrombus gradually undergoes liquefaction necrosis (Fig. 16). This is considered an important factor contributing to eventual rupture of the aneurysm.

Fig. 17. Photograph made at operation showing characteristic fusiform appearance of arteriosclerotic aneurysm of abdominal aorta arising just below renal arteries and extending down to bifurcation.

Clinical Manifestations. The signs and symptoms of aneurysms of the aorta usually result from encroachment upon adjacent structures. Accordingly, these manifestations depend largely upon the type, location, and size of the lesion. In its early stages, an aneurysm of the thoracic aorta may be asymptomatic or associated with only slight discomfort. In some instances, it may attain full development without causing significant subjective symptoms until the acute episode of fatal rupture occurs. In most cases, however, clinical manifestations reflecting progressive encroachment upon adjacent structures become apparent. Thus, compression of the vena cava and innominate veins by aneurysms of the ascending aorta and arch produces venous distention and edema of the shoulders, head, and neck. Dyspnea and cough result from compression of the air passages, and death by suffocation is not uncommon. Blood streaked sputum is an ominous sign that rupture of the aneurysm into the trachea and bronchus is imminent. Hoarseness may be produced by traction or stretching of the recurrent laryngeal nerve as it passes around a large aneurysm of the aortic arch. Sacciform aneurysms arising an-

Fig. 18. Roentgenogram of chest of patient showing large shadow projecting into right lung field which proved to be a large sacciform aneurysm arising from ascending aorta as depicted in diagram on right.

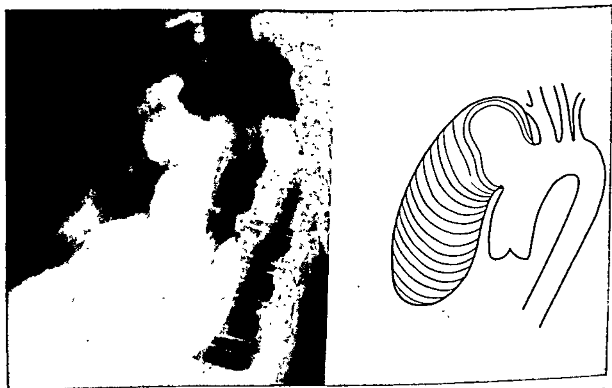

Fig. 19. Angiocardiogram made in same patient as in Figure 18, demonstrating sacciform aneurysm arising from ascending aorta. As depicted in the diagram on the right most of the lumen of the aneurysm is filled with thrombus, thus restricting apparent size of lumen as indicated by the radiopaque dye. This patient was successfully treated by resection of the aneurysm and repair by aortorrhaphy as shown in Figure 32.

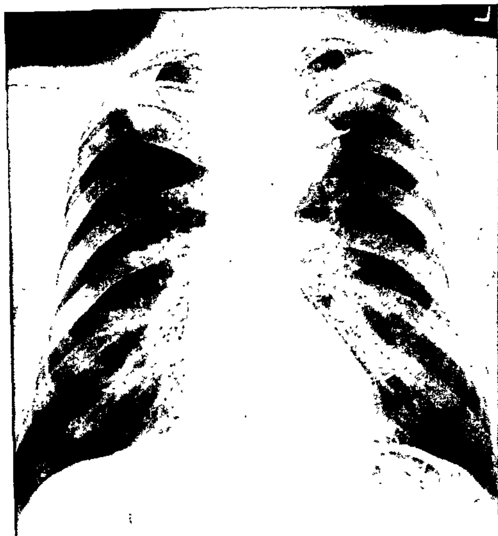

Fig. 20. Roentgenogram of chest showing rounded shadow in upper left mediastinum representing sacciform aneurysm of distal part of aortic arch, believed to be of syphilitic origin.

teriorly from the ascending aorta or transverse arch may progress to produce erosion of the sternum and ribs with the appearance of a pulsatile tumefaction on the anterior thoracic wall. Later, the skin overlying such a mass may become inflamed and may even ulcerate. Aneurysms in the distal portion of the aortic arch and descending thoracic aorta, particularly those of syphilitic origin, may produce erosion of vertebrae and ribs posteriorly (Fig. 15). Under these circumstances, pain may be radicular and excruciating. Cardiac decompensation is usually associated with a diffuse aneurysm of the ascending aorta that produces aortic valvular incompetence.

Diagnosis. The diagnosis of an aneurysm of the thoracic aorta may be suggested by the clinical manifestations described in the preceding paragraph along with roentgenographic demonstration of a pulsating mediastinal mass (Figs. 18, 20, 23, 26). In many instances, however, differentiation from a solid tumor may be difficult because transmitted pulsations from the contracting ventricles may give an appearance of expansion of the lesion, or the presence of a thrombus in the sac may restrict intrinsic pulsation (Figs. 18, 19, 20, 23). Aortography provides the best means of diagnosis since it permits visualization of the aorta and can establish the diagnosis of an aneurysm by the demon-

Fig. 21. Angiocardiogram of same patient as in Figure 20, showing precise location and intraluminal dimensions of sacciform aneurysm.

stration of contrast medium in the sac (Figs. 19, 21, 23, 27).

Aneurysms of the abdominal aorta may be associated with few or no clinical manifestations in their early stages and may remain silent until the acute episode of rupture takes place. Generally, however, they are characterized by a pulsating mass in the abdomen accompanied by varying degrees of discomfort. Later, the patient may experience pain in the upper part of the abdomen or lower portion of the back with extension into the groin or lower extremities. Pain is a particularly important and sometimes ominous sign, for it often represents rapid, progressive enlargement of the aneurysm and may signify imminent or even actual rupture of the aneurysm with retroperitoneal extravasation of blood. The most common and important physical finding is the presence of an expansile pulsating mass, which usually arises at or above the level of the umbilicus and may extend well below this level into the pelvis. The mass may be movable and nontender, but with rapid enlargement and imminent perforation it tends to become fixed and tender.

The diagnosis of an aneurysm of the abdominal aorta is usually not difficult since the presence of an expansile pulsating abdominal tumor may be considered pathognomonic. It can usually be confirmed by roentgenographic studies. Although the diagnosis may be established by lumbar aortography, experience has shown that this is usually unnessary. In the majority of cases

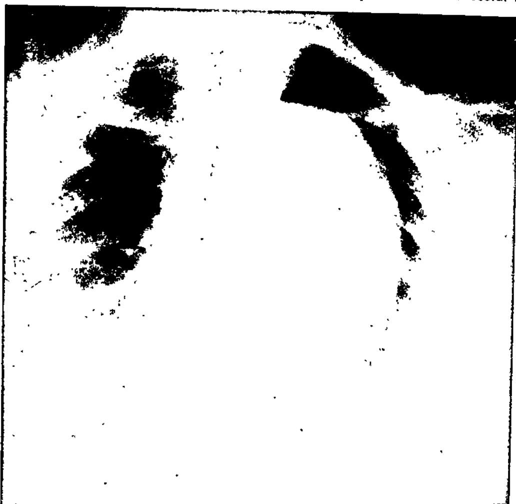

Fig. 26. Roentgenographic demonstration of huge fusiform aneurysm involving most of descending thoracic aorta considered to be arteriosclerotic in origin.

it is possible to demonstrate the presence of the aneurysm in ordinary plain roentgenograms of the abdomen, particularly in the lateral or oblique projections, owing to calcification in its wall (Fig. 30).

Prognosis. Studies on the natural course of the disease have demonstrated conclusively that an aortic aneurysm is a grave disease producing, in most instances, disabling symptoms and ultimate death by rupture and hemorrhage. From an analysis of a series of 1,113 patients with aneurysm of the thoracic aorta, for example, Kampmeier concluded that the average expected duration of life after the onset of symptoms was six to eight months, varying somewhat with the level of involvement. Admittedly, an occasional striking exception will occur, as exemplified by Kampmeier's report of two patients surviving 14 and 15 years, respectively. Although the average duration of life in aneurysms of the abdominal aorta is somewhat longer, the prognosis in this disease is also grave. Estes, for example, in his analysis of 101 patients with this condition, estimated that only 10 per cent of the patients aged 65 years would survive eight years, whereas 65 per cent of normal persons of this age would have a life expectancy of this duration. He also found that within a year after the diagnosis was made, one third of them were dead; one half had died within three years; and more than three fourths had died within five years, usually from rupture. Moreover, the degree of symptoms had no relationship to prognosis, since the patients who were asymptomatic at the time of diagnosis lived no longer than those who had symptoms. Others have reported a similar or even worse prognosis. Wright, for example, in his follow-up study of 68 cases found that only about 4 per cent of the patients had survived five years. Thus, the pres-

ence of an aortic aneurysm, regardless of type or location, is a serious and constant menace to the patient and demands prompt treatment.

Treatment. In the past, treatment of aneurysm of the aorta was directed toward obliteration of the aneurysm by inducing thrombosis within the lesion or by reinforcing the wall to forestall perforation. Such procedures proved to be inadequate and may now be considered obsolete. The only effective treatment consists in extirpation of the aneurysm with restoration of normal aortic continuity and function. This may be accomplished by one of several methods depending upon the type and location of the lesion. In sacciform aneurysms, for example, it is usually possible to apply an occluding clamp across the relatively narrow neck of the lesion and in this way to perform tangential excision of the aneurysm with repair by lateral aortorrhaphy (Fig. 32). In fusiform aneurysms, the entire segment of aorta involved by the aneurysm must be removed and replaced by an aortic graft (Figs. 25, 29, 31, 34). For this reason, temporary arrest of circulation through this segment of aorta by the application of occluding clamps immediately above and below the aneurysm is necessary during performance of the procedure. Under these circumstances, and depending upon the level of occlusion, serious consequences may ensue because of the cardiac strain produced and because of the possible ischemic effect upon tissues located distal to the occlusion. In general, the higher the level of occlusion and the longer the period of interruption of aortic circulation, the greater is the risk from such disturbances, particularly for aneurysms arising above the level of the renal arteries, since below this level temporary interruption of aortic circulation is well tolerated. To overcome this problem, one of several approaches may be employed, depending upon the nature and location of the lesion, including hypothermia, temporary shunts, extracorporeal

Fig. 31. Photograph made at operation following resection of aneurysm of abdominal aorta and showing functioning dacron bifurcation graft used to replace excised segment of aorta. The aneurysm in this case arose somewhat higher than usual to involve left renal artery, but circulation to left kidney was restored by end-to-side anastomosis of left renal artery to dacron graft.

circulation, and performance of the procedure in a manner to minimize the period of circulatory arrest (Fig. 33). Replacement of the excised segment of the aorta may be done with the use of an aortic homograft or a suitable substitute of plastic materials, such as nylon or dacron woven tubes. In recent years, our experience has led us to believe that the flexible, knitted, seamless dacron tube is the most satisfactory vascular replacement for this purpose.

Results of these methods of extirpational therapy in our experience with approximately 650 cases of aneurysms of the aorta have been most gratifying and support the conviction that it provides the most effective form of management for this disease. Moreover, there are few contraindications to application of this method of treatment. So long as the proximal portion of the ascending aorta is uninvolved, excision of the lesion is feasible, regardless of its location. The most important contraindications to operations are concerned with serious associated systemic disease, such as severe or disabling cardiac, renal, or cerebral disturbances.

The operative mortality varies with the type and location of the lesion and is particularly influenced by certain factors, such as advancing age, pre-existing heart disease, and acute rupture of the aneurysm. Aneurysms of the thoracic aorta, for example, are associated with a higher operative fatality rate than those of the abdominal aorta, the respective figures being on the order of 25 to 30 per cent and 5 to 10 per cent. The influence of age is shown by the fact that the fatality rate in patients in the eighth decade of life is more than twice that of patients in the fourth and fifth decades. Similarly, the fatality rate in patients with pre-existing heart disease was more than three times greater than that in patients without heart disease. One of the most important factors contributing to operative deaths is acute rupture of the aneurysm. This is well demonstrated by the fact that operative mortality in our series of aneurysms of the abdominal aorta was more than four times greater in the group with rupture than in those with nonperforated aneurysm, the respective figures being about 33 per cent and 7 per cent. There is reason to believe that improvement in the surgical management of these patients, as well as in the actual technical performance of the operation derived from increasing experience, should permit further reduction in the risk. This is well exemplified by the progressive decrease in the operative fatality rate of approximately 20 per cent in our first 100 cases of aneurysms of the abdominal aorta to

Fig. 32. 4 per cent in our last 100 cases. Finally, studies of long term results of operation with follow-up observations extending over a period of five years reveal a significant increase in life expectancy.

DISSECTING ANEURYSM OF THE AORTA

Dissecting aneurysm of the aorta is a distinct clinical and pathologic entity characterized by hemorrhagic intramural separation of the aortic wall in the region of the media usually communicating with the normal lumen by an intimal tear. Its incidence has been variously reported between 0.1 and 1 per cent of necropsy cases, but with recent increasing awareness of the condition, there is reason to believe that the actual incidence may be higher than that generally reported. Males are affected about twice as often as females with the highest age incidence in the fourth to seventh decades.

The etiology of the disease remains obscure, although certain factors have been considered to have a causal relationship owing to their frequent association with its occurrence. These include arachnodactyly or Marfan's syndrome, pregnancy, hypertension, coarctation, and idiopathic kyphoscoliosis. The possibility of a toxic factor or a specific protein deficiency has also been suggested from certain experimental studies showing the occurrence of aortic dissection and rupture in rats fed sweet-pea meal or aminonitriles.

Pathogenesis and Pathology. The underlying predominant lesion appears to be degeneration *of the elements of the media*, whether it is to be considered a form of the classic "medionecrosis cystica" of Erdheim or of "faults" of Shennan. It is apparently unrelated to atherosclerosis or syphilis. The pathogenesis of the initial rupture or tear in the intima and media is not well understood. According to the prevailing hypothesis the lesion develops as an intramural hematoma from rupture of the thin-walled vasa vasorum within an area of focal medionecrosis with secondary rupture of the intima. Some observers, however, are inclined to the belief that certain mechanical factors may play a role in this process, including conversion of the longitudinal force during diastole into a transverse force with lateral stretching and

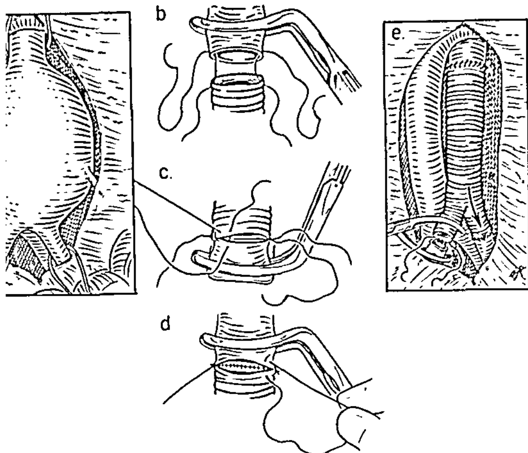

Fig. 31. Photograph made at operation following resection of aneurysm of abdominal aorta and showing functioning dacron bifurcation graft used to replace excised segment of aorta. circulation, and performance of the procedure in a manner to minimize the period of circulatory arrest (Fig. 33). Replacement of the excised segment of the aorta may be done with the use of an aortic homograft or a suitable substitute of plastic materials, such as nylon or dacron woven tubes. In recent years, our experience has led us to believe that the flexible, knitted, seamless dacron tube is the most satisfactory vascular replacement for this purpose.

Results of these methods of extirpational therapy in our experience with approximately 650 cases of aneurysms of the aorta have been most gratifying and support the conviction that it provides the most effective form of management for this disease. Moreover, there are few contraindications to application of this method of treatment. So long as the proximal portion of the ascending aorta is uninvolved, excision of the lesion is feasible, regardless of its location. The most important contraindications to operations are concerned with serious associated systemic disease, such as severe or disabling cardiac, renal, or cerebral disturbances.

The operative mortality varies with the type and location of the lesion and is particularly influenced by certain factors, such as advancing age, pre-existing heart disease, and acute rupture of the aneurysm. Aneurysms of the thoracic aorta, for example, are associated with a higher operative fatality rate than those of the abdominal aorta, the respective figures being on the order of 25 to 30 per cent and 5 to 10 per cent. The influence of age is shown by the fact that the fatality rate in patients in the eighth decade of life is more than twice that of patients in the fourth and fifth decades. Similarly, the fatality rate in patients with pre-existing heart disease was more than three times greater than that in patients without heart disease. One of the most important factors contributing to operative deaths is acute rupture of the aneurysm. This is well demonstrated by the fact that operative mortality in our series of aneurysms of the abdominal aorta was more than four times greater in the group with rupture than in those with nonperforated aneurysm, the respective figures being about 33 per cent and 7 per cent. There is reason to believe that improvement in the surgical management of these patients, as well as in the actual technical performance of the operation derived from increasing experience, should permit further reduction in the risk. This is well exemplified by the progressive decrease in the operative fatality rate of approximately 20 per cent in our first 100 cases of aneurysms of the abdominal aorta to

Drawing showing method of resection of aneurysm of abdominal aorta. a, after entering cavity through long mid-line incision, the small intestine and its mesentery are retracted to ie aneurysm is exposed by linear incision of overlying peritoneum with mobilization of surround- 'es. Umbilical tapes encircle aorta immediately above aneurysm and common iliac arteries im- below. Occluding clamps are then applied at level shown by encircling umbilical tapes and esected. Excised segment of aorta is then replaced with graft. b, anastomosis of graft to proximal aorta is shown using laterally placed anchoring sutures of No. 0000 arterial silk. c, one of the ien used to perform the posterior layer of the anastomosis using continuous through-and-through the other suture is used to complete the anterior layer of the anastomosis. e, after completing iortic anastomosis and the left common iliac anastomosis, blood flow through graft and into left emity is restored while remaining anastomosis to right common iliac artery is being performed.

ɔeripheral manifestations may de- erebral or neurologic disturbances, rly hemiplegia or paraplegia, are not on, while in some cases abdominal ıs may be predominant. In still other ıal disturbances and even renal fail- develop. Not infrequently, interfer- h peripheral arterial flow in the ex- ; occurs and may be erroneously :d to acute arterial embolism.

ional findings on examination in- e presence of an aortic diastolic mur- from one fourth to one half of the 'hich is particularly significant in pa- ı whom such a murmur did not exist previously. Hypertension is present in more than half the cases. Rarely ecchymosis in the lower part of the neck, upper portion of the chest, or lumbar or abdominal area may be observed.

Diagnosis. The most important factor in the diagnosis of dissecting aneurysm is awareness of its possible occurrence, particularly in the presence of the characteristic clinical manifestations. The acute onset, the severe chest pain, the subsequent radiation or "marching" of manifestations to other regions, and the history of hypertension are highly suggestive of the diagnosis. In its early stages the clinical picture is most often con-

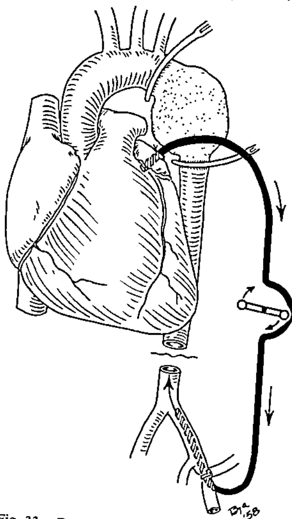

Fig. 33. Drawing illustrating method of resection of fusiform aneurysm of descending thoracic aorta with the use of controlled extracorporeal circulation to overcome ischemic effects of arrest of aortic circulation during performance of procedure. Oxygenated blood is removed from left auricle by means of plastic catheter inserted through appendage and then pumped into distal aorta through catheter inserted into left common femoral artery.

distention of the aorta, fixation of the ends of the aortic arch by the pulmonary artery and bronchi, and sudden increase in blood pressure from trauma or other causes.

The dissection commonly begins as a transverse tear in the intima and media a few centimeters above the aortic valves or in the descending thoracic aorta near the origin of the left subclavian artery or in the ligamentum arteriosum (Figs. 35, 38). Once this occurs, separation of the intramural layers of the aorta by the forceful stream of blood produces dissection, usually at the junction of the middle and outer thirds of the media.

This dissection may then progress circumferentially to involve all or a portion of the aorta and distally down to the bifurcation and even lower to invade the femoral arteries. As branches are encountered, they may be sheared off, or the dissecting process may extend along them for varying distances, thus diminishing or completely interrupting the blood supply to these areas. The extent and course of this process are variable. In the most acute and severe form dissection is rapid, and finally, terminal perforation occurs through the adventitia into the pericardium, mediastinum, pleural or peritoneal cavities, with death in a few hours or days. The subacute type may begin abruptly but may then progress gradually over a period of days or weeks to terminal adventitial rupture and death. In still other more chronic forms of the disease, the dissected passage may reenter the true lumen of the aorta to form a "double-barreled" aorta (Fig. 38). The false passage may then become covered with an endothelium or become obliterated by formation of thrombi and subsequent fibrous tissue organization.

Clinical Manifestations. Owing to the variation in extent and progression of the dissecting process, the clinical manifestations may be protean, with symptoms and signs occurring first in the chest and then extending more or less rapidly to other regions, such as the back, head, neck, shoulders, abdomen, groin, and lower extremities. This sequence or "marching" of manifestation from one region to another is a reflection of the progress of the dissection and the consequent injurious or ischemic effects upon the organs supplied by the major arterial branches of the aorta.

Perhaps the most striking manifestation of the disease is the sudden onset of severe, almost indescribable pain in the chest or epigastrium which may extend along the course of the ribs to the back and then up into the neck and shoulders or down into the abdomen. In some instances, the onset may be marked by loss of consciousness. Shock with significant lowering of blood pressure is frequently present. Depending upon the degree of interference with blood supply to the central nervous system, abdominal viscera, or extremities, a variety of neurologic abdomi-

Fig. 36. Fig. 37. Angiocardiogram of same patient as Figure 36 showing characteristic double aortic lumen produced by relative difference in concentration of dye in true and false aortic lumens of dissecting aneurysm.

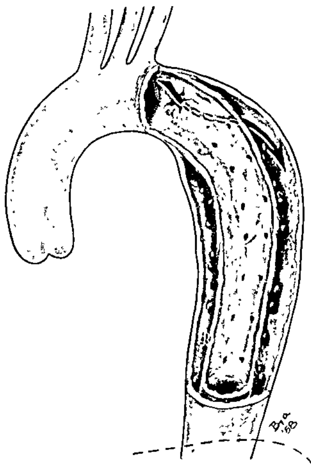

Fig. 35. Drawing illustrating gross pathologic features of dissecting aneurysm of aorta in which the dissecting process arises below the level of the origin of the left subclavian artery. Part of wall has been cut away to show separation of medial layer with false lumen surrounding true lumen and intimal tear through which lumens communicate.

fused with that of myocardial infarction, but in most cases of dissecting aneurysm, the electrocardiogram shows either a normal pattern or evidence only of left ventricular hypertrophy. The occurrence, however, of an electrocardiographic picture of acute coronary occlusion does not exclude the presence of dissecting aneurysm.

Perhaps the most significant diagnostic studies are those obtained by roentgenologic examination. Characteristically, roentgenograms of the chest show widening and radiolucence of the aortic arch and descending thoracic aorta. The most common finding is widening of the supracardiac shadow, involving the entire thoracic aorta or some segment of it (Fig. 36). This may be better evaluated by comparison with roentgenograms of the chest taken prior to the dissection. Another common radiologic finding is that of a double aortic shadow, consisting of a somewhat dense central core and an outer, more radiolucent portion representing the dissected passage. Evidence of pleural effusion, particularly on the left, is another important feature. Sectional roentgenography may also provide characteristic findings, demonstrating widening of the ascending aortic arch, and thus may permit differentiation of a nonvascular mediastinal lesion. Angiocardiography is probably the most valuable diagnostic procedure. In this type of examination the dye appears heavily concentrated in the true aortic lumen, whereas the false passage appears as a lateral or medial, somewhat superimposed, less dense channel (Fig. 37).

Prognosis. The prognosis in dissecting aneurysm of the aorta is extremely grave. In the classic study by Shennan, for example, death occurred within 24 hours after onset in 58 per cent and in one day to one week in 26 per cent of the patients. Somewhat similar figures have been reported by others. Death may occur rapidly from rupture into the pleural, pericardial, or peritoneal cavities or more slowly from progressive mediastinal or retroperitoneal hemorrhage, cardiac failure, or renal failure. Only in about 10 to 15 per cent of patients with the chronic or healed type of dissection is there a chance of significant survival, and even in this group further dissection may take place or death may result from cardiac failure.

Treatment. Until recently, treatment of this condition was unsatisfactory. In recent years, however, a method has been devised that appears to provide an effective surgical approach to the disease. The underlying principle of this approach is based upon nature's method of healing in which spontaneous re-entry of the dissected passage at some distal point in the aorta permits restoration of peripheral circulation, removes the increasing tension upon the outer wall, and thus prevents its rupture. The operative procedure is thus directed toward interruption of the progress of the dissection by creation of conditions compatible with function or correction of the process by actual removal and repair.

Accordingly, two methods of surgical

Drawing showing method of surgical treatment of dissecting aneurysm of aorta using controlled extracorporeal circulation to combat ischemic effects of arrest of blood flow in aorta. a, blood is removed from left auricle through catheter inserted in auricular appendage and pumped into distal aorta through catheter inserted in left common femoral artery. By this means circulation is maintained in aorta distal to site of application of occluding clamps for resection of aneurysm. b, after excising segment of dissecting aneurysmal process above its origin, the false lumen in the distal end is obliterated by sewing outer and inner walls together with continuous suture. c, anastomosis of graft to upper aortic opening is done by continuous suture with No. 0000 arterial silk. d, completed anastomosis of graft to lower opening in aorta permits restoration of aortic continuity.

riche's syndrome, is a distinct clinical and pathological entity characterized by partial or complete obstruction of the aorta in the region of its bifurcation and producing manifestations of arterial insufficiency of the lower extremities. Although sporadic reports describing the condition had appeared much earlier, Leriche deserves credit for directing attention to the condition as a definite entity, first in 1923 and later for a more thorough description of the syndrome and its differentiation from other vascular disturbances. Since then, and probably as a consequence of the further interest that was aroused by these reports and by the wider use of aortography, it is now recognized as one of the most common causes of arterial insufficiency of the lower extremities. The predominant etiologic factor responsible for this condition is arteriosclerosis or atherosclerosis, and only rarely do other factors, such as trauma, thromboangiitis obliterans, and atypical forms of coarctation, play a role in its causation.

Pathology. The arteriosclerotic lesion begins with intimal proliferation and deposition of lipid material in the subintimal layer of the arterial wall. Continuing deposition of this substance and local changes in the deposit itself result in the formation of an atheroma. This lesion may be extensive, but it is more frequently localized, often being only a few centimeters in length. As the atheroma enlarges, it tends to project into the arterial lumen, gradually producing obstruction to

Fig. 38. Photographs of resected segment of dissecting aneurysm of thoracic aorta removed at operation in same patient as Figures 36 and 37 showing, left, gross appearance of intact specimen with arrows above and below representing true lumen; and, above, sagittal view with arrow pointing to intimal tear through which true lumen communicated with false lumen. Lower end of this photograph shows cross sectional view of specimen demonstrating characteristic "double-barreled" aorta with smaller true lumen and larger false lumen produced by dissecting aneurysm.

treatment may be employed, depending upon the site and extent of the dissecting process. The first is indicated in cases in which the dissection begins in the ascending aorta and consists of creation of a re-entry passage from the false to the true aortic lumen. This is done by cross-clamping the descending thoracic aorta, dividing it completely between clamps, obliterating the false passage below by approximating the outer and inner layers, excising a small segment from the inner wall above to permit re-entry into the true lumen, and then completing the procedure by end-to-end anastomosis. Blood flow is then directed from the double aortic lumen above into the single normal lumen below.

The second method is indicated in cases in which the dissection begins near the origin of the left subclavian artery and may be considered a more curative procedure since it removes the origin of the dissecting process and obliterates the false passage (Fig. 39). It consists of excision of the segment involved in the origin of the dissection and replacement with an aortic homograft after the distal false passage has been obliterated by suturing together the edges of the inner and outer walls. An important consideration in the postoperative management is control of hypertension. Results of this form of therapy have been quite gratifying. The operative mortality has been about 25 per cent, and follow-up observations during a period of more than three years have indicated maintenance of good functional activity.

THROMBO-OBLITERATIVE DISEASE OF THE ABDOMINAL AORTA

Thrombo-obliterative disease or arteriosclerotic occlusive disease of the abdominal aorta, also termed insidious thrombosis of the aorta, chronic aortoiliac thrombosis, or Le-

Fig. 39. riche's syndrome, is a distinct clinical and pathological entity characterized by partial or complete obstruction of the aorta in the region of its bifurcation and producing manifestations of arterial insufficiency of the lower extremities. Although sporadic reports describing the condition had appeared much earlier, Leriche deserves credit for directing attention to the condition as a definite entity, first in 1923 and later for a more thorough description of the syndrome and its differentiation from other vascular disturbances. Since then, and probably as a consequence of the further interest that was aroused by these reports and by the wider use of aortography, it is now recognized as one of the most common causes of arterial insufficiency of the lower extremities. The predominant etiologic factor responsible for this condition is arteriosclerosis or atherosclerosis, and only rarely do other factors, such as trauma, thromboangiitis obliterans, and atypical forms of coarctation, play a role in its causation.

Pathology. The arteriosclerotic lesion begins with intimal proliferation and deposition of lipid material in the subintimal layer of the arterial wall. Continuing deposition of this substance and local changes in the deposit itself result in the formation of an atheroma. This lesion may be extensive, but it is more frequently localized, often being only a few centimeters in length. As the atheroma enlarges, it tends to project into the arterial lumen, gradually producing obstruction to

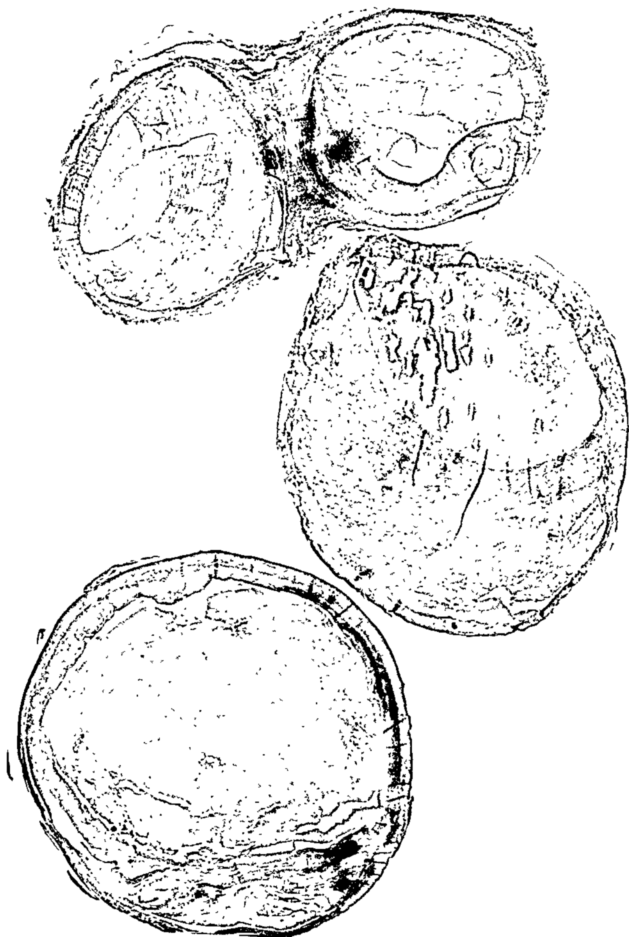
Fig. 40. Sagittal section of resected segment of abdominal aorta and bifurcation in a case with complete occlusive disease, showing extensive atheromatous mural changes, most pronounced in region of bifurcation, with superimposed thrombosis in various stages of organization.

blood flow. At first only partial interference to circulation occurs, but as the lumen becomes reduced to a critical level, thrombosis develops so that the arterial lumen becomes completely occluded. With the development of a superimposed thrombus, the occluding lesion extends both proximally and distally until a collateral arterial channel is reached, through which blood flows at a rate vigorous enough to prevent thrombosis. The occluding lesion under these circumstances consists of the atheromatous mass and thrombus in various stages of organization. The intraluminal thrombus undergoes reorganization by fibrous tissue, and the inflammatory reaction of healing incited by the thrombus and the foreign-body reaction stimulated by the atheroma produce local arterial invasion by fibrous tissue that results in the incorporation of the involved arterial segment within dense fibrous or scar tissue. The extent of this reaction depends, of course, on the duration of the occlusion. Acute occlusions may show little or no such reaction while those of long duration may be associated with advanced changes. The terminal aorta in patients with longstanding disease has occasionally been found to be largely replaced by, or incorporated in, dense fibrous scar tissue.

The arteriosclerotic lesion producing obstruction of the aortic and iliac arteries is located in the common iliac artery, either at its bifurcation into external and internal iliac arteries or at its origin from the aorta, and may assume several recognizable forms depending upon the degree and extent of involvement. Accordingly, it may be classified into those producing 1. incomplete or 2. complete occlusion. In the former type the lesion is limited to the atheroma and may involve one or both iliac arteries. In some instances, one of the common iliac arteries becomes completely occluded, the lumen being filled with organizing thrombus superimposed on the atheromatous lesion. When both common iliac arteries become similarly involved, the terminal aorta becomes completely occluded and the thrombotic process

gradually propagates upward to the renal arteries, and ultimately occlusion of these vessels may occur with terminal renal failure (Fig. 40).

Histologic studies of the diseased segments further support the concept that the occlusive pathologic changes arising about the aortic bifurcation and common iliac arteries can extend by propagation of the thrombotic process to an adjacent portion of the aorta (Fig. 41). Although it is conceivable that the partially occlusive lesions of the iliac arteries represent stages in the development of disease toward complete aortic occlusion, certain significant differences have been observed in these two forms of the condition. Among these the most impressive feature has been the fact that a high proportion of the cases with complete aortic occlusion seem to have a well-localized process, with the obliterative lesion confined to the terminal aorta and bifurcation and with a relatively normal patent peripheral arterial bed (Figs. 42, 43). On the other hand, in those with incomplete occlusion, the disease tends to be much less localized and to be more commonly associated with atherosclerotic occlusive lesions of the peripheral arterial tree (Figs. 44, 45).



This process of occlusion fortunately is gradual, and because of its frequently insidious nature, collateral channels are able to enlarge as the main arterial routes become progressively obstructed. As a result of this natural alteration, gangrene usually does not occur immediately after occlusion; however, in view of the reduction in the volume of peripheral blood flow, chronic arterial insufficiency ensues.

Clinical Considerations. The disease occurs predominantly in the male sex in the fifth to seventh decades of life. In our series the ratio of males to females was approximately 10:1. Among the patients with diabetes, however, this difference in sex ratio was much less pronounced. In this connection, too, diabetes was most commonly encountered in the younger age group. Approximately 90 per cent of the cases occur in the fifth, sixth, and seventh decades, with the highest incidence, approximately 40 per cent, in the sixth decade. The youngest patient in our series of cases was 26 years of age and the oldest 81 years. Of particular significance is the fact that patients with complete occlusion of the aorta were, on the average, about a decade younger than those with incomplete occlusion.

The symptoms and physical findings of chronic occlusion of the aorta and iliac arteries vary with the extent and duration of ischemia as well as with the location of the lesion. The clinical manifestations may be mild, moderate, or severe. In the earlier stages of the disease, the patients have only mild intermittent claudication and complain of a feeling of fatigue, weakness, or tightness in the lower legs or thighs on walking a short distance. Characteristically, these sensations disappear almost immediately upon resting, only to return again on further walking. On physical examination, pulses in the lower extremities are diminished or absent and the other signs of ischemia are often absent. Occasionally, no abnormalities are found; however, the intermittent nature of the complaint, occurring only during episodes requiring increased circulation, is highly suggestive of early arterial insufficiency, and additional specialized studies to be described later are advisable. In these cases, the lesion is still well localized and usually only partially occludes the arterial lumen.

As the disease progresses, evidences of moderately severe peripheral ischemia become apparent. This is manifested by rather severe pain when the patient walks short distances, resulting in considerable limitation of his routine activities. The pain may occur in any part of the lower extremities but often is first noted in the thighs, buttocks, or in the back. The most significant finding on physical examination is absence of pulses throughout the extremity. Other findings are atrophy of the involved extremities, loss of hair, and decreased temperature of the feet. If obstruction is unilateral, the clinical manifestations will, of course, be limited to the involved side.

In the more advanced stages of the disease, manifestations of ischemic changes that are pregangrenous or associated with early gangrenous lesions develop. Such patients have severe or terminal arterial insufficiency and unless properly treated are destined to have

amputation. These patients usually have had mild to moderate manifestations of the disease for years, with gradual progression until pain is present at rest (rest pain), particularly at night when the extremities are elevated (night pain). On physical examination the examiner notes absent pulses beyond the point of obstruction in the involved extremities, cold extremities, blanching on elevation, dependent rubor, slow venous filling, and cutaneous lesions ranging from ulceration to gangrene.

Diagnosis. The diagnosis of this disease can usually be made on the basis of the characteristic clinical manifestations and physical findings. Of particular significance in this connection is its differentiation from Buerger's disease or thromboangiitis obliterans, since the more effective forms of surgical treatment, such as thromboendarterectomy and arterial graft procedures, are generally not applicable to the latter condition. Buerger's disease may be readily differentiated clinically from this form of arteriosclerotic occlusive disease of the aorta on the basis of several characteristic features. For one thing, Buerger's disease characteristically begins in the third or fourth decade of life and only rarely is its onset in the fifth decade. Arteriosclerotic occlusive disease, on the other hand, becomes manifest later in life, usually in the fifth to the seventh decades. A history of migratory phlebitis may often be elicited in Buerger's disease and is not a characteristic feature of arteriosclerotic occlusive disease. Moreover, Buerger's disease usually involves the medium sized vessels and tends to appear first in the arterial tree below the knee and only in its later stages does it involve the femoral artery in the region of the groin. Accordingly, femoral arterial pulsations are usually present in Buerger's disease, whereas in arteriosclerotic occlusive disease of the terminal abdominal aorta, femoral arterial pulsations are absent or greatly diminished. In doubtful cases, however, and in all cases in which occlusion in the iliofemoral region is suspected, arteriographic studies are essential not only to confirm the diagnosis but also to demonstrate the presence or absence of a patent segment of artery distal to the occlusion.

Although the diagnosis of thrombo-obliterative disease of the abdominal aorta can usually be made on the basis of the characteristic clinical findings, certain additional methods of study may be necessary in order to confirm the diagnosis and to provide information essential to proper therapy. Among these, lumbar aortography is the most important because it not only establishes the diagnosis but it also provides precise information concerning the location of the occlusive lesion and its extent both proximally and distally (Figs. 42, 43, 44, 45). In this procedure, radiopaque material is injected into the abdominal aorta above the lesion and an abdominal roentgenogram is taken immediately on completion of the injection. The distal aorta and iliac arteries are thus visualized, so that the presence, nature, and extent of the lesion can be determined. Technically, this procedure is performed with use of a local or general anesthetic with the patient lying prone over the cassette containing the x-ray film. A seven-inch No. 17 gauge needle is inserted through the back on the left into the abdominal aorta opposite the twelfth dorsal vertebra. An organic iodide compound, preferably 70 per cent Urokon, is injected in doses of 30 ml. or less and the x-ray film is exposed as the injection is being completed. This technic of aortography has proved safe and satisfactory in our hands in more than 350 consecutive cases.

Treatment. Treatment of arterial insufficiency is directed toward restoration of a pulsatile blood flow throughout the lower extremities. The restored circulation permits return of normal function and provides normal reparative powers for the extremity. The localized nature of the occlusion, being as-

Fig 41 Low power photomicrographs of cross sections of aorta at various levels in resected specimen in case of thrombo-obliterative disease of aorta. Top, section taken at level of aortic bifurcation near origin of common iliac arteries, showing characteristic extensive atheromatous mural changes and superimposed thrombotic process producing complete occlusion of lumens. Middle, section taken at higher level near origin of inferior mesenteric artery, showing somewhat less extensive atheromatous mural involvement with organized thrombus occluding remaining lumen of aorta. Bottom, section taken at a still higher level on the aorta a few centimeters below origin of renal arteries shows progressive diminution in extent of atherosclerotic mural changes with more freshly organized thrombus filling lumen of aorta.

Fig. 42. Lumbar aortogram in a patient with thrombo-obliterative disease of abdominal aorta showing complete obstruction of aortic lumen. Occlusion arises just above bifurcation and extends distally to involve iliac arteries, but the femoral arteries are patent, thus demonstrating characteristic segmental nature of occlusive lesion.

Fig. 43. Lumbar aortogram in patient with thrombo-obliterative disease of abdominal aorta. The occlusive lesion has progressed proximally to origin of renal arteries and is beginning to encroach upon opening of right renal artery. Distally the occlusive process involves the iliac arteries, but the femoral arteries below this level are patent. (Note silver clips on each side of lumbar vertebrae representing lumbar sympathectomy performed previously for treatment of arterial insufficiency of lower extremities.)

Fig. 44. Lumbar aortogram in patient with thrombo-obliterative disease of abdominal aorta of the incomplete occlusive type associated with segmental occlusion of right femoral artery.

sociated in most cases with reasonably normal channels both above and below the obstruction, permits application of recently developed vascular technics for this purpose. These include thromboendarterectomy, excision of the obstructive arterial segment with graft replacement, bypassing the occlusion by means of end-to-side anastomoses of the graft above and below the lesion, or a combination of these procedures (Fig. 46). The indications for these various methods of treatment are dependent upon the location, extent, and nature of the occlusive process.

Short, discrete, occlusive lesions in vessels with normal outer layers may be simply removed by thromboendarterectomy. A well-defined cleavage plane exists between the involved intima and the uninvolved medial layer of the artery. Thromboendarterectomy is performed by temporarily occluding the artery to prevent bleeding, opening the involved artery, dissecting out the obstruction through the plane previously mentioned, and suture repairing the incision in the artery (Figs. 47, 48). Since this procedure is simple to perform and obviates the need for an arterial substitute, it would appear to be the ideal operation; however, it can be satisfactorily applied in only about one third of the cases.

In some patients, the arteriosclerotic lesion may involve the outer layers of the arterial wall to such extent that endarterectomy is not feasible. In cases of this type in which the mural atherosclerotic process about the bifurcation is extensive and destructive but fairly well localized, resection with graft replacement is the procedure of choice. In still other patients, the occlusion may involve a long segment of the aorta, common and external iliac arteries. Under these circumstances, both endarterectomy and excision with graft replacement may be undesirable because of the extent of the operative procedures on the one hand and the risk of collateral vascular injury on the other. Rather, it is preferable to bypass the region of disease. This is accomplished by suturing the ends of a suitable arterial substitute both above and below the occlusion without significantly disturbing the collateral channels (Fig. 49). Although both homografts and various types of plastic tubes have been successfully employed for vascular replacements, the most satisfactory material in our experience for this purpose has proved to be a specially designed flexible dacron tube available in different sizes and with branches

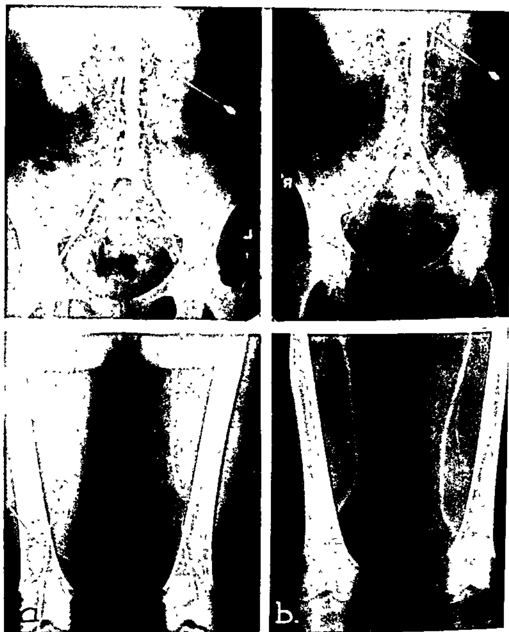


Fig. 45. a, lumbar aortogram made preoperatively in patient with incomplete occlusion of terminal abdominal aorta and iliac arteries associated with segmental occlusion of both femoral arteries. b, lumbar aortogram made following surgical treatment, consisting of thromboendarterectomy of abdominal aorta and iliac arteries and bypass grafts from femoral to popliteal arteries bilaterally, showing restoration of normal circulation.

for replacement of any operable arterial segment (Fig. 49).

All patients with arteriosclerotic occlusive lesions of the distal aorta and iliac arteries are candidates for one or a combination of these forms of therapy, and normal circulation can be restored in almost all instances with relief of symptoms and preservation of extremities. This approach, however, is rarely applicable in occlusive lesions of the aorta and iliac arteries as a result of thromboangiitis obliterans. This lesion is diffuse, and by the time the larger channels have become involved, the smaller distal vessels have already become occluded; and in the absence of distal patent channels, direct operative measures are impossible. Under these circumstances, treatment is directed toward increasing collateral blood flow, local protective care of the lower extremities, and

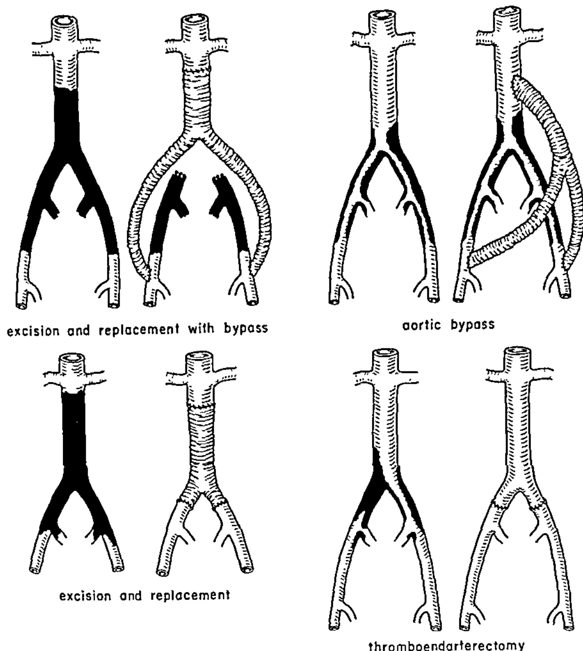

Fig. 46. Diagrammatic drawing showing various methods of surgical treatment of thrombo-obliterative disease of abdominal aorta.

withdrawal of harmful influences. By eliminating vasoconstrictor tonus and increasing cutaneous blood flow, lumbar sympathectomy is the most helpful and constant method of promoting collateral circulation and should be considered in every case. Daily foot baths should be taken to promote cleanliness and prevent infection. Habitual use of tobacco and other vasoconstrictor agents should be prohibited in order to obtain the maximum blood flow.

The results obtained by these methods of direct operative treatment of thrombo-obliterative disease of the abdominal aorta and iliac arteries have been most gratifying. In our series of over 400 cases in which these methods of therapy have been employed, excellent results with complete relief of symp-

Drawing illustrating a, type of well-localized lesion in which thromboendarterectomy may be performed satisfactorily; b, technic of performance of procedure by applying occluding clamps above and below the lesion to arrest circulation through the segment of vessel following which right iliac artery is transected; and c, d, separation of thrombotic and intimal occlusive processes from outer adventitial and medial layer of artery by well-developed cleavage plane; e, following complete removal of the occlusive process, arterial continuity is restored by end-to-end anastomosis of vessels.

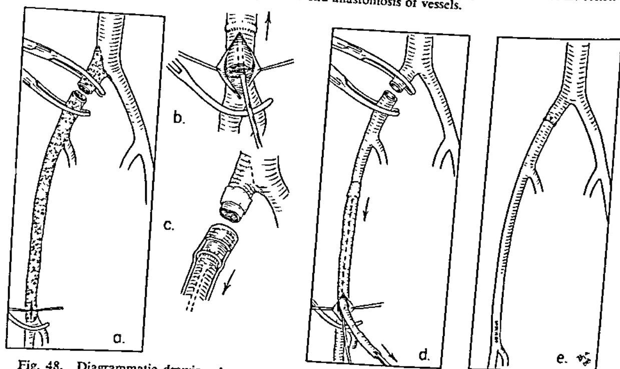

Fig. 48. Diagrammatic drawing showing method of performing thromboendarterectomy in external iliac artery using ring strippers developed by authors for this purpose.

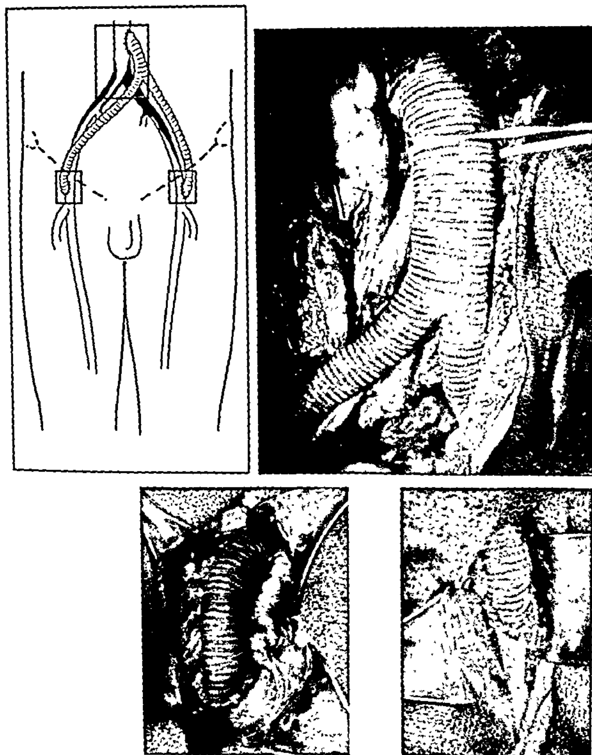

Fig. 49. Photographs made at operation showing completed procedure of bypass dacron graft from abdominal aorta above to both common femoral arteries below as diagrammatically illustrated in upper left.

toms and restoration of normal pulsatile circulation in the lower extremities was obtained in approximately 90 per cent of the cases. The risk of operation is relatively low, the operative mortality in our series being only about 2 per cent.

In the selection of patients for this form of surgical treatment, our experience would suggest that it is applicable in the majority of patients with this type of arteriosclerotic occlusive disease of the abdominal aorta and iliac arteries. There are few contraindications to operation, the most important being the presence of severe or disabling cerebral, cardiac, pulmonary, or renal systemic disease. Compensated heart disease, hypertension, and diabetes are not contraindications to operation. Age in itself is also not a contraindication to operation.

THROMBO-OBLITERATIVE DISEASE OF THE BRANCHES OF THE AORTIC ARCH

Thrombo-obliterative disease of the branches of the aortic arch is a clinical entity resulting from occlusion of one or more of the major branches arising from the aortic arch. It is also known as the aortic arch syndrome, pulseless disease, reverse coarctation, Takayasu's disease, and Martorell's syndrome.

Although the condition was well described by Broadbent in 1875, except for Takayasu's report in 1908 and subsequent reports of other Japanese ophthalmologists, little interest has been shown in the disease until recently. Shimizu and Sano, in 1951, received wide recognition for their report with its eye-catching title, "Pulseless Disease," and undoubtedly caused greater awareness of the condition. Since then, an increasing number of reports has appeared in both the American and the European literature. Contrary, however, to the earlier indications that the disease was predominantly of Japanese origin, these recent reports suggest that it has widespread geographical distribution and probably occurs more frequently than previously realized.

The etiology is not entirely clear although various contributing etiologic factors have been proposed, including syphilitic aortitis, aneurysm of the aortic arch, nonspecific arteritis, atheromatosis, and trauma. More recent pathologic study of specimens removed surgically indicates that arteriosclerosis is perhaps the most frequent cause of this condition. The most important pathologic feature of the lesion is its localized nature, involving primarily the innominate, carotid, and subclavian arteries (Figs. 50, 51). Although all branches of the aortic arch may be involved, the lesion may be localized to only one branch. The disease rarely extends beyond the course of these vessels in the neck and proximally is limited to their origin from the aortic arch. Thus the obliterative lesion is segmental in character with relatively normal arterial lumens both above and below the occlusion. In this respect, the disease appears to be similar to the Leriche syndrome (thrombo-obliterative disease of the abdominal aorta).

Clinical Considerations. The clinical manifestations are those of arterial insufficiency and depend upon the aortic branch involved and the extent of the occlusive process. In general these may be considered according to the part affected by the arterial insufficiency: brain, eyes, face, and upper extremities. The neurologic symptoms vary from mild headache, vertigo, and syncope to complete paralysis. Symptoms referable to the eye consist of varying degrees of temporary blindness. In the face, atrophy of skin and muscle is common and actual ulceration may be present. In the upper extremities, symptoms are usually mild, consisting of weakness, intermittent claudication, and easy fatigability.

The most striking findings on physical examination are absence of peripheral pulses beyond the point of occlusion. Occlusion of the innominate artery is associated with absence of pulses in the right side of the neck and in the right arm. Separate origins of the left carotid and left subclavian arteries from the aortic arch make involvement of both arteries necessary to produce arterial insufficiency and absence of pulsations in the left side of the neck and in the left arm.

The precise location and extent of the lesion is determined by angio-aortography. In this procedure 50 ml. of a 70 per cent solu-

Fig. 50. Drawing showing a, complete segmental occlusion involving innominate artery arising at opening from aortic arch and extending to bifurcation of common carotid artery; and b, method of treatment my using bypass dacron graft from ascending aorta to right subclavian and right common carotid artery.

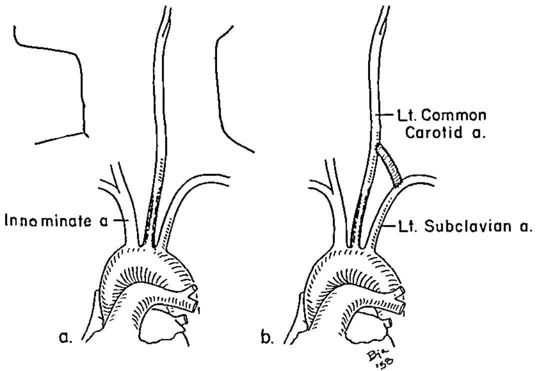

Fig. 51. Drawing illustrating a, segmental occlusion involving left common carotid artery which is incomplete but well-localized; and b, method of treatment by use of bypass graft from uninvolved left subclavian artery to left common carotid artery distal to site of occlusion.

tion of Urokon is injected into an antecubital vein and a roentgenogram is made of the chest and neck after an interval equal to the previously determined arm-to-tongue circulation time. At the time of exposure, the contrast material is located in the aortic arch and its major branches. The occlusive lesion in these vessels is outlined by its displacement of contrast material.

Treatment. Effective therapy is surgical and is directed toward restoration of normal pulsatile blood flow distal to the occlusion. The localized nature of the lesion permits application of the direct operative measures previously described for thrombo-obliterative disease of the aorta. In the milder forms of the disease, when the lesion is short and well localized, the occlusive segment may be removed by thromboendarterectomy. The use of an end-to-side bypass graft is technically easier and safer for the more diffuse lesions. Occlusive lesions of the innominate artery require a bifurcation graft (Fig. 50). The main trunk of the bifurcation graft is sutured to the ascending aorta, and the two remaining limbs of the graft are sutured to the right subclavian and right carotid arteries respectively. An occlusive lesion of the left common carotid artery may be bypassed by suturing one end of a graft to the aortic arch and the other to the cervical segment of the carotid artery. If the left subclavian artery is not involved, an occlusive lesion of the left carotid artery may be more simply bypassed by suturing one end of a graft to the supraclavicular segment of the left subclavian artery and the other end to the carotid distal to the occlusion (Fig. 51). Occlusion of the left subclavian artery, when short, is discrete and may be treated by endarterectomy. More extensive occlusions are bypassed from the aortic arch proximally to the normal artery distal to the occlusion.

The results of this form of therapy have been highly gratifying, with restoration of normal pulsatile circulation to the parts beyond the obstructing lesion in over 90 per cent of the cases. Restoration of normal circulation has provided relief of symptoms and resumption of normal activity. In our series of about 25 cases there has been no mortality.

THE ENDOCRINE GLANDS

In spite of constantly accumulating knowledge concerning the functions of the endocrine glands, endocrinology remains complex. The treatment of many of the diseases of these glands is primarily surgical. It is probable that, as more knowledge accumulates in this field, still more surgical procedures will be adaptable for treatment of disease of these organs. However, the complexity of certain of the endocrine glands interferes considerably in diagnosis and in the application of various therapeutic procedures. Many of the glands contain more than one type of secreting structure, such as the medulla and cortex of the adrenal and the anterior and the posterior lobes of the pituitary gland. Many of them are directly affected in their activity by impulses carried by the autonomic nervous system. Finally, the endocrines have an intimate relationship to each other, reacting in a balanced antagonistic or synergistic manner (Fig. 1). The production of hyperactivity of the thyroid gland by an extract of the anterior pituitary gland is an example of the relationship of one gland to the function of another. The pituitary gland (anterior lobe particularly) is known to exert important controlling influences not only over the thyroid but also over the adrenal cortex and the gonads. The stimulation of the adrenal cortex by ACTH (adrenocorticotrophic hormone), with production of cortisone and other steroids important in physiologic processes, illustrates the vital significance of the functions of the endocrine glands.

THYROID

Physiology. The thyroid is the most important organ in the body in the maintenance of metabolic rate at a level compatible with good health and efficiency, but it is not essential to life. The active principle of the thyroid is a tissue catalyst; it was isolated and named thyroxin by Kendall (1914) and synthesized a number of years later by Harington (1927). It has been estimated (Kendall) that there are about 14 mg. of thyroxin in the human body.

Our knowledge of the formation of thyroxin is not clear. However, it appears that iodine is converted to sodium iodide, which unites to tyrosine (by an oxidase reaction) to form diiodotyrosine. Another oxidation reaction combines two molecules of diiodotyrosine to form thyroxin, which is released under the control of the thyrotropic hormone of the anterior pituitary gland (1). Free iodinated amino acids, such as triiodothyronin, may exert a role in thyroid function, as indicated by their presence in the thyroid gland. Antithyroid drugs, such as propylthiouracil, reduce thyroid activity, presumably by blocking an essential oxidation step in the formation of thyroxin, thus interfering with the combination of iodine with tyrosine (2). In normal persons, excessive stimluation of metabolism by administration of thyroxin produces tachycardia, weakness, loss of weight, increased appetite, and other manifestations (except exophthalmos) noted in toxic goiter (hyperthyroidism). Diminution or depriva-

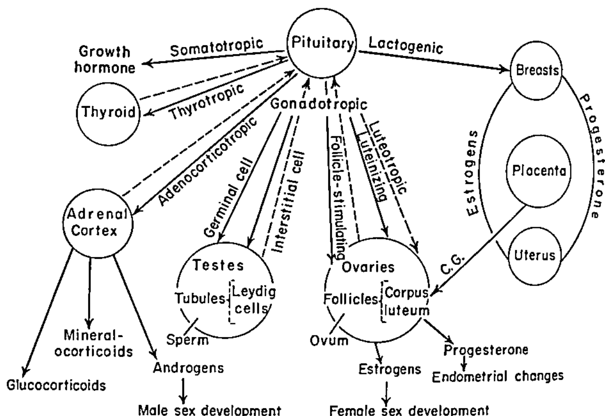

Fig. 1. Diagram of endocrine relationships. The solid lines with arrows indicate the glands stimulated and the hormones produced through the tropic, governing and regulatory activity of the anterior pituitary gland. The dotted lines with reverse arrows suggest the effects of the hormones of the "target glands" in reducing secretion of pituitary tropic hormones. During pregnancy the placenta produces large amounts of chorionic gonadotropin (C.G.) of estrogen, and of progesterone.

tion of the active principle of the thyroid gland in children produces a syndrome known as cretinism, in which stunted growth, dulled mentality, coarse features, and so forth, are prominent manifestations. An absence of thyroid secretion in adults produces myxedema, important manifestations of which are physical and mental lethargy, thick skin, and loss of hair, as discussed in detail later.

Classification of Diseases of the Thyroid Gland. Often there is confusion in the discussion of various diseases of the thyroid, primarily because many authorities use different terms to designate the same disease. It is important to standardize the classification in order to eliminate confusion which may arise by use of multiple terms. The classification (excluding tumors, thyroiditis, and hypothyroidism) recommended by a committee (3) appointed by the American Society for the Study of Goiter years ago appears still to be the most practical: diffuse nontoxic goiter, nodular nontoxic goiter, diffuse toxic goiter, and nodular toxic goiter.

DIFFUSE NONTOXIC GOITER

Although this type of goiter (frequently called simple colloid goiter) is the most prevalent of the various kinds encountered, it is the least serious from the standpoint of the effects on the patient. It is, to a certain extent, geographical but is encountered most commonly in young women at puberty, during pregnancy, or during some other functional strain.

Etiology. Years ago it was thought that a deficiency of iodine in food and water was the primary cause of nontoxic diffuse goiter. However, since the widespread use of iodized salt and wide distribution of food products from the various parts of the country have not eliminated the disease (even though a sharp decline in incidence is noted) it is obvious that some other factor is important

in causation. It is most likely that the numerous goitrogenic compounds (thiourea, thiouracil, thiocyanate, *sulfanilamides*) and foods (cabbage, rutabagas, soy beans, Brussels sprouts, cauliflower, 4) containing such products are of more importance. Years ago it was shown (McCarrison and associates, Cole and Womack, and others) that certain fats, contaminated food, and various types of chronic infections might produce goiter in animals. Heredity is at times a factor since mother and daughter often have the disease. This "hereditary" factor might not be truly hereditary, but rather congenital; it could be related to the ingestion of goitrogenic compounds by the mother during gestation, since it is know that ingestion of propylthiouracil by the mother during pregnancy may result in production of goiter in the newborn infant (*5*). *The circumstances mentioned above may* result in a failure of the enzymatic system of the thyroid to produce enough thyroid hormone; this failure probably results in compensatory action of the pituitary with production of abnormal thyroid response, i.e., goiter.

Pathology. The chief gross pathologic features of diffuse nontoxic goiter are a slight but generalized and symmetrical enlargement and hypertrophy of the gland, associated with the presence of an excess amount of colloid secretion as noted on cut section. Microscopically, the acini are larger than normal and the cells flattened. However, numerous areas of hyperplasia, consisting of heightening of the cells with layering and plication, are usually noted here and there throughout the gland.

Clinical Manifestations. The clinical manifestations of diffuse nontoxic goiter are really very few. The most important is enlargement of the neck, produced by the hypertrophied thyroid gland. This enlargement is never very marked; rarely does it constitute a cosmetic blemish, and in many instances is noticeable only on careful examination. The basal metabolism is normal or often, somewhat lower than normal. There is no tachycardia, tremor of the fingers, or exophthalmos. Rarely does this type of goiter become so large as to produce pressure symptoms related to breathing and deglutition. However, if present in a pregnant woman, this type of goiter, if untreated by iodine, or the like, may lead to the production of cretinism *in the offspring.*

Treatment. Treatment cannot be considered extremely important, because symptoms are rarely produced by this disease and because a mild hypertrophy appears as a normal physiologic phenomenon during puberty and pregnancy. However, there appear to be definite reasons for prophylactic therapy in goitrous regions by the routine administration of iodine. This favorable effect of iodine on the disease was first definitely demonstrated by Marine and Kimball (1921) when they reported the eradication and prevention of goiter in the school children of Akron, Ohio, through the administration of iodine in the drinking water. Only a few milligrams of iodine (either as a free element or as iodides) *per day is necessary. Beneficial effect is ob*tained by giving this small dose for a few days three or four times a year. Actually, there is enough iodine in iodized salt to supply this need.

Another indication for treatment lies in the fact that mild myxedema occasionally develops when a diffuse goiter has been present for a long time. When hypothyroidism is present, desiccated thyroid, 1 to 3 grains daily, should be given in addition to iodine. It is especially important that the goiter not be allowed to exist in women throughout the childbearing period since there is a definite tendency to transmit simple goiter congenitally, frequently with an associated cretinism in the offspring. Rarely does iodine fail to effect at least a significant decrease in the size of diffuse nontoxic goiters. With few exceptions, iodine will prevent the myxedema which is occasionally seen in this type of goiter, but of more importance is the fact that the drug, when given to a goitrous pregnant woman, will rarely fail to prevent the development of goiter in the child. Surgical excision in diffuse nontoxic goiter of recent duration is distinctly contraindicated since the enlargement is to a great extent physiologic, i.e., caused by the demand for increased thyroid secretion. In "goiter belts," diffuse nontoxic goiter frequently persists beyond the period of physiologic strain (puberty, pregnancy, and so forth). Not uncommonly it becomes nodular and takes on the character-

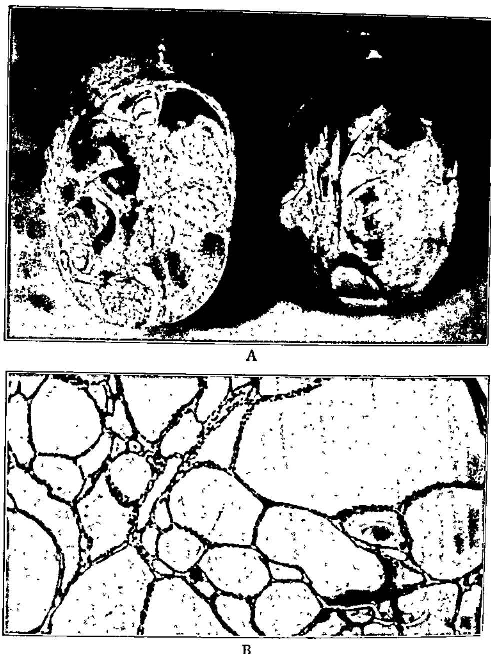

Fig. 2. Nodular goiter removed from a patient without evidence of hyperthyroidism. A, cut and external surface of a large nodule which represented an entire lobe on one side. Note the lack of homogeneity of the cut surface; this is produced by the profuse deposition of scar tissue and the large acini or cysts containing colloid. In its gross appearance, such a goiter can scarcely be differentiated from a toxic nodular goiter. B, microscopic section reveals flat acinous cells, scanty interstitial tissue, and large acini containing colloid. Such a gland is frequently spoken of as a colloid goiter.

istics of nodular nontoxic goiter as described below.

NODULAR NONTOXIC GOITER

The occasional transformation of diffuse nontoxic goiter to nodular nontoxic goiter as just described suggests that the latter is simply an advanced stage of the former, but proof is lacking.

The pathogenesis of nodular nontoxic goiter can best be understood by first outlining its *pathologic features*. Grossly, there is an asymmetrical enlargement of the gland with nodules distributed diffusely throughout. On cut section, the nodules are found to consist of tissue containing a large amount of glairy, gelatinous material which is called colloid (Fig. 2); hence, the frequent use of

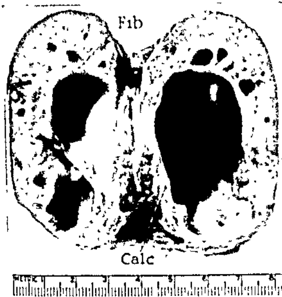

Fig. 3. Cystic adenoma. Note also fibrous tissue and calcification. Patient had no symptoms of hyperthyroidism.

the term colloid goiter. Occasionally, these nodules contain a thin brownish fluid (cystic goiter, Fig. 3). Less frequently, areas of hemorrhage are encountered. If the goiter has been present for several years, areas of calcification may be found in the fibrous tissue between the nodules. Microscopically, the acini are found to be widely dilated. It is apparent that the largest acini or cavities containing colloid are formed by the rupture of the walls of numerous smaller acini with consequent coalescence. The acinous cells are flat or cuboidal. Throughout the gland, however, will be found areas of hyperplasia where the cells are columnar and plicated, the acini small and devoid of colloid. Areas of lymphocytic infiltration are not uncommon.

Of more importance than the degenerative processes (cysts, calcification) mentioned in the preceding paragraph, are the hyperplastic changes which may take place. Nodular goiters frequently become toxic; less commonly carcinomatous changes develop in nodular goiter.

The *pathogenesis* of nodular nontoxic goiter is related to alternating periods of stimulation and involution. In that respect it may be the end result of the adolescent enlargement of endemic goiter. Clinical and experimental proof of the supposition that development of the numerous nodules throughout the gland in nodular nontoxic goiter is dependent upon frequent remission and exacerbations of the hyperplastic process (as brought about by physiologic need and strain) has been offered by Rienhoff (1926) and others. When the urgency for increased function is past, the gland involutes into a resting stage with flattened cells lining the acini, which become filled with colloid. The hyperplastic and involutional changes are largely confined to focal areas throughout the gland. These areas become circumscribed and surrounded by varying amounts of fibrous tissue which may encapsulate them; such nodules, which are often called adenomas (but perhaps erroneously), may be solitary *but usually are multiple.* However, there is one type of adenoma, viz., *fetal adenoma,* which is generally believed to be of actual neoplastic origin. Such nodules are sharply circumscribed, usually solitary, grayish or white on cut section (Fig. 4), contain very little colloid, and are of more solid consistency than the involutional type of adenoma already described. Microscopically, the acini are very small and interstitial tissue is profuse in amount, resembling, as the name implies, fetal thyroid tissue.

Clinical Manifestations. The clinical manifestations of nodular nontoxic goiter are in reality few. The patient may have an asymmetrical enlargement of the thyroid for years without any symptoms (Fig. 5). Occasionally there is a history of the presence of a symmetrical, nontoxic diffuse goiter during puberty or pregnancy for a few months before the asymmetrical nodular enlargement is noted. Although nodules or part of a lobe not infrequently descend behind the sternum or clavicle, they usually enlarge outward in the direction of least resistance, sometimes producing a tumor so unsightly as to lead the patient to request its removal for cosmetic reasons alone. As the goiter enlarges, there is an increasing tendency for the production of pressure symptoms consisting of difficulty in deglutition and breathing. The respiratory difficulty usually consists of such symptoms as coughing, a slight transitory "smothered" sensation, or attacks of actual orthopnea.

The esophageal obstruction is rarely se-

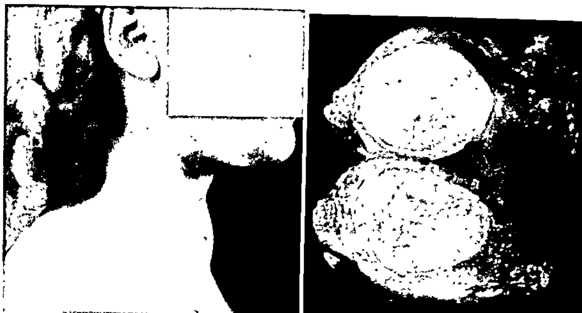

Fig. 4. Fetal adenoma. The patient, a female aged 28, first noted a nodule in the neck six years ago. Growth had been gradual. There were no manifestations of thyrotoxicosis.

vere. Occasionally, when the goiter descends downward into the mediastinum it may produce a superior caval obstruction (Fig. 6) which, however, is more common in carcinoma of the thyroid. The pressure may be caused by the thyroid encircling or compressing the trachea or esophagus, or by intrathoracic extension. Patients afflicted with nodular, nontoxic goiter over a period of years are apt to develop mild symptoms of myxedema which may require therapy with desiccated thyroid. On the other hand, thyrotoxicosis occasionally develops in the presence of nodular nontoxic goiter, particularly in the third and fourth decades of life. For some unknown reason, thyrotoxicosis of this type develops most commonly in the United States and only infrequently in goitrous regions, such as Switzerland, where nodular nontoxic goiter is prevalent.

Fig. 5. Photograph of a colored female with a nontoxic nodular goiter. The patient, aged 59, had noted a mass in the neck for 20 years; it started to grow four years ago. Recently she has had a slight choking sensation. At operation a large solitary mass, 5 cm. in diameter, was found on the right, and several small ones on the left.

Upon examination, the nodules are moderately firm except that cystic nodules are fluctuant. The mass is not movable vertically, but can be displaced to either side with the trachea. When the patient swallows, the goiter moves with the larynx. This characteristic is particularly valuable in differentiating goitrous tumors from various other masses in the neck. X-ray of the neck often shows marked deviation of the trachea.

Treatment. The treatment of nodular nontoxic goiter is preventive or surgical. The nodular as well as the diffuse type of nontoxic goiter may be prevented, at least to a great extent, by the administration of iodine in childhood and early adulthood. Furthermore, it has been shown in Switzerland that the administration of iodine to expectant mothers with nodular nontoxic goiter decreases the incidence of goiter in the children. Iodine, however, cannot be expected to cure nodular goiter, but it is valuable from a prophylactic

Fig. 6. Infrared photograph of a patient with a substernal goiter. The patient had a large nontoxic nodular goiter which extended into the superior mediastinum retrosternally. The infrared photo reveals the vast network of dilated veins which had developed as collaterals because the jugular veins were compressed by the goiter.

standpoint and to a less extent in prevention of progressive growth. It should not be administered over a long period of time to patients with nodular nontoxic goiter, because of the slight possibility of inciting the gland to hyperactivity.

Once this type of goiter develops, surgery offers the only means of eradicating it. Various indications for excision may be enumerated, the most important of which are: 1. relief of tracheal or esophageal obstruction; 2. danger of development of a toxic goiter; 3. danger of development of carcinoma; and 4. cosmetic reasons. The danger of development of carcinoma is greater than realized, as is emphasized by the fact that in a series of 448 thyroidectomies performed for nontoxic nodular goiter (in a goiter belt, Chicago between 1936 and 1952) Cole and associates (6) found carcinoma in 15.6 per cent of cases. The average incidence in seven other reports from various parts of the United States was 10.3 per cent. The solitary nodule is more dangerous than the multinodular gland as indicated by the fact that carcinoma *was found in 20.9 per cent of the solitary nod*ules, compared to 8.7 per cent of multinodular glands. This danger alone seems sufficient to justify removal of nontoxic nodular goiter, particularly if it is of the solitary nodular type. Operative treatment consists of the removal of the diseased gland. To prevent myxedema, a small portion of the most normal appearing thyroid tissue is left; if all is diseased, the entire gland is removed, but an effort is made to leave a gram or two of normal appearing gland on the less diseased side. As a rule, the posterior capsule of the gland must be left undisturbed; otherwise, tetany may develop through loss of the parathyroid glands. Particular care must be exercised in removal of large goiters lest the recurrent laryngeal nerves be injured.

DIFFUSE TOXIC GOITER

(Graves' Disease, Basedow's Disease, Exophthalmic Goiter, Hyperthyroidism)

This disease has apparently decreased markedly throughout the United States dur-

ing the past 20 years (perhaps as much as 50 per cent) as has also toxic nodular goiter.

Etiology. *It occurs more commonly in* women than men (ratio 4:1 or 5:1) and in young adult life, apparently produced by the secretion of an excessive amount of the thyroid principle, thyroxin. Some authorities are of the opinion that the etiologic factor producing the disease is not normal thyroxin, but a toxic and chemically distorted substance secreted by the diseased thyroid, but evidence supports the theory that most of the symptoms, at least, are caused by a true hypersecretion of the active principle. Up to the present time, however, there are a number of possible explanations for this excessive secretion. One is that it is presumably brought about by the stimulative action of some other endocrine gland. Since we know that the administration of certain extracts (hormones) of the pituitary gland produces hyperplasia of the thyroid gland of animals with many of the manifestations of hyperthyroidism, including exophthalmos, it would appear that the hyperplasia of toxic goiter might be due to an excessive secretion of this pituitary (thyrotropic) hormone. Although this hormone has been given to human beings on numerous occasions for various reasons, the authors are not aware of the production of hyperthyroid symptoms in any instance.

A surprisingly large percentage of patients with toxic goiter, especially of the diffuse type, date their symptoms from an acute respiratory infection from which they "did not completely recover." Less frequently, psychic shocks have been known to precipitate symptoms of toxic goiter. The factors just men*tioned should be considered contributory in* the development of toxic diffuse goiter; the exciting cause is as yet undiscovered.

Iodine Metabolism. It has long been known that the thyroid is the only organ in the body containing iodine in any significant quantity and that the iodine content of the organ is decreased in toxic goiter. Unquestionably, lack of iodine is of some importance in the development of toxic diffuse goiter, because, as in the nontoxic types just described, the disease is most prevalent in goiter belts where the iodine content of water and food is low. In both types of toxic goiter there is a negative iodine balance, i.e., more iodine is being excreted than is ingested. The blood *iodine is above* normal. It appears possible that the use of iodized salt has been the most important factor in the decreased incidence of thyrotoxicosis, but no proof is available.

Pathology. The thyroid gland in toxic diffuse goiter is friable, extremely vascular, and usually but not always enlarged. Because of the lack of colloid, the cut surface is beefy instead of glairy (Fig. 7). Microscopically, the acini are columnar instead of cuboidal and are layered as well as plicated within the lumen of the acinus (Fig. 8). If the patient has received iodine for more than a few days, the friability of the gland is lost and the normal glairy appearance of the cut surface is regained in part; furthermore, the columnar cell becomes cuboidal, the acinus larger and contains more colloid. If the disease has been present for a long time, cardiac hypertrophy may develop. The glycogen content of the liver is greatly reduced, and in fatal cases of hyperthyroidism, considerable destruction of hepatic cells may be noted microscopically. The exophthalmos, which frequently accompanies the disease, is apparently due to an edema and swelling of the retrobulbar structures including the muscles.

Clinical Manifestations. One of the first symptoms is the gradual development of a nervous irritability. The patient is restless and is reluctant to remain quiet for any length of time. Changes in personality are common and the patient becomes angered or upset emotionally without due provocation. Household cares and the demands made by children may be so irritating to women afflicted with the disease as to be almost unbearable. The *mind may* be very active, and frequently the patient plans more activities than she is capable of performing. Fatigue occurs readily and weakness is complained of. Loss of weight is a fairly constant manifestation in spite of an increased appetite. Increased sweating is usually complained of. Palpitation may be present. Intolerance to heat and tolerance to cold are commonly noted. Difficulty in sleeping is almost a universal complaint, especially if the disease is severe. In highly toxic individuals, diarrhea and occasionally vomiting occur.

The patient is apt to have spontaneous

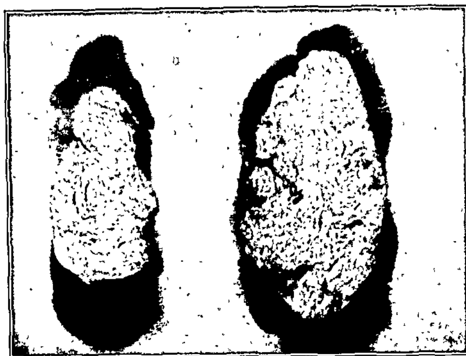

Fig. 7. Two examples of the thyroid (cut surface) of two patients with diffuse toxic goiter (Graves' disease). Each specimen has the typical beefy, somewhat homogeneous appearance, but the lobe on the left contains considerable scar tissue which is not present on the right.

remissions so that symptoms may disappear almost entirely. These remissions may last for months, but usually symptoms return and occasionally severe exacerbations occur which may be so intense as to be designated as thyroid "crises." If the disease is severe or of long duration, symptoms of cardiac disease, such as dyspnea and edema, may appear.

Examination reveals a restless patient. The thyroid gland is usually diffusely enlarged, but severe toxicity may be present without enlargement. Exophthalmos is present in many (Fig. 9), but by no means all, patients with diffuse toxic goiter. With the exophthalmos, a widening of the palpebral fissure is demonstrable (Dalrymple's sign) and diminished frequency of winking with imperfect closure of the lids during the act (Stellwag's sign). There may be a lag of the upper lid as the eye follows the finger downward (von Graefe's sign). Difficult in convergence (Moebius sign) when the patient looks at close objects may be demonstrable. A fine tremor of the fingers is noted, particularly when they are extended and abducted. The skin is warm and moist, particularly that on the palms. The face may be flushed and an anxious expression, which has been described as "frozen terror," may be noted. Tachycardia, which is increased sharply by mild exercise or other stimuli, is a reliable sign. Auricular fibrillation is only rarely present; it is more common in toxic nodular goiter. If the gland is appreciably enlarged, a thrill may be palpable over it or the vessels entering the gland, and a bruit heard by auscultation. A pulsation of the expansile type is usually palpable over the gland. The systolic blood pressure is usually elevated and the pulse pressure distinctly high.

One of the most reliable signs of toxic goiter is an increase in the *basal metabolic rate*. In severe cases this may be elevated as much as 60 to 90 per cent above normal. A rise of greater than 10 to 15 per cent above normal is considered indicative of the disease unless another cause for the elevation can be found. However, the BMR is frequently misleading because numerous diseases (leukemia, polycythemia, tuberculosis, heart disease) produce a high rate, and occasionally true hyperthyroidism may be present with an apparently normal rate. For this rea-

ing the past 20 years (perhaps as much as 50 per cent) as has also toxic nodular goiter.

Etiology. It occurs more commonly in women than men (ratio 4:1 or 5:1) and in young adult life, apparently produced by the secretion of an excessive amount of the thyroid principle, thyroxin. Some authorities are of the opinion that the etiologic factor producing the disease is not normal thyroxin, but a toxic and chemically distorted substance secreted by the diseased thyroid, but evidence supports the theory that most of the symptoms, at least, are caused by a true hypersecretion of the active principle. Up to the present time, however, there are a number of possible explanations for this excessive secretion. One is that it is presumably brought about by the stimulative action of some other endocrine gland. Since we know that the administration of certain extracts (hormones) of the pituitary gland produces hyperplasia of the thyroid gland of animals with many of the manifestations of hyperthyroidism, including exophthalmos, it would appear that the hyperplasia of toxic goiter might be due to an excessive secretion of this pituitary (thyrotropic) hormone. Although this hormone has been given to human beings on numerous occasions for various reasons, the authors are not aware of the production of hyperthyroid symptoms in any instance.

A surprisingly large percentage of patients with toxic goiter, especially of the diffuse type, date their symptoms from an acute respiratory infection from which they "did not completely recover." Less frequently, psychic shocks have been known to precipitate symptoms of toxic goiter. The factors just mentioned should be considered contributory in the development of toxic diffuse goiter; the exciting cause is as yet undiscovered.

Iodine Metabolism. It has long been known that the thyroid is the only organ in the body containing iodine in any significant quantity and that the iodine content of the organ is decreased in toxic goiter. Unquestionably, lack of iodine is of some importance in the development of toxic diffuse goiter, because, as in the nontoxic types just described, the disease is most prevalent in goiter belts where the iodine content of water and food is low. In both types of toxic goiter there is a negative iodine balance, i.e., more iodine is being excreted than is ingested. The blood iodine is above normal. It appears possible that the use of iodized salt has been the most important factor in the decreased incidence of thyrotoxicosis, but no proof is available.

Pathology. The thyroid gland in toxic diffuse goiter is friable, extremely vascular, and usually but not always enlarged. Because of the lack of colloid, the cut surface is beefy instead of glairy (Fig. 7). Microscopically, the acini are columnar instead of cuboidal and are layered as well as plicated within the lumen of the acinus (Fig. 8). If the patient has received iodine for more than a few days, the friability of the gland is lost and the normal glairy appearance of the cut surface is regained in part; furthermore, the columnar cell becomes cuboidal, the acinus larger and contains more colloid. If the disease has been present for a long time, cardiac hypertrophy may develop. The glycogen content of the liver is greatly reduced, and in fatal cases of hyperthyroidism, considerable destruction of hepatic cells may be noted microscopically. The exophthalmos, which frequently accompanies the disease, is apparently due to an edema and swelling of the retrobulbar structures including the muscles.

Clinical Manifestations. One of the first symptoms is the gradual development of a nervous irritability. The patient is restless and is reluctant to remain quiet for any length of time. Changes in personality are common and the patient becomes angered or upset emotionally without due provocation. Household cares and the demands made by children may be so irritating to women afflicted with the disease as to be almost unbearable. The mind may be very active, and frequently the patient plans more activities than she is capable of performing. Fatigue occurs readily and weakness is complained of. Loss of weight is a fairly constant manifestation in spite of an increased appetite. Increased sweating is usually complained of. Palpitation may be present. Intolerance to heat and tolerance to cold are commonly noted. Difficulty in sleeping is almost a universal complaint, especially if the disease is severe. In highly toxic individuals, diarrhea and occasionally vomiting occur.

The patient is apt to have spontaneous

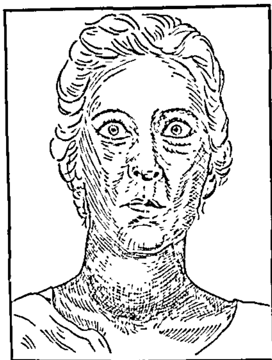

Fig. 9. Patient with appearance typical of exophthalmic goiter. Note the exophthalmos, apprehensive expression, and diffuse swelling in the neck.

Analysis of the blood for PBI (without ingestion of radioactive iodine) reveals a higher level in hyperthyroid patients than in normal people; in fact, the level is increased in an amount proportionate to the increase in metabolism. The normal PBI level is 4 to 8 μg. per 100 ml. of blood serum. Hyperthyroid persons may have levels of 9 to 12 μg. in mild cases, of 20 μg. or more in severe cases. The blood cholesterol is usually decreased in hyperthyroidism, but changes in level are not consistent enough to be of diagnostic value.

One of the most effective mechanisms in the differential diagnosis of patients with mild symptoms suggestive of hyperthyroidism is the administration of a course of iodine (10 to 15 drops of Lugol's solution per day). If the patient has thyrotoxicosis, symptoms are invariably improved within six to eight days after institution of iodine therapy. The antithyroid drugs are not very effective in this differentiation because the action in reducing thyrotoxicosis is so slow.

Treatment. The introduction of *iodine* by Plummer (1923) was a very important step in the treatment of thyrotoxicosis. However, even though the response of hyperthyroidism to iodine is rapid (with reduction in the BMR two to three points per day for 10 to 15 days), the effect nearly always wears off and after a few weeks no more beneficial effect is sustained. For this reason, iodine should be used in thyrotoxicosis only in preparation for operation, except in the occasional instance when toxicity is mild, the gland small, or the diagnosis doubtful.

In spite of the introduction of antithyroid drugs *thyroidectomy* remains a very effective method of treatment for hyperthyroidism and is perhaps the most popular. In a detailed follow-up study of 1,630 patients having thyroidectomy for hyperthyroidism, Cattell (8) noted good results in 90 to 95 per cent of cases. In 1,000 consecutive cases, the operative mortality rate was 0.2 per cent; tetany occurred in 1.5 per cent, nerve injury in 1 per cent, and recurrence in 2.4 per cent of cases.

Radioactive iodine is very effective in eliminating hyperthyroidism but it is difficult to estimate the correct dosage by the method utilized at the present time, namely, according to the estimated weight of the thyroid. At present there is disagreement as to the use of thyroidectomy or radioactive iodine in the treatment of toxic diffuse goiter. However, practically all workers in thyroid diseases would agree that radioactive iodine therapy is indicated in most patients with recurrent hyperthyroidism following thyroidectomy, in hyperthyroidism complicated by some other serious disease, in patients refusing operation, and in patients who are poor operative risks. Agreed contraindications to I^{131} therapy may be listed as follows: hyperthyroidism in children, toxic nodular goiter (especially if a solitary nodule is present), and hyperthyroidism in pregnancy or lactation. The debatable patients are those past 40 years of age with toxic diffuse goiter. In 628 hyperthyroid patients treated with I^{131}, Clark and Rule (9) report good results in 82.8 per cent; in this group, 17.2 per cent developed varying degrees of hypothyroidism. In 56.1 per cent of their patients, only one dose was required to obtain the desired result; two doses were required in 25.5 per cent; and three or more doses in the remaining 18.4 per cent. The average total dose in patients treated by Crile and Mc-

Fig. 8. Microscopical appearance of the thyroid in Graves' disease (diffuse toxic goiter). The sectio were taken from two patients with approximately the same degree of toxicity; operation after 12 days pr operative treatment with iodine. A, this section reveals the typical response of the gland to iodine therap The acinous cells in general are columnar, but not high; the acini are large and contain considerable colloi Numerous small areas are found, however, where the cells are high columnar, plicated and layered, indic ative of a hyperactive gland. B, this section exhibits practically no response to iodine. The acini are smal and contain no colloid; the cells are high, plicated and layered. Patients with glands of this type are slightl more apt to suffer recurrence of the goiter than patients whose thyroid responded to iodine.

son, other methods of diagnosing hyperthyroidism are being developed.

Measurement of the *uptake of radioactive iodine* is a very good method of differentiating hyperthyroidism from other diseases having similar symptoms. Werner and associates (7) have noted that following the oral administration of between 40 and 100 μc. of radioactive iodine (I^{131}) more iodine is taken up by the thyroid in patients with hyperthyroidism than in euthyroid (normal) individuals. The uptake of iodine at the end of 24 hours is measured with a Geiger counter placed 15 cm. from the neck. In euthyroid patients, the radioiodine uptake by the thyroid ranges between 10 and 45 per cent; in about 90 per cent of these patients the uptake will be below 35 per cent. In patients with hyperthyroidism, the uptake is above 35 per cent in 90 to 95 per cent of cases. Analysis of the level of *protein-bound iodine* (PBI) may add to accuracy of the radioactive iodine test. In hyperthyroid patients 24 hours after ingestion of I^{131}, 95 per cent or more of the radioiodine in the blood is present as PBI; in euthyroid individuals, less than 45 per cent of the iodine will be present as PBI.

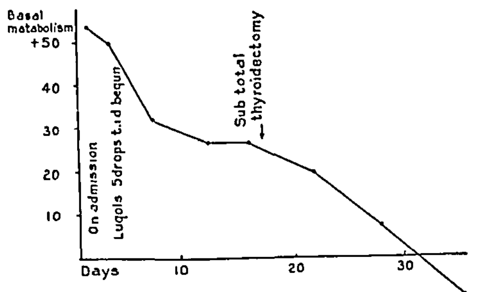

Chart 1. Basal metabolic curve in a patient with exophthalmic goiter exhibiting typical response to iodine therapy and subtotal thyroidectomy. As noted, iodine therapy will not bring the elevated basal metabolic rate to normal, but thyroidectomy will if sufficient gland is removed. Propyl-thiouracil alone will bring the rate to normal, but recurrence usually develops.

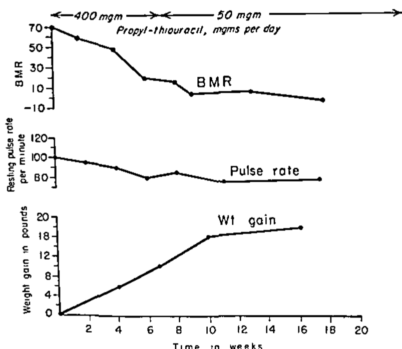

Chart 2. The treatment of thyrotoxicosis with propyl-thiouracil. The reduction of the basal metabolic rate from 70+ to 0 in nine weeks represents about the average rate of response. In this patient the resting pulse rate dropped to 80 after five or six weeks of therapy; weight gain was likewise registered early.

Cullagh (10) was 14 mc., which corresponds roughly to 100 μc. per gram of thyroid tissue. Chapman and his associates (11) recently reviewed 10 years of experiences treating hyperthyroidism with radioactive iodine. Of 400 patients treated, 8 per cent developed myxedema; 50 patients required two or more doses. The average interval between treatment and the development of a normal basal metabolic rate was two months.

Severe thyroid crisis may develop after radioactive iodine therapy but is extremely rare. Since radioautography reveals collection of radioactive iodine in innumerable pinpoint areas in thyroids of patients treated with I^{131}, it would appear that carcinoma might develop occasionally in these areas of radiation burns; however, none have been reported following this therapy. Experimentally, Doniach (12) has reported the development of an occasional cancer in the thyroid when radioactive iodine and methylthiouracil were given to rats. *X-ray therapy* has been used in the treatment of hyperthyroidism but it is much less effective than radioactive iodine.

Antithyroid drugs which block the formation of the active principle (thyroxine) of the thyroid gland may be effective in eliminating hyperthyroidism. The thiouracil compounds were originally studied and introduced by Astwood (13). Propylthiouracil and methylthiouracil are the ones being used most commonly at the present time. Another effective antithyroid drug, 1-methyl-2-mercaptoimidazole (tapazole), has been introduced more recently. The first two drugs are given in a dose of 300 to 600 mg. per day in divided doses and the latter in a dose of 15 to 60 mg. per day. Each of these drugs will, in responsive cases, reduce the BMR about one point per day. Toxic reactions (e.g., fever, urticaria, dermatitis, and neutropenia) are uncommon with each of the three drugs mentioned, occurring in about 2 per cent of cases. Insufficient dosage is a common error. Bartels and Kohn (14) have reported that doses of propylthiouracil in amounts equal to 600 to 1,000 mg. per day seldom result in significant reactions. Certainly, 300 mg. per day should be the minimum dose utilized unless sensitization is present. In many patients, if a maintenance dose (15 to 25 per cent of the therapeutic dose) is given for six months after the BMR has returned to normal, a permanent remission is obtained in a large proportion of cases. If patients are selected who have small glands, mild toxicity, and short duration of symptoms, permanent remission following prolonged therapy with antithyroid drugs may develop in 40 to 50 per cent of cases. However, since it is difficult to predict which patients will respond permanently, most physicians are using the antithyroid drugs as preparation for thyroidectomy. When they are used for this purpose, iodine should be given for 12 to 18 days before the date of operation to reduce the increased vascularity usually created by the drugs. The antithyroid drug should be omitted four or five days before thyroidectomy to prevent the rare but dangerous possibility of operating on a patient developing a reaction at this particular time. Obviously, any significant reaction to an antithyroid drug will be a contraindication for its continued use; another one may be tried cautiously. Utilization of antithyroid drugs and iodine in preparation for thyroidectomy will reduce the operative mortality rate. For example, over a 10-year period at Illinois Research Hospital before introduction of antithyroid drugs, the operative mortality rate was 0.9 per cent. In about 400 thyroidectomies for toxic diffuse and toxic nodular goiter since beginning the use of antithyroid drugs to prepare the patients, the operative mortality rate has been 0.

During treatment with antithyroid drugs or iodine, a sedative such as phenobarbital may be necessary to permit rest during the day and to insure adequate sleep. The caloric intake should be increased. While toxicity is pronounced, manual labor should be prohibited. The patient should be spared the ill effects of mental trauma. He should be encouraged to rest during the day, but complete bed rest is unwise (because of resultant muscle atrophy) unless toxicity is very severe or cardiac decompensation is present.

Excellent *postoperative* care is very important in maintaining a low or zero mortality rate following thyroidectomy. The wound should be watched closely for postoperative hemorrhage or infection. If hemorrhage develops, it usually manifests itself within 2 to 10 hours following operation. The presence

Fig. 10. Persistent exophthalmos. The patient, a Negro woman aged thirty, had exophthalmos at the time of operation two-and-one-half years ago. The exophthalmos receded slightly within a few months following operation, but during the past year has increased slightly. There is no evidence of recurrence of the hyperthyroidism. Exophthalmos usually recedes following operation, but in many patients it persists indefinitely.

thyroid tissue had been removed. However, in spite of adequate removal of glandular tissue and proper postoperative care, recurrences will occur occasionally (2 to 8 per cent of cases) and again disable the patient. Recurrent thyrotoxicosis following thyroidectomy is usually best treated with radioactive iodine.

When exophthalmos is so severe as to threaten loss of sight through ulceration of the cornea and papilledema, decompression of the orbit as suggested by Naffziger (16) may be indicated. This is particularly the case when thyroidectomy has failed to relieve exophthalmos, as is occasionally noted; in a few cases, indeed, exophthalmos may become more pronounced in spite of an adequate thyroid operation (Fig. 10). When proptosis is severe and progressive, suddenly lowering the metabolic rate by subtotal thyroidectomy may be contraindicated and slower, medical measures may be preferable. ACTH and triiodothyronine (particularly the former) are reported effective in the treatment of severe exophthalmos (McCullagh, et al., J. Clin. Endocrinol., 17:1277, 1957).

NODULAR TOXIC GOITER
(Toxic Adenoma)

For years there has been considerable discussion as to whether or not this disease was etiologically different from toxic diffuse goiter. Although the main symptoms of toxicity are similar, there are a few prominent differences, namely, that the symptoms of toxic nodular goiter are milder, and exophthalmos much less common than in toxic diffuse goiter. Moreover, the nodular disease occurs 10 to 15 years later in life than the diffuse type. In our experience with 571 patients with thyroid disease (1948 to 1956), the average age of patients with toxic diffuse goiter was 34.5 years; for toxic nodular goiter, 48.6 years; for nontoxic nodular goiter, 47.1 years; for carcinoma, 48.2 years; and for thyroiditis, 39.3 years.

Pathologically, the gland in toxic adenoma is nodular and asymmetrical. The adenomatous changes may be localized to one area (presenting as a nodule), but are usually diffused throughout the gland. Small areas of hyperplasia are almost always demonstrable at various points in the gland (Fig. 11). The

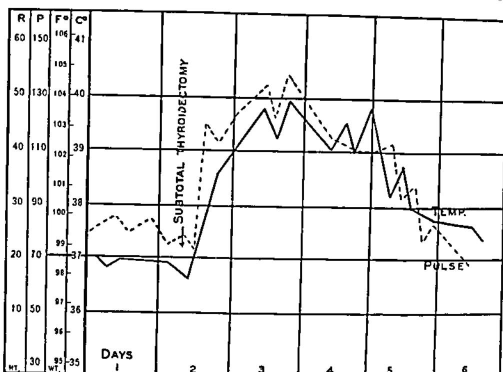

Chart 3. Temperature and pulse of patient who sustained a "crisis" following subtotal thyroidectomy. In typical cases the temperature and pulse rate begin to rise a few hours after operation, reach their maximum 24 or more hours following thyroidectomy, but recede in two or three days. Reactions of this type may be fatal, but are extremely uncommon at the present time due to preoperative use of antithyroid compounds.

of respiratory stridor demands immediate inspection of the wound. If a blood clot is causing the stridor, the wound must be opened immediately, the clot evacuated, and the bleeding controlled. If cyanosis remains after evacuation of the clot, tracheotomy may be necessary. If the stridor is due to recurrent laryngeal nerve paralysis, tracheotomy will likewise probably be necessary. If the paralysis is due to pressure from edema or mild trauma, the tube can usually be removed in a few weeks; if both nerves have been cut, the tracheotomy will probably have to be permanent unless the nerves can be successfully resutured. The operation designed by King (15) (attaching the arytenoid to the thyroid cartilage, with consequent widening of the aperture between the cords) is usually successful in restoring the airway sufficiently to allow removal of the tracheotomy tube. When considerable myocardial damage (as evidenced commonly by auricular fibrillation) is present, the need for oxygen will be more acute. Intravenous fluids must be given more slowly and in smaller quantities. Digitalis is used before operation in patients with cardiac decompensation. Its postoperative use may become necessary if pulmonary congestion or other signs of heart failure appear.

A disturbing complication of thyroidectomy is the rare occurrence of so-called thyroid "crisis" which may develop during the first day or two following operation if thyrotoxicity is severe and has not been adequately controlled by preoperative use of antithyroid drugs. This complication is characterized by extreme tachycardia, fever, marked excitability, and occasionally delirium. Treatment consists of cortisone, intravenous sodium iodide, oxygen therapy, and heavy doses of narcotics. The patient must be kept cool, with electric fans, wet towels, or an air-conditioned room in warm weather. Intravenous glucose is essential. Blood transfusions may also be indicated. It should be remembered that crisis may develop in the untreated patient. Occasionally a patient is brought to the emergency room as a new patient in a crisis.

Recurrence of thyrotoxicosis after thyroidectomy is usually indicative of an incomplete operation; i.e., that an insufficient amount of

Fig. 12. Toxic nodular goiter (toxic adenoma). Note the absence of exophthalmos. The patient aged 51 had a basal metabolic rate of 43+ on admission; after six days of iodine therapy (at the time the photograph was taken) the BMR had dropped to 29+.

in toxic nodular goiter than in toxic diffuse goiter. This may be due in part to the fact that the manifestations in the former disease are so insidious that they may exist for years before the patient is aware of symptoms; but a more logical explanation would appear to be that patients with nodular toxic goiter are older and therefore have hearts with less reserve. This myocardial damage may be uncomplicated or be associated with auricular fibrillation. In either case, shortness of breath, orthopnea, weakness, and swelling of ankles, may be complained of.

Examination reveals a nodular enlarged gland (Fig. 12) with or without a thrill and bruit. Frequently, the nodular enlargement is confined to one lobe; occasionally, the only abnormality made out in the gland is the presence of a solitary nodule. Exophthalmos or other eye signs are rarely encountered. Restlessness and irritability are usually demonstrable and a fine tremor of the fingers upon extension and abduction is always present. The palms of the hands are unusually moist. Tachycardia is noted, and if auricular fibrillation is present there will be an irregularity of the pulse with a pulse deficit. There is usually an elevation of the pulse pressure. The basal metabolic rate is elevated (15 to 50 per cent above normal), but not as high as in toxic diffuse goiter.

Treatment. Patients with toxic nodular goiter are treated similarly to those with toxic diffuse goiter. The response to various antithyroid drugs or iodine may not be as spectacular as it is in toxic diffuse goiter, but this is probably because the toxicity is not as great and morphologic changes have taken place in the gland. Surgical treatment, i.e., subtotal thyroidectomy, is especially efficacious because recurrences are seldom encountered; the resection, therefore, need not be so radical. Moreover, unless severe myocardial damage has been sustained, the symptoms of heart failure are usually relieved and the heart will be restored to a fairly normal function. The hyperthyroidism in toxic nodular goiter can be neutralized by radioactive iodine, but most clinicians prefer thyroidectomy to eliminate the nodule or nodules.

SUBSTERNAL OR RETROCLAVICULAR GOITER

Occasionally, large masses of thyroid tissue (toxic or nontoxic adenomas) are encountered behind the sternum. The mechanism of the development of a retrosternal goiter is dependent to a great extent upon the down-

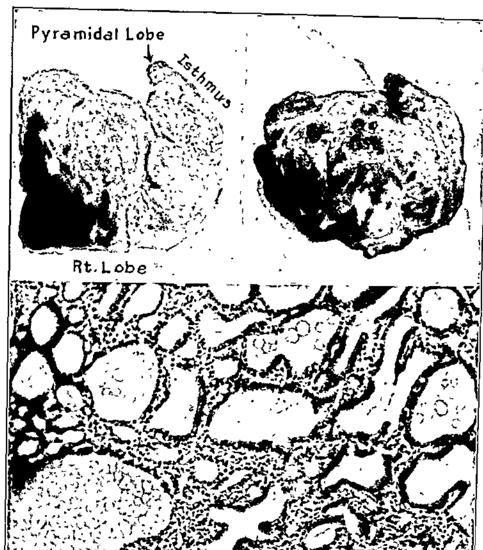

Fig. 11. Pathologic features of the thyroid in toxic nodular goiter. Above, external surface and cross section of a nodular goiter removed from a patient with toxic adenoma. The lobulations circumscribed by fibrous tissue are readily discernible in the cross section; Below, photomicrograph of tissue removed from Above. Large acini filled with colloid are numerous, but here and there are scattered areas where the acini are small, the cell tall columnar, plicated and layered, indicative of hyperactivity.

gland may encircle or compress the trachea and esophagus and produce obstructive signs. Occasionally, a large adenomatous nodule descends and is located behind the clavicle or sternum (se p. 1063). Rarely, the entire gland descends into the thorax so that nothing *more than the upper margin is palpable in the* suprasternal notch. On cut section the gland reveals globular masses of colloid-containing tissue surrounded by a fibrous capsule. Dense deposits of fibrous tissue may occur at any point throughout the gland. In addition there may be areas of beefy tissue resembling the gland seen in toxic diffuse goiter.

Clinical Manifestations. The disease is not greatly unlike toxic diffuse goiter. However, it occurs in persons 10 or 15 years older, is a milder disease, develops more insidiously, and is less often accompanied by exophthalmos or other eye signs. Crises are rarely encountered. Usually there is a history of the *presence of a nodular* enlarged thyroid for years before toxic symptoms develop. "Nervousness," weakness, and unusual susceptibility to fatigue are early *symptoms.* Irritability and emotional instability are likewise apt to be present. Difficulty in sleeping is also a fairly common complaint.

There is a greater tendency for the development of symptoms of cardiac decompensation

symptoms are present although mild hypothyroidism may be present. The thyroid is usually enlarged. Microscopic section reveals chronic inflammation, mild fibrosis, and partial to moderate loss of the alveolar architecture. The etiology is unknown, but Paine and associates (17) have shown that antibodies may be found in the blood stream, suggesting that autoimmunization against constituents of the patient's own thyroid gland may be an important etiologic factor. Many clinicians and pathologists would include these cases in the Hashimoto group.

Riedel's Struma (Ligneous Thyroiditis, Chronic Thyroiditis). Many years ago, Riedel described a rare type of disease characterized by woody hardness of the thyroid gland but associated with no known etiologic factor. Microscopically, there is a diffuse deposition of scar tissue, with a diminished number of alveoli of irregular shape and size, scattered about the gland. The gland becomes so adherent to the surrounding tissue, and the parenchyma so fibrosed that frequently it is impossible to identify the margin of glandular tissue. Mild symptoms of obstruction to the trachea and esophagus may be produced. Operation is indicated only when necessary to relieve obstruction; usually this can be accomplished by excising the isthmus.

Hashimoto's Thyroiditis. This is a chronic degenerating disease in which lymphoid infiltration and an increase in germinal centers are encountered; a variable amount of fibrosis is present. The disease is more common in females than in males and is more prevalent in mid-adult life. In a study made by Wickman and associates (17a) of 30 cases, all were females; the average age was 44. It usually affects both lobes, which gradually enlarge with mild but not marked nodularity. Symptoms are few, although most of the patients have hypothyroidism. Pain and tenderness are usually absent. Occasionally the enlargement is so marked that compression signs are produced. Except to relieve obstruction, operation is not indicated. However, it is often difficult to differentiate this disease from carcinoma, although the disease is more diffuse than anaplasia of the thyroid. In *treatment*, desiccated thyroid is fairly-specific; large doses may be indicated.

MYXEDEMA

Although a severe degree of hypothyroidism may result from the removal of too much thyroid tissue in the treatment of toxic goiter, rarely is it comparable to idiopathic myxedema. The idiopathic disease may rarely follow toxic goiter or acute and chronic thyroiditis, but in most instances there is no history of antecedent thyroid disease. The gland is small and microscopically a sharp diminution of acinar tissue with increase in amount of fibrous tissue is noted.

Clinical Manifestations. The development of clinical manifestations is so insidious that the disease may be far advanced before the patient is aware of its presence. The patient becomes mentally dull, the speech slow and "thick," as if the tongue were too large for the mouth. Constipation is rarely absent. The appetite is poor. Early in the disease the patient notes that he is very sensitive to cold and requires an unusually large amount of sleep. A gain in weight is the rule. The temperature is subnormal and the pulse rate slow. There is a masklike expression of the face, the features of which are enlarged as if swollen (Fig. 13). The skin and subcutaneous tissue over the entire body is thickened. Sweating is diminished. The hair is dry and thin. Diagnosis is readily confirmed by a basal metabolic test which will reveal a metabolic rate 20 to 40 per cent below normal. However, many patients with a low BMR do not manifest symptoms of myxedema. The blood cholesterol is high. The serum protein-bound iodine is low, and the radioactive iodine uptake is very low.

Treatment. The treatment consists almost entirely of administration of desiccated thyroid or thyroxin. It usually requires 30 to 60 grains of desiccated thyroid given over a period of several weeks to bring the patient's basal metabolism up to normal; the amount necessary for maintenance of a normal metabolism is determined by the effect on the heart rate and basal metabolic rate. Treatment should be begun with small doses (0.5 to 1 grain daily) and increased very slowly since it will take several weeks for the full effect of desiccated thyroid to become manifested. After the metabolic rate has been brought to normal, the maintenance dose (1 to 3 grains daily) is determined and is continued indefinitely.

ward growth of the enlarged gland. *It should* be emphasized that goiters of this type are at first retroclavicular in type; most of them remain so permanently. If growth of the gland persists, the mass is apt to descend, moving toward the mid-line behind the sternum. The pedicle connecting these adenomas with the thyroid itself may become greatly narrowed. On rare occasions, the retrosternal mass may have no connections with the thyroid because of its development in an aberrant thyroid or *because of atrophy of the pedicle.*

Clinical Manifestations. The clinical manifestations of substernal goiter are varied but are primarily due to the effects of pressure. Substernal goiter may be a source of considerable discomfort and be serious because of obstruction to the trachea and esophagus. There is apt to be a sensation of tightness or fullness in the upper portion of the chest, but more frequently the first symptom complained of by the patient is dyspnea or orthopnea. The dyspnea is, of course, caused by pressure on the trachea, which may progress to such an extent as to produce an audible stridor. Occasionally, mild dysphagia is present. Periodic short attacks of choking, terminating in coughing, are quite common, particularly at night while the patient is asleep. There may be dilatation of the veins of the neck or of the upper part of the chest due to compression of the thyroid or the jugular and subclavian veins. A fullness of the neck or in the suprasternal notch may or may not be visible. Deviation of the trachea, or even of the larynx from the mid-line, is an important diagnostic sign and can be demonstrated by the x-ray. X-ray, moreover, may show an abnormal shadow in the superior mediastinum which may be suggestive of a retrosternal goiter. If the substernal mass is sufficiently large, it may be demonstrable because of dullness to percussion. Differential diagnosis is frequently difficult because of the confusion with such lesions as aneurysm, thymoma, dermoid cyst, and Hodgkin's disease. The expansile type of pulsation noted fluoroscopically in an aneurysm should identify this lesion. X-ray therapy may be useful at times in establishing a diagnosis since nearly all the primary malignant tumors occurring in this region are remarkably sensitive to radiation; roentgenologically, a rapid *and marked diminution in size* will be noted following x-ray therapy in contrast to a slight or no decrease in size of a substernal goiter. Dermoid cysts will, of course, not be altered in size by radiation.

Substernal thyroids producing no symptoms need not be removed. If either obstructive or toxic symptoms are produced, excision is advisable. This may be done in most instances through an ordinary thyroid incision and the mass removed by blunt dissection *with the finger.* However, these masses must be removed with care because of the proximity of the recurrent laryngeal nerves and the danger of injury to them. When the goiter is located farther down in the mediastinum, thoracotomy will be necessary because the mass usually has a separate blood supply, arising in the mediastinum.

THYROIDITIS

Acute and Subacute Thyroiditis. *Pyogenic infection* of the thyroid is a rare disease. It is usually seen in young adults secondary to a primary focus elsewhere, such as acute pharyngitis, and is usually confined to the lower portion of one lobe. Tenderness, fever, and severe pain are usually present. Abscess formation is rare; if it does occur, incision and drainage is indicated.

More commonly, acute thyroiditis of the *nonsuppurative* type is encountered. The etiology is obscure, but the causative factor may be a virus. Histologically, a foreign body type of reaction with giant cells is noted; fibrosis is diffuse. Pain and tenderness are variable in degree; occasionally fever is present, especially at onset. Pain may be present on swallowing and may radiate to the ears. With rare exception, the involved area in the thyroid is indurated; the entire lobe is usually involved. Ultimately both lobes become involved. Cortisone is specific in relieving this condition but symptoms often return after cessation of therapy. X-ray therapy and propylthiouracil are often effective. *Operation is not indicated,* particularly since the disease is self-limited and results in no permanent damage.

Chronic Nonspecific Thyroiditis. There is a group of patients with *chronic thyroiditis* with a microscopic appearance not identifiable as Riedel's struma or Hashimoto's disease which are described below. Very few

of tumors of the thyroid arise as separate tumors and not in pre-existing nodules. In our series, only 9 per cent of patients with nontoxic nodular goiter were males, whereas 36 per cent of patients with cancer of the thyroid were males; this indicates that the danger of cancer in nodular goiter is about four times greater in males than in females.

The incidence of carcinoma of the thyroid is actually higher in childhood than in adults. In our series of children with nodules in the neck, 31.1 per cent were malignant (19). This figure is close to the 29 per cent in 145 cases assembled from the literature by Winship and Chase (20).

In our series, the average age of patients with benign nontoxic nodular goiter was 44.5 years, compared to 47.5 years for cancer. The duration of enlargement of the neck was 11.8 years in nontoxic nodular goiter but only 4.1 years in patients with cancer.

There is considerable speculation as to why carcinoma is more common in nodular goiter of children than of adults. In a study of 28 patients 18 years of age and younger, Duffy and Fitzgerald (21) found that 10 of them had had irradiation (x-ray) to the thymus between the ages of 4 and 16 months. In a series of 15 children 15 years of age and under, Clark (22) reported that all had x-ray therapy in infancy to the head, neck, or upper thorax for benign conditions in those areas. In our series (19), all of 10 children 15 years of age or younger had x-ray therapy to the head or neck between the ages of two months and six years; the dose varied between 200 r and 625 r (average 430 r). In spite of the seemingly very significant evidence presented above, many workers in this field are not convinced irradiation in infancy has a relationship to the development of carcinoma.

Pathology. Numerous classifications of carcinoma of the thyroid have been suggested; there is so little agreement that McDermott and associates (23) have offered a simplified classification in which all types are classified into one of three groups: 1. papillary; 2. follicular; and 3. undifferentiated. In their series of 179 cases they classified 50 per cent as papillary and 25 per cent in each of the other two groups. All pathologists and clinicians agree that papillary tumors are more common than any other type, and are more prevalent in young people than in elderly ones. It is well known that papillary tumors are less malignant than other types; distant metastases by way of the blood stream are uncommon although metastasis occurs early to the lymph nodes. Metastasis by the blood stream is common in the other types, particularly in the undifferentiated tumors in which it often occurs by the time the tumor has manifested itself in the neck.

CLINICAL MANIFESTATIONS. It is very difficult to differentiate benign nodular goiter from carcinoma unless the latter has metastasized. In a study of manifestations of the two lesions made recently we (19) noted that recent increase in size, cough, lack of symptoms, and feeling of pressure was slightly more common in benign nontoxic nodular goiter, whereas dysphagia was slightly more common in carcinoma. Consistency of the nodule was of no value in differentiation. Only two manifestations were of true value. Hoarseness was twice as frequent in malignancy, vocal cord paralysis was several times more common in carcinoma; it was noted in 28.8 per cent of 45 consecutive cases examined, indicating that extension of the cancer outside the thyroid capsule or metastases are fairly common by the time patients are first seen.

Treatment. Most surgeons (24, 25, 26, 27, 28) favor radical neck dissection for carcinoma of the thyroid although Crile (29) favors a conservative type of operation. Total thyroidectomy (both lobes) is favored by most surgeons recommending radical resection because removal of all normal thyroid tissue allows a greater pick-up of radioactive iodine in case that agent is chosen for supplemental therapy. Removing all normal thyroid tissue decreases the blood level of circulating thyroid hormone, thus stimulating the pituitary to secrete an increased quantity of thyroid-stimulating hormone (TSH) which causes greater concentration of the injected radioactive iodine in the metastases (30). When I^{131} was first introduced in the therapy of carcinoma of the thyroid, it was hoped that this agent would greatly improve the results. However, it was soon discovered that in 85 per cent of cases, thyroid carcinoma would not pick up enough iodine to offer therapeutic benefit (31).

Fig. 13. Characteristic facial appearance in myxedema. Note the thickening and puffiness of the eyelids and the coarseness of all the features. (From Graham. Surgical Diagnosis, Vol. 2. W. B. Saunders.)

CRETINISM

This is a disease of childhood consisting physiologically of a diminution or absence of thyroid secretion. Cretinism may be endemic, i.e., occur in localities where goiter is prevalent, or may be encountered in the sporadic form, a type in which the child is born of healthy parents and in a region where goiter is not prevalent. Cretinism is apt to develop in a child when the mother has been suffering from diffuse nontoxic goiter during pregnancy. The glandular defect is no doubt present at birth, but so long as the child is breast fed manifestations of the disease do not appear. The disease is quite common in Switzerland.

The child grows at a slower rate than average and appears stupid and unusually placid. The skin is dry. The face is large and appears bloated, and the nose is broad and flattened. The tongue, which is presumably too large for the oral cavity, protrudes through a thick-lipped mouth. Talking and walking are delayed and teeth are slow to appear. The temperature may be subnormal. The basal metabolism is below normal. If the disease is severe, dwarfism may result.

Treatment. The treatment must be instituted early in childhood if mental apathy or idiocy is to be prevented. Growth responds fairly well to the administration of desiccated thyroid, but correction of the mental dullness or idiocy is much more difficult to obtain, particularly if treatment is not started within the first year or two of life.

MALIGNANT TUMORS OF THE THYROID

There is much controversy about various phases of carcinoma of the thyroid, including incidence, diagnosis, and treatment. The incidence in nontoxic nodular goiter is reported between 5 and 17 per cent. At Illinois Research Hospital (1936 to 1953) we encountered carcinoma in 15.6 per cent of patients with nontoxic nodular goiter (18, 19). In the solitary nontoxic nodule the incidence was 20.9 per cent, compared to 8.7 per cent in multinodular nontoxic goiter. We encountered cancer in only 1.0 per cent of patients with toxic nodular goiter and in only 0.1 per cent in patients with toxic diffuse goiter. Considerable disagreement exists relative to the origin of carcinoma of the thyroid, but most workers in this field now believe the majority

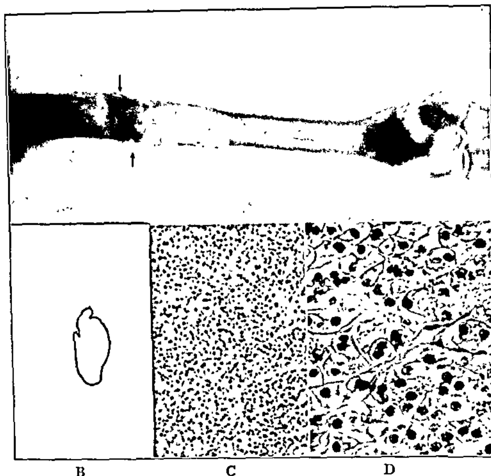

Fig. 14. Hyperparathyroidism. The patient came to the hospital because of a fracture of the humerus, sustained after only slight exertion. X-ray revealed a fracture at the site of a cyst in the shaft of the bone; numerous cysts were found in other bones. Serum calcium was 13.3 mg. per cent, but dropped to 9.8 mg. per cent the day following removal of the parathyroid tumor. A renal calculus was revealed by x-ray; it did not disappear following operation (observed for five years). A, x-ray of humerus showing cystic defects in the bone and the healed fracture (seven months after admission). X-rays three or four years later revealed deposition of calcium in these defects; B, actual size of the parathyroid tumor removed; C, low power photomicrograph; and D, high power photomicrograph of the tumor. (Courtesy, Dr. I. Y. Olch.)

ease. In hyperparathyroidism, calcium is removed from the bones and excreted through the urine. There may be diffuse demineralization of bone or cystic damage (osteitis fibrosa cystica of von Recklinghausen, Fig. 14). Renal stones are frequently formed. Although the relationship of parathyroid hyperplasia to osteitis fibrosa was probably first noted by Askanazy, the successful removal of an adenoma was not reported until 1926 by Mandl.

Clinical Manifestations. The earliest symptoms noted by the patient are apt to be muscular weakness, pains in the extremities and back, and polyuria. In a group of cases reported by Churchill and Cope (36), a surprisingly large percentage complained first of weakness, pains in the legs and thighs (particularly upon walking), backache, and difficulty in walking as produced by disturbance in gait. Occasionally a spontaneous ("pathologic") fracture through a cyst or decalcified bone is the first manifestation noted. Tumors (with or without associated tenderness) may be noted on the surface of the bones (humerus, mandible, radius, ulna). Deformity, such as kyphosis, shortening of the spine, flatfoot, and so forth, created by actual softening of the bones may occur and may therefore be readily confused with Paget's and other diseases of the bone. Lassitude, undue fatigue, and constipation are usually complained of. Polyuria and polydipsia, presumably attrib-

When administration of I^{131} is considered in addition to total thyroidectomy, Mack and associates (32) suggest that several weeks after operation I^{131} be given to locate residual functioning thyroid tissue. Studies should include 24-hour uptake and 96-hour urinary excretion of I^{131}. The body is scanned with a directional scintillation counter for extrathyroidal I^{131}. If no iodine is found, they refer the patient back at intervals of six months or one year for restudy. If and when metastases are found, a therapeutic dose of I^{131} is given. Some authorities give TSH or propylthiouracil (in large doses for months) in preparation of patients with carcinoma for therapy with I^{131}. Serious reactions from TSH have been reported. Maloof and associates (33) warn that the beneficial effect of TSH may be outweighed by the growth stimulus imparted to the metastases.

Since neither I^{131} nor x-ray therapy are very effective in the treatment of thyroid metastases, most clinicians now resort to administration of desiccated thyroid in doses equal to 3 grains per day. This therapy will cause regression of the metastases in many cases, and appears to prolong life, although cures are not to be expected from it.

If a small papillary tumor should be found in the center of a thyroid lobe without any evidence of invasion to the exterior, total lobectomy on that side may be sufficient, particularly if the patient is young; this tumor is much less invasive in young patients in whom it metastasizes primarily to lymph nodes, rarely to distant organs such as lungs and bone. However, when the tumor has invaded outward to the capsule or local metastases are present (in the absence of known distal lesions), a radical neck dissection on the affected side is indicated. Frazell and Foote (28) have demonstrated the need for a radical operation by examining the excised specimen of patients subjected to radical neck dissection in the absence of palpable metastatic nodes and finding positive nodes in 61 per cent of the specimens removed. It would appear unwise to do a local excision of the tumor when the nodes are positive in such a large percentage of cases, though not palpable.

Results. The results of treatment vary considerably in the various reports found in the literature (19). However, the majority of the reports reveal a five-year survival rate between 35 and 40 per cent. The best results are obtained in papillary tumor. A five-year survival rate of 73 per cent for this type of tumor is reported by McDermott and associates (23), but this figure is a "cumulative" rate calculated according to standard "life table" methods, excluding the expected normal death rate.

MISCELLANEOUS DISEASES OF THE THYROID

Tuberculosis, syphilis, and even actinomycosis of the thyroid occur, but they are so rare as not to justify discussion here. Primary sarcoma of the thyroid is exceedingly rare, if it occurs at all.

THE PARATHYROID GLANDS

The parathyroid glands are small glandular structures, usually four in number, measuring 3 to 6 mm. in diameter. They are usually located in the posterior capsule of the thyroid; occasionally they are found in the mediastinum. Their function in body metabolism is so important that excision of all parathyroid tissue is followed by death or severe tetany. The control of calcium metabolism is the most important function of the parathyroids. Hyperparathyroidism and tetany (hypoparathyroidism), which are the two most important diseases attributed to the parathyroids, are associated respectively with an elevation and diminution of calcium in the blood. Calcium is found in the blood serum in two forms: 1. ionizable calcium; and 2. calcium bound to protein. Ionizable calcium is the type which is altered by hyperparathyroidism and hypoparathyroidism. The symptoms are evidently dependent chiefly upon this disturbance in the blood calcium level.

HYPERPARATHYROIDISM

This disease may be produced by a generalized hyperplasia of all the parathyroid glands or by a definite adenomatous enlargement of one of the parathyroids (rarely more than one); in either case excess production of the active principle (parathormone, isolated by Hanson, 34, and Collip, 35) of the gland is the factor responsible for the dis-

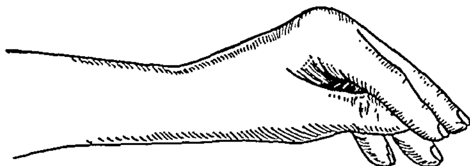

Fig. 15. Typical position of hand in parathyroid tetany.

room during induction of anesthesia and is frequently encountered in excited or hysterical persons. "Gastric tetany" caused by depletion of the acid of the stomach contents by persistent vomiting is likewise a manifestation of alkalosis.

Parathyroid tetany following subtotal thyroidectomy (for toxic goiter) is manifested usually within 24 or 48 hours after operation, but may not appear until two or three weeks later. In the latter instance, it is assumed that fibrosis resulting from excessive trauma associated with the operation is the cause of the tetany, whereas in the former instance the disease is caused by removal of the glands or severe direct trauma to them. The serum calcium drops from its normal level of about 10 mg. per 100 ml. to only 7 or even 5 mg. per 100 ml. Symptoms are rarely produced if the serum calcium is 8 or above. Perhaps the most common early manifestation is muscular weakness and twitching. This is often exemplified first by the patient's inability to grasp and lift a glass of water. Restlessness, irritability, headache, and tachycardia are common. Numbness of the hands, feet, or face and "drawing" or cramps of hands or feet may occur.

Pain associated with spasm of the muscles may be noted in the extremities and is apt to radiate downward, particularly in the arms. Diagnosis is certain when the typical carpopedal spasm, consisting of flexion at the metacarpophalangeal joints with adduction of the thumb (Fig. 15) and a similar contraction of the feet, develops. The wrist and elbow are likewise strongly flexed. Occasionally, spasm of the laryngeal muscles will be sufficient to produce respiratory difficulty. The muscular spasm of the hand may be induced by pressure interfering with the blood supply of the nerves, such as that produced by a tourniquet (Trousseau's sign). Irritability of the muscles may be so pronounced that tapping over the nerve may instigate a spasm. This is particularly true when the face is lightly tapped over the facial nerve (Chvostek's sign).

Treatment. Since the epochal discovery by Hanson (34) and Collip (35) of the active principle of the parathyroid gland, the treatment of acute parathyroid tetany is much more logical and efficient. Parathyroid extract should be given all severe cases (particularly the acute cases following thyroidectomy) and in almost every case will effect a marked improvement in the patient's symptoms. Intravenous calcium gluconate is effectual in mild cases but should not be used as the only method of treatment in the early or severe cases. If a fatal outcome can be prevented during the first few days after operation, the disease rarely terminates in death. Parathyroid extract exerts its maximum effect four to six hours after intramuscular injection and most of its calcium-elevating action is spent in 24 hours. Unfortunately, continued daily use of parathyroid extract leads in most patients to a gradually diminishing response until the hormone finally becomes ineffectual. Treatment with dihydrotachysterol (A.T.10), as reported by MacBryde (39) and others, is particularly valuable because the patient does not become resistant to its action as he frequently does to parathormone. Calcium lactate by mouth taken as a powder well stirred in water or milk, in doses of 5 grams two to four times daily, is advisable as daily therapy in the chronic cases. The addition of large doses of vitamin D to the oral calcium is effective in many chronic cases.

uted to the increased excretion of calcium and phosphorus are commonly noted.

Renal calculi are so common in this disease that hyperparathyroidism should be given diagnostic consideration in all patients with stones, particularly if they are bilateral and of the stag-horn type. Hematuria and signs of renal infection are often the most common manifestations; moreover, renal complications are the most common causes of death.

Rarely is the parathyroid tumor *palpable*. In 5 to 10 per cent of cases there will be two adenomas present, a fact the surgeon must keep in mind during operation (37).

X-ray examination of the bones is of great aid in arriving at a correct diagnosis. With few exceptions there is a generalized decalcification (osteoporosis) of the bones, which is revealed in the roentgenogram as a diffuse atrophy and moth-eaten appearance throughout the skeleton. Localized bone defects, particularly noted in the long bones and mandible, may be one of two kinds: 1. bone cysts containing thin brownish fluid; or 2. benign giant cell tumors (osteoclastomas). These cysts or tumors are usually multiple, as are shown by the x-ray. It is difficult to differentiate the cyst from the solid tumor roentgenologically, except that the solid tumors reveal more bony trabeculations through the defect. Renal calculi, containing large amounts of calcium, are commonly noted, may be bilateral and fill the entire pelvis of the kidney.

Laboratory data, particularly determination of the amount of calcium and phosphorus *in the blood, are perhaps the most reliable* means of establishing a diagnosis. Typical findings consist of the elevation of serum calcium from a normal of about 10 to a level varying from 12 to 20 or more mg. per 100 ml. of serum, and a depression of the serum phosphorus from a normal of about 4 down to 1.5 to 3.5 mg. per 100 ml. There is usually a negative calcium balance, i.e., more calcium is excreted in the urine and feces than is ingested in the food. The plasma alkaline phosphatase level, which is dependent largely upon the amount of bone change, may be elevated from a normal of 2 to 4 Bodansky units to 30 to 40.

Treatment. Excision of the tumor offers the only hope of relief. If the tumor is not readily found, it will be necessary to conduct a very thorough exploration of the neck, because the tumor, in many instances, will be located in an aberrant position. For example, in 58 adenomas found in 54 patients, Cope (36) reported that 11 were found in the anterior and five in the posterior mediastinum. Intratracheal anesthesia aids considerably in doing a thorough exploration. If possible, all the parathyroids (four or five) should be inspected since occasionally more than one will *be the seat of disease. Symptoms rapidly disappear* following removal of the tumor and the serum calcium drops to normal (within 12 to 24 hours). Following removal of the tumor, the bone lesions of the giant cell type disappear after a few months, but the bone cysts usually remain much longer. The small rarefied areas become recalcified. The renal calculi cease to enlarge, but do not disappear spontaneously. They are treated as are other kidney stones. Removal of the parathyroid tumor is occasionally followed by severe but usually transient tetany which is treated by parathyroid extract injections, intravenous or oral calcium, vitamin D, or dihydrotachysterol (A.T.10) as in tetany following accidental parathyroid injury or removal in thyroid operations. However, postoperative hypoparathyroidism tends to diminish and disappear unless the amount of parathyroid tissue remaining is grossly inadequate. If a tumor is not found, all parathyroids should be inspected for hyperplasia. Resection of two or three hyperplastic parathyroids is occasionally curative.

TETANY (Hypoparathyroidism)

The most common type of hypoparathyroidism is that seen following removal of parathyroids during thyroidectomy. However, there are other types of tetany in which the pathogenesis is not associated with the parathyroids. For example, the tetany observed frequently in children with rickets is apparently caused by avitaminosis D with failure to absorb and retain adequate amounts of calcium; it is characterized by a lowered *blood calcium level but is not* related to parathyroid deficiency. Tetany produced by overbreathing (with resultant alkalosis), as first described by Grant and Goldman (38), is occasionally seen in patients in the operating

travenous injection of sodium chloride and glucose.

Surgery finds a place in the therapy of Addison's disease through the subcutaneous implantation of pellets of desoxycorticosterone acetate. The required maintenance dose of desoxycorticosterone (DOCA) when administered by intramuscular injections in oil is first ascertained. One pellet is then implanted for each 0.5 mg. daily required by injection. The pellets weigh 75 or 125 mg. each and are usually implanted in the infrascapular region. The necessary number of pellets (usually between 2 and 10) may be inserted radially from a single small incision, a small forceps and a nasal speculum being useful for this purpose. Implantation may also be accomplished by a trocar with plunger. The absorption per pellet per day varies from 0.3 to 0.9 mg. A store of the hormone is thus established, which will last for many months. The appearance of hypertension, headaches, edema, rapid weight gain, or cardiac symptoms suggests hormone overdosage and may necessitate removal of some of the pellets.

It has been shown that elderly patients with malnutrition and other serious decrements may have severe adrenal insufficiency (42, 43), without obvious clinical evidence; such patients will respond markedly under ACTH or cortisone, which may improve operability sharply. Howland and associates (44) have emphasized that hypotension during surgery, with failure to respond with adequate blood replacement, may be the result of adrenocortical insufficiency; therapy under such circumstances should be intravenous hydrocortisone, 100 mg. given over a period of several hours.

HYPERFUNCTION OF THE ADRENALS

The clinical conditions produced by hyperadrenocorticism are variable and may be identified as Cushing's syndrome at one extreme and the adrenogenital syndrome at the other extreme. In the former condition, hyperplasia of the cortex is the abnormality usually producing the disease, whereas in the latter a tumor is usually found in the cortex.

Cushing's Syndrome. This condition, described by Cushing in 1932, was known originally as pituitary basophilism. The cause is unknown, although the manifestations are the same as those produced by prolonged administration of corticosteroids or by hyperfunction of the adrenal cortex. There is proof that the adrenal cortex is an important etiologic factor since removal of most of the hyperfunctioning adrenals results in cure. The syndrome is most frequently encountered in young females. Basophil tumors of the pituitary gland are found in about one third of the cases. Likewise, either a hyperplasia or a tumor of the adrenal cortex is found; tumors are present in about one third of the cases and often are malignant. It appears rather definite that the syndrome is mediated by the adrenal cortex.

Protein depletion is usually present because of the excessive production of glucocorticoids by the adrenal cortex, but obesity is fairly characteristic. The fat is deposited particularly over the trunk and face; the latter is rounded, giving rise to the expression "moon faced." A fat pad develops in the cervicodorsal region and has been characterized as a buffalo hump. The skin is thin, and bruises (patches of ecchymosis) are common because of increased capillary fragility; striae are usually present. Osteoporosis with decreased strength of bones is common. An insulin-resistant diabetes is usually present. Amenorrhea in females and impotence in males are common. Hirsutism develops in most female patients. At times, marked personality changes develop, with irritability or depression. Acne is common; cutaneous patches of pigmentation may occur. There is a greatly increased susceptibility to infection.

Important laboratory findings are hyperglycemia, decreased glucose tolerance test, glycosuria, eosinopenia, lymphopenia, leukocytosis, and an increased urinary corticosteroid excretion (17-hydroxycorticoids). The urinary 17-ketosteroids are usually normal or increased. Removal of the hyperplastic adrenals (leaving a few grams of tissue) results in a cure; the physical characteristics of the disease disappear after a few months, and a normal appearance is regained. If a tumor is found and removed, results will also be good.

Adrenogenital Syndrome (Virilism). The condition is presumably caused by an increased production of androgens by the adrenal cortex. If it develops in utero, pseudo-

THE ADRENALS (SUPRARENAL GLANDS)

Our knowledge of lesions of the adrenal glands progressed slowly up to a few years ago. True enough, in 1855 Addison described a clinical syndrome associated with a destructive disease of the adrenals. Many decades later (1928), Hartman and associates, and Rogoff and Stewart independently announced the prolongation of life of adrenalectomized animals by injection of adrenal cortex extracts. The discovery of ACTH and isolation of various adrenal corticoids during the past few years has allowed rapid accumulation of knowledge about diseases of the adrenal (40).

Up to the present time, chemists have isolated or identified 30 steroids from the adrenal cortex (41). Of this group, seven have demonstrable physiologic activity. They are: 17-hydroxy-11-dehydrocorticosterone (cortisone), desoxy-17-hydroxycorticosterone, 11-desoxycorticosterone, aldosterone, corticosterone, 17-hydroxycorticosterone-11-dehydrocorticosterone, and 11-desoxycorticosterone (DCA). The known adrenal cortical steroids fall into three groups according to physiologic activity: 1. those affecting primarily electrolyte and fluid balance (the desoxycorticosterones), which cause salt and water retention and promote potassium excretion; 2. those accelerating protein breakdown and increasing glucose production (the corticosterones); (cortisone, now being used in rheumatoid arthritis and in a wide variety of conditions, belongs to this group); and 3. those with androgenic activity, which are masculinizing and promote protein storage, the typical one being androsterone.

It is now recognized that adrenocortical functions are highly important in the maintenance of normal physiology. The response to stress particularly depends upon the relative integrity of the chain: central nervous system—anterior pituitary—adrenal cortex.

ADRENOCORTICAL INSUFFICIENCY

This may be acute or chronic and is characterized by: 1. a loss in sodium ion, chiefly through the urine, resulting in chloride loss, water loss, hemoconcentration and a fall in blood pressure; 2. an increase in the blood potassium, associated with a decrease in the excretion of potassium; 3. serious disturbance in carbohydrate metabolism, resulting in lowered blood sugar and a greatly reduced glycogen content of liver and muscle. Acute adrenocortical insufficiency can be produced in many species by bilateral adrenalectomy and is followed by death in a week or two. In the human being, removal or destruction of both adrenals will result in death within 24 to 72 hours. Delirium may develop, with lapse into unconsciousness with a very low blood pressure, rapid weak pulse, and hyperpyrexia. Anuria is common and muscular weakness is pronounced.

During the past several years, since bilateral adrenalectomy has been performed for the treatment of advanced cancer, acute insufficiency has been encountered occasionally when the maintenance dosage of cortisone has been omitted erroneously or is inadequate. As much as 100 to 200 mg. cortisone (by mouth) or an equal amount of hydrocortisone (by vein) over a 24-hour period, may be necessary to correct the deficiency. Acute cortical atrophy is produced by prolonged therapy with cortisone. This has a very important surgical significance if a patient needs a surgical operation while taking cortisone; if the surgeon is not aware of the prolonged cortisone therapy, and he operates without giving 200 to 300 mg. cortisone on the day of operation with reduced dosage for the next several days, the patient will usually die of shock which does not respond to blood transfusion.

Chronic adrenocortical insufficiency produces manifestations first described by Thomas Addison in 1849, and the disease is now generally given his name. The chief symptoms of Addison's disease are brownish pigmentation of the skin, weakness, loss of appetite, low blood pressure, and frequently, vomiting and diarrhea. In most cases, tuberculosis of the adrenal glands is responsible, while diffuse atrophy is the next most common cause. Rarely carcinoma, sarcoma, or adrenal hemorrhage is present. The treatment of acute severe adrenocortical insufficiency, such as occurs in the crises of Addison's disease, consists primarily of large doses of cortisone as suggested above, along with the in-

travenous injection of sodium chloride and glucose.

Surgery finds a place in the therapy of Addison's disease through the subcutaneous implantation of pellets of desoxycorticosterone acetate. The required maintenance dose of desoxycorticosterone (DOCA) when administered by intramuscular injections in oil is first ascertained. One pellet is then implanted for each 0.5 mg. daily required by injection. The pellets weigh 75 or 125 mg. each and are usually implanted in the infrascapular region. The necessary number of pellets (usually between 2 and 10) may be inserted radially from a single small incision, a small forceps and a nasal speculum being useful for this purpose. Implantation may also be accomplished by a trocar with plunger. The absorption per pellet per day varies from 0.3 to 0.9 mg. A store of the hormone is thus established, which will last for many months. The appearance of hypertension, headaches, edema, rapid weight gain, or cardiac symptoms suggests hormone overdosage and may necessitate removal of some of the pellets.

It has been shown that elderly patients with malnutrition and other serious decrements may have severe adrenal insufficiency (42, 43), without obvious clinical evidence; such patients will respond markedly under ACTH or cortisone, which may improve operability sharply. Howland and associates (44) have emphasized that hypotension during surgery, with failure to respond with adequate blood replacement, may be the result of adrenocortical insufficiency; therapy under such circumstances should be intravenous hydrocortisone, 100 mg. given over a period of several hours.

HYPERFUNCTION OF THE ADRENALS

The clinical conditions produced by hyperadrenocorticism are variable and may be identified as Cushing's syndrome at one extreme and the adrenogenital syndrome at the other extreme. *In the former condition*, hyperplasia of the cortex is the abnormality usually producing the disease, whereas in the latter a tumor is usually found in the cortex.

Cushing's Syndrome. This condition, described by Cushing in 1932, was known originally as pituitary basophilism. The cause is unknown, although the manifestations are the same as those produced by prolonged administration of corticosteroids or by hyperfunction of the adrenal cortex. There is proof that the adrenal cortex is an important etiologic factor since removal of most of the hyperfunctioning adrenals results in cure. The *syndrome is most frequently encountered in* young females. Basophil tumors of the pituitary gland are found in about one third of the cases. Likewise, either a hyperplasia or a tumor of the adrenal cortex is found; tumors are present in about one third of the cases and often are malignant. It appears rather definite that the syndrome is mediated by the adrenal cortex.

Protein depletion is usually present because of the excessive production of glucocorticoids by the adrenal cortex, but obesity is fairly characteristic. The fat is deposited particularly over the trunk and face; the latter is rounded, giving rise to the expression "moon faced." A fat pad develops in the cervicodorsal region and has been characterized as a buffalo hump. The skin is thin, and bruises (patches of ecchymosis) are common because of increased capillary fragility; striae are usually present. Osteoporosis with decreased strength of bones is common. An insulin-resistant diabetes is usually present. Amenorrhea in females and impotence in males are common. Hirsutism develops in most female patients. At times, marked personality changes develop, with irritability or depression. Acne is common; cutaneous patches of pigmentation may occur. There is a greatly increased susceptibility to infection.

Important laboratory findings are hyperglycemia, decreased glucose tolerance test, glycosuria, eosinopenia, lymphopenia, leukocytosis, and an increased urinary corticosteroid excretion (17-hydroxycorticoids). The urinary 17-ketosteroids are usually normal or increased. Removal of the hyperplastic adrenals (leaving a few grams of tissue) results in a cure; the physical characteristics of the disease disappear after a few months, and a normal appearance is regained. If a tumor is found and removed, results will also be good.

Adrenogenital Syndrome (Virilism). The condition is presumably caused by an increased production of androgens by the adrenal cortex. If it develops in utero, pseudo-

THE ADRENALS (SUPRARENAL GLANDS)

Our knowledge of lesions of the adrenal glands progressed slowly up to a few years ago. True enough, in 1855 Addison described a clinical syndrome associated with a destructive disease of the adrenals. Many decades later (1928), Hartman and associates, and Rogoff and Stewart independently announced the prolongation of life of adrenalectomized animals by injection of adrenal cortex extracts. The discovery of ACTH and isolation of various adrenal corticoids during the past few years has allowed rapid accumulation of knowledge about diseases of the adrenal (40).

Up to the present time, chemists have isolated or identified 30 steroids from the adrenal cortex (41). Of this group, seven have demonstrable physiologic activity. They are: 17-hydroxy-11-dehydrocorticosterone (cortisone), desoxy-17-hydroxycorticosterone, 11-desoxycorticosterone, aldosterone, corticosterone, 17-hydroxycorticosterone-11-dehydrocorticosterone, and 11-desoxycorticosterone (DCA). The known adrenal cortical steroids fall into three groups according to physiologic activity: 1. those affecting primarily electrolyte and fluid balance (the desoxycorticosterones), which cause salt and water retention and promote potassium excretion; 2. those accelerating protein breakdown and increasing glucose production (the corticosterones); (cortisone, now being used in rheumatoid arthritis and in a wide variety of conditions, belongs to this group); and 3. those with androgenic activity, which are masculinizing and promote protein storage, the typical one being androsterone.

It is now recognized that adrenocortical functions are highly important in the maintenance of normal physiology. The response to stress particularly depends upon the relative integrity of the chain: central nervous system—anterior pituitary—adrenal cortex.

ADRENOCORTICAL INSUFFICIENCY

This may be acute or chronic and is characterized by: 1. a loss in sodium ion, chiefly through the urine, resulting in chloride loss, water loss, hemoconcentration and a fall in blood pressure; 2. an increase in the blood potassium, associated with a decrease in the excretion of potassium; 3. serious disturbance in carbohydrate metabolism, resulting in lowered blood sugar and a greatly reduced glycogen content of liver and muscle. Acute adrenocortical insufficiency can be produced in many species by bilateral adrenalectomy and is followed by death in a week or two. In the human being, removal or destruction of both adrenals will result in death within *24 to 72 hours. Delirium may develop,* with lapse into unconsciousness with a very low blood pressure, rapid weak pulse, and hyperpyrexia. Anuria is common and muscular weakness is pronounced.

During the past several years, since bilateral adrenalectomy has been performed for the treatment of advanced cancer, acute insufficiency has been encountered occasionally when the maintenance dosage of cortisone has been omitted erroneously or is inadequate. As much as 100 to 200 mg. cortisone (by mouth) or an equal amount of hydrocortisone (by vein) over a 24-hour period, may be necessary to correct the deficiency. Acute cortical atrophy is produced by prolonged therapy with cortisone. This has a very important surgical significance if a patient needs a surgical operation while taking cortisone; if the surgeon is not aware of the prolonged cortisone therapy, and he operates without giving 200 to 300 mg. cortisone on the day of operation with reduced dosage for the next several days, the patient will usually die of shock which does not respond to blood transfusion.

Chronic adrenocortical insufficiency produces manifestations first described by Thomas Addison in 1849, and the disease is now generally given his name. The chief symptoms of Addison's disease are brownish pigmentation of the skin, weakness, loss of appetite, low blood pressure, and frequently, vomiting and diarrhea. In most cases, tuberculosis of the adrenal glands is responsible, while diffuse atrophy is the next most common cause. Rarely carcinoma, sarcoma, or *adrenal hemorrhage is present.* The treatment of acute severe adrenocortical insufficiency, such as occurs in the crises of Addison's disease, consists primarily of large doses of cortisone as suggested above, along with the in-

ties occur simultaneously. Hirsutism involves the face, extremities, and trunk, although the hair on the scalp may be thin. Menses are irregular, scanty, and often absent. Libido is diminished. As the clitoris enlarges, the breasts, ovaries, and uterus decrease in size. The voice deepens, and extreme degrees of muscular development, with masculine configuration are striking.

Mixed syndromes often occur, exhibiting characteristics of virilism (masculinization) and Cushing's disease. These are usually due to adrenocortical hyperplasia, but occasionally tumors will be found. In patients with the mixed syndrome, the excretion of 17-hydroxycorticoids will usually be high.

Primary Aldosteronism. This syndrome was originally described by Conn (45). The important features are hypokalemic alkalosis, hypernatremia, paresthesia, intermittent tetany, periodic muscular weakness, paralysis, polyuria, polydipsia, and hypertension without edema. There is no increase in secretion of 17-ketosteroids or of 17-hydroxycorticoids.

No more than a dozen cases have been reported to date, but with few exceptions, a cortical tumor has been found. Biopsy of the tumor reveals a marked increase in aldosterone (45).

Within a day or two following removal of the tumor, a diuresis of sodium develops along with a retention of potassium; within a week or two the blood levels and excretion of sodium and potassium should be normal. Likewise, the blood pressure should fall to a normal level.

Tumors of the Medulla. Perhaps the most common tumor of the medulla is the neuroblastoma, which, however, has no endocrine function. These tumors are found most commonly in infancy and childhood; they are classified as sympathogoniomas, sympathoblastomas, or ganglioneuromas, depending upon the maturity of the cell. They tend to be malignant in children but are less apt to be malignant in adults.

Pheochromocytomas (Chromaffin Cell Tumors). These are endocrine tumors producing epinephrine and norepinephrine. They are usually benign; in about 10 per cent of cases they occur outside the adrenal (41), in which case they may be classified as paragangliomas. They vary greatly in size. Occasionally, when malignant they may produce functioning metastases.

The most significant symptoms are hypertension, palpitation, sweating, precordial distress, and tachycardia, which are of a paroxysmal type, fluctuating usually within a wide range. Periodic attacks of flushing and pallor of the skin caused by vasodilatation and vasoconstriction may be observed. Headache is a prominent symptom. Nausea and vomiting may be present; dyspnea and a sensation of choking may be complained of. Surgeons should always suspect pheochromocytomas in patients who develop unexplained hypertension during any operative procedure. Discovery of the cause of paroxysmal hypertension is important, since it may be surgically curable and because maintenance of hypertension may result in serious damage to the health or even death. At autopsy, pulmonary edema and cardiac hypertrophy are notable findings.

The hypertension associated with pheochromocytomas is often difficult to differentiate from essential hypertension. Adrenolytic drugs, such as regitine, dibenamine, or benzodioxane, may be helpful in differentiation as they block transmission of sympathetic nerve impulses at the myoneuric junctions and thus produce a lowering of blood pressure in patients with pheochrome tumors but not in those with essential hypertension. However, this test is by no means infallible.

Pyelography or plain roentgen films of the abdomen may reveal displacement of the upper pole of the kidney by a tumor mass. Of more value, however, is the presacral injection of oxygen as originated by Scarinci (1950). The patient is placed in the knee-chest position and a No. 18 or No. 19 needle inserted at a point equidistant from anal orifice and the tip of the coccyx in the mid-line (46). The tip of the needle is advanced between the coccyx and posterior wall of the rectum, guided by a finger in the rectum. With the aid of a three-way stopcock and 50 ml. syringe, 1,000 to 1,400 ml. of oxygen is injected over a period of 10 or 15 minutes. Less is used for children. Reactions are few and limited to a feeling of fullness or dull back pain. Immediately after injection,

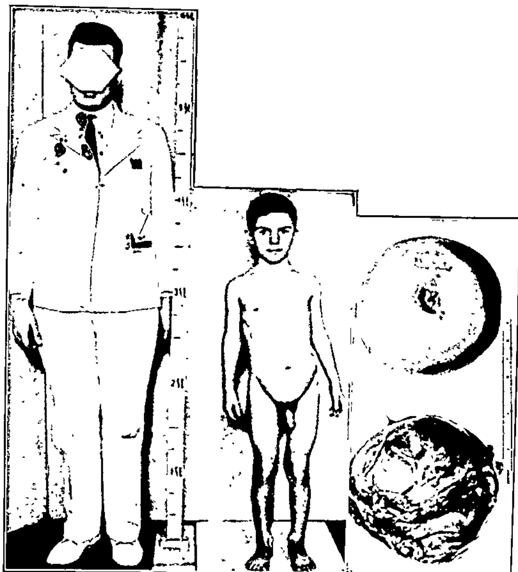

Fig. 16. Adrenogenital syndrome due to adenoma of adrenal cortex. Patient is a boy aged four years and 11 months; note the adult-size genitalia and pubic hair. A slight mustache is developing. On the right, encapsulated tumor removed successfully from the left adrenal; an apple is illustrated for comparison. As stated in the text, males are affected infrequently. (From Lisser. Transactions of the Association of American Physicians.)

hermaphroditism may be found at birth. In the preadolescent male, precocious puberty may be present; in the preadolescent and adult female, heterosexual characteristics may develop. In addition to the high androgen secretion there is a marked anabolic effect in protein metabolism; the patients are usually well developed muscularly.

Postnatal adrenal virilism encountered in females before puberty is usually due to an adrenocortical tumor. The virilism may develop shortly after birth and usually progresses rapidly. One of the most prominent characteristics in females is hypertrophy of the clitoris. Axillary and pubic hair are present as in adults.

In the male, the genitals develop rapidly, often attaining adult size at the age of five or six years (Fig. 16). Varying degrees of obesity may develop along with the increased muscle mass. The excretion of 17-ketosteroids is high, ranging from 25 to 100 mg. in 24 hours.

On most occasions, the condition is produced by a tumor; if not, diffuse hyperplasia of the cortex is present. When the patient is a female, development of masculine characteristics and suppression of feminine characteris-

Fig. 18. Photomicrograph of adenoma of pancreas which was producing typical symptoms of hypoglycemia, and was successfully removed. The cells which are similar to the so-called beta cells of the islets of Langerhans are arranged in sinuous cords. Dense connective tissue separates the cells into imperfect lobules.

tion), particularly because microscopic proof of actual hyperplasia is only rarely demonstrable.

HYPOGLYCEMIA DUE TO TUMORS OF THE ISLETS

The first case of hyperinsulinism due to a tumor of the pancreas was reported by Wilder and associates (47). This patient suffered from a carcinoma of the islets which rapidly metastasized and caused death.

Microscopically, it is difficult to determine whether a tumor of the islets is benign or malignant. However, from the clinical standpoint it is apparent that most of them are benign. The first histologic study of a series of cases, as reported by O'Leary and Womack (48), indicates that the adenomas are tumors with cells "closely allied to the beta cells of the normal islets of Langerhans." The microscopic structure of an adenoma may resemble that of a normal islet, i.e., cuboidal and pyramidal cells in columns adjacent to capillaries or rosettes of cells around a capillary (Fig. 18). Occasionally, the cells are arranged in a duct-like structure. Mitotic figures are occasionally seen. Usually the tumors are completely encapsulated, are commonly small (0.25 to 2 cm. in diameter) and are of a bluish-pink color. They are readily identified except for a slight resemblance to lymph nodes.

Clinical Manifestations. The symptoms of hypoglycemia due to tumor are dramatic but extremely variable. The most common manifestations are attacks of weakness, lassitude, and mental confusion occurring several hours after meals, particularly in the morning before breakfast. Between attacks the patient may complain of being unusually hungry and not infrequently has a craving for sweet food, such as candy. Occasionally, the patient will make the discovery that partaking of food between meals, particularly at night, will prevent the development of symptoms. The patient fatigues readily and for that reason is unable to perform much manual labor. Profuse sweating and trembling of the extremities are not uncommon. The type of mental change varies from mild confusion to attacks of unconsciousness with convulsions and is frequently erroneously diagnosed as idiopathic epilepsy, brain tumor, and so forth. The mild attacks may closely resemble the petit mal attacks of epilepsy. The patient rarely has any recollection of incidents happening during these mental disorders. Such attacks differ from epilepsy insofar as they are not accompanied by aura (unless hunger, weakness, and malaise are considered as

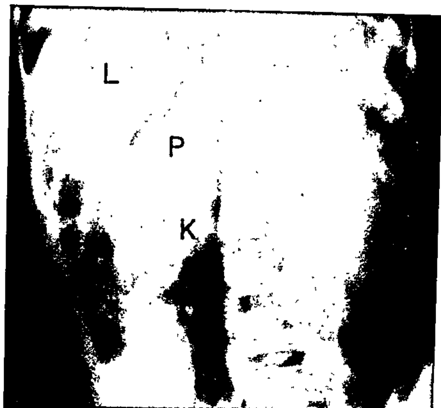

Fig. 17. Pheochromocytoma outlined by presacral injection of oxygen. The tumor is outlined by the procedure. L—liver, P—pheochromocytoma, and K—kidney.

the patient is placed supine on a tilting fluoroscopic table in a semi-erect position, and films taken. Good outlines of the kidneys and adjacent structures are usually obtained, with satisfactory demonstration of the tumor if present (Fig. 17).

Removal of the tumor is curative. However, immediately after its removal it is usually necessary to give norepinephrine for a few hours to maintain blood pressure. Cortical hormones are not necessary.

PANCREAS

In this chapter will be considered the endocrine diseases of the pancreas; the inflammatory and neoplastic lesions are discussed in Chapter 29. The former are related to the internal secretions, whereas the latter are related to the external.

The islets of Langerhans secrete insulin and are therefore presumably affected in diseases which are dependent either upon diminished secretion of insulin (diabetes, hypoinsulinism, hyperglycemia) or increased secretion (hyperinsulinism, hypoglycemia). Only the latter disease (hyperinsulinism), which may be caused by adenomas or carcinoma of the islets, will be considered here since diabetes is primarily of medical importance.

Although the most serious cases of hypoglycemia are caused by tumors (adenoma or carcinoma) of the islets, such patients comprise only a small number of those actually suffering from hypoglycemia. *Spontaneous hypoglycemia* from many causes is relatively common but that caused by true *hyperinsulinism* is quite rare. Hepatic insufficiency may be a direct cause of hypoglycemia. Deficiency in the secretion of the anterior lobe of the pituitary body may likewise result in hypoglycemia, which may be produced experimentally by removal of the anterior pituitary, but may be alleviated by pancreatectomy. Hypoglycemia may be a prominent feature in adrenal cortex deficiency (Addison's disease). In the absence of a tumor, hypoglycemia has also been attributed to a diffuse hyperplasia of the islets, but it appears more logical to explain the hypoglycemia in such cases by a mechanism similar to that just described (i.e., pituitary or adrenal hypofunc-

HYPOGLYCEMIA NOT DUE TO TUMORS OF THE ISLETS

This type of hypoglycemia is in reality much more common than that caused by adenomas. Although a few of these are due to actual hypertrophy and hyperplasia of the islets, the majority are probably due to hepatic insufficiency or to disease of the adrenal or pituitary glands. Detailed accounts of these types of hypoglycemia, including differential diagnosis and the use of insulin tolerance tests, have been discussed by MacBryde (52). Occasionally, hypoglycemia develops as an aftermath of diabetes.

Various mechanisms may result in spontaneous hypoglycemia not due to islet cell tumor. There are two possible explanations for its development, viz.: 1. insulin may be produced in excessive quantities or 2. there is a diminution below normal in insulin-resistant factors, thus making the patient more sensitive to insulin and its effects. Insulin tolerance tests should be of considerable aid in determining which mechanism is at fault. When the administration of a few units of insulin produces serious symptoms of hypoglycemia, it appears that sensitivity to in*sulin plays a role in the hypoglycemia.* The term hyperinsulinism should be applied only when production of insulin is increased.

The *clinical manifestations* of hypoglycemia of the types just mentioned are not unlike those encountered in hypoglycemia produced by adenomas of the islets. However, in the former types the symptoms are milder and mental disturbances are encountered only on rare occasions. The most common symptoms are weakness, malaise, headache, and easy fatigue. The patient usually experiences undue hunger, particularly for sweet foods.

The *treatment* of hypoglycemia not caused by tumors should at first be medical, with particular attention to the diet. Limitation of the carbohydrate in the diet to an amount barely sufficient to control symptoms, and maintenance of this diet (which should be high in its protein and fat content) over an extended period of time frequently result in recovery. Small frequent meals are employed, with a feeding at bedtime. The favorable effect exerted by the low carbohydrate diet may be explained by the diminution in the stimulus for production of insulin. The dietary measures have been discussed in detail by MacBryde (52).

Frequently, it is impossible to exclude the possibility of a pancreatic adenoma, particularly if the symptoms are severe and *not relieved by appropriate medical treatment.* In such instances, celiotomy should be performed. If no tumor is found, subtotal pancreatectomy may be indicated.

In a study of 56 cases of idiopathic hypoglycemia studied by Howard and associates (50), good results were reported in 46 per cent following subtotal pancreatectomy.

ULCEROGENIC TUMORS OF THE PANCREAS

Zollinger and associates (53) have called attention to the relationship of nonbeta islet cell adenomas (not producing insulin) of the pancreas and peptic ulceration. They have recorded data on 24 patients (their own and others encountered in the literature) which emphasize the desirability of inspecting the pancreas in every patient operated on for peptic ulcer, particularly if the patient has had a previous and unsuccessful operation *for peptic ulcer.*

PITUITARY (HYPOPHYSIS)

The pituitary gland is a small structure connected by a slender stalk to the base of the brain and isolated in a protected manner by its position within the sella turcica. The gland is composed of an anterior and a posterior lobe. The anterior lobe (pars anterior) is composed of chromophil cells with protoplasm containing granules which stain with acid or basic dyes and chromophobe cells whose protoplasm contains very few granules and stain feebly. The posterior lobe is composed of several structures, including the pars nervosa and pars tuberalis. The pars intermedia is usually considered to be a separate independent structure.

The *functions* of the hypophysis are concerned chiefly with the secretion of hormones, of which there are at least six.

1. The *adrenocorticotropic hormone* is perhaps the most important of those known at the present time. Its chief action is to stimulate the production of one (cortisone) or

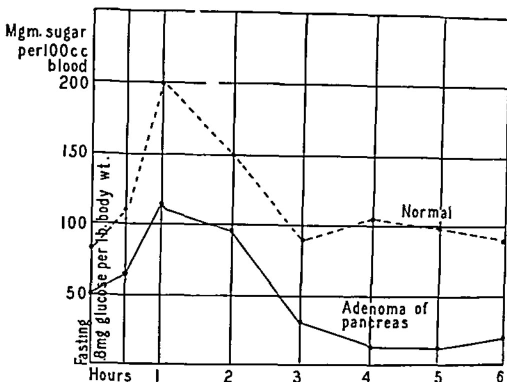

Fig. 19. Comparative sugar tolerance curves of normal individual and patient with an adenoma of the pancreas producing symptoms of hypoglycemia. The blood sugar level in the patient with the adenoma (solid line) does not rise as high as the level of the normal individual (dotted line). It usually begins at a lower fasting level and falls rapidly after ingestion of glucose to subnormal levels.

such). The intravenous administration of glucose rarely fails to relieve the patient of his mental symptoms if they are caused by a true hypoglycemia. If the attacks of hypoglycemia recur frequently or persist over a long enough time, an actual permanent mental deterioration may develop. Speech may be slurred and tremulous; occasionally, there is a hesitation in speech as if there were a mild aphasia. Rarely are any neurologic signs other than a positive Babinski present. The patient may die in an attack.

Laboratory data are of extreme value in arriving at a correct diagnosis. The fasting blood sugar is below normal and may be as low as 30 or 40 mg. (true sugar) per 100 ml. of blood, or lower during attacks; in children, the blood sugar may be as low as 20. The carbohydrate tolerance is usually increased (Fig. 19). The subcutaneous administration of epinephrine and pituitrin in patients with islet tumors usually produces only a mild elevation in the blood sugar level, but with alleviation of the symptoms mentioned above. Patients with functional hypoglycemia are more sensitive to insulin than normal; patients with islet tumors are usually less sensitive than normal.

Treatment. If there is a reasonable possibility that the hypoglycemia is caused by an adenoma of the pancreas, an operation is usually indicated (unless there are physical contraindications), because excision of adenomas of this type has been remarkably successful. The likelihood of an adenoma being the cause of the hypoglycemia is increased by exclusion of other causes by careful study, as discussed further under the next heading. Obviously, if the hypoglycemia is caused by carcinoma of the islets which has already metastasized, operation will be of no value. Fortunately, such tumors are much less frequent than benign adenomas. The pancreas is most readily exposed by making an incision through the gastrocolic omentum. Any neoplastic growths encountered should be excised. Although most tumors are located in the tail or body of the pancreas the entire organ must be inspected because of the variability in location of the tumors. A more detailed description of this disease may be found in publications elsewhere (49, 50, 51).

tary would obviously halt progression of the disease and may be followed by considerable improvement.

NEOPLASM (ADENOMAS) OF THE PITUITARY

Neoplastic growths of the pituitary may give rise to various symptoms referable to disturbance in the secretions of the gland, most of which can be classified roughly into those produced by hyperfunction or hypofunction. Most of these tumors involve primarily the anterior lobe. Manifestations of increased intracranial pressure may be produced by these tumors but are not as pronounced as those due to other brain tumors. Manifestations due to pressure on adjacent structures ("neighborhood symptoms") are often characteristic; the most important of these symptoms is disturbance in vision, because of pressure upon the optic tracts at or near the chiasm.

Chromophil Adenoma. Tumors involving the chromophil cells (those taking an acidophilic or basophilic stain readily) are usually associated with symptoms of hyperfunction. For example, an adenoma containing acidophilic cells results in certain growth manifestations, thereby substantiating the supposition that the acidophilic cells elaborate the growth hormone. If the tumor manifests itself in young people before the epiphyses close, *gigantism* results (Fig. 20). This in reality is the explanation for the famous giants in history. In most instances the disease effects the male. The eunuchoid features frequently encountered in these patients are presumably due to a deficiency of testicular hormone, the secretion of which may be inhibited by the overproduction of an anterior pituitary hormone. The bone and muscular tissue resulting from this growth stimulus appear to have a normal gross and histologic appearance, but patients afflicted with this disease do not possess a corresponding muscular strength and are very susceptible to complicating diseases, particularly infections. Surgical treatment (partial hypophysectomy) is followed by uncertain results. Testosterone propionate should be given in males and estrogens in females when hypogonadism is present.

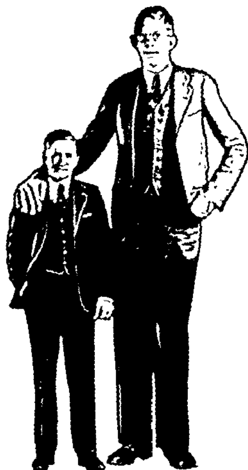

Fig. 20. Gigantism. The patient, sometimes known as the Alton giant, was 22 years old at the time of his death. He was 8 feet 9½ inches tall and weighed 491 pounds; he wore a size 36 shoe. (Courtesy, Peters Shoe Company.)

Acromegaly is produced when the adenoma manifests itself after the epiphyses have closed. It develops insidiously and slowly; the first manifestation noted by the patient is usually that larger shoes, hats, and gloves are required to fit him. The head becomes large, and the lips and tongue thickened. The lower jaw protrudes so far that the teeth of the upper and the lower jaws do not approximate (prognathism). The brow and nose are prominent. Hypertropic changes in the skin associated with wrinkling are noted, particularly about the face (Fig. 21).

In almost all instances of gigantism or acromegaly, examination by the x-ray reveals an enlargement of the sella. There is usually an accompanying erosion of the sella which is manifested by a thinning, but rarely a rough-

more hormones of the adrenal gland. ACTH and cortisone are useful in the treatment of rheumatoid arthritis (54) and of a number of other conditions, especially allergic disorders and certain eye and skin diseases; but of more importance is the tremendous influence of these hormones on numerous body functions.

2. The action of the *growth* or *somatotropic hormone* is clearly illustrated by the production of gigantism following experimental administration of an extract of the anterior lobe and by the dwarfism which follows hypophysectomy in young animals.

3. The presence of a *gonadotropic hormone* was suggested independently in 1926 and in 1927 by P. E. Smith (55) and Aschheim and Zondek (56). The latter authors noted that a gonadotropic substance similar to extracts of anterior pituitary was present in large quantities in the urine of pregnant women, a fact which they made use of in developing a test for pregnancy. In view of recent work it appears that there are two urinary gonadotropic hormones, one of which has been designated as the "follicle-stimulating hormone" and the other, the "luteinizing hormone," the latter of which may be of placental origin ("chorionic gonadotropin"). The gonadotropic hormone also acts as a *stimulus to the growth of the male organs.*

4. Experimental evidence of the *thyrotropic hormone* was discovered years ago (Loeb, Aron, in 1929), but isolation of thyrotropin (thyroid-stimulating hormone, TSH) much more recently. When given to animals, a marked hyperplasia of the thyroid results; activity of the thyroid cells is increased and I^{131} (when given to the patient) accumulates in the thyroid to a much greater degree.

5. The anterior lobe of the hypophysis also elaborates a *lactogenic hormone* (prolactine) which stimulates the secretion of milk by the mammary gland.

6. The anterior lobe of the hypophysis also secretes a *diabetogenic substance* which, when injected into hypophysectomized animals, will produce hyperglycemia and glycosuria.

The functions already discussed are performed by the anterior pituitary lobe. However, one of the first substances known to be elaborated by the hypophysis is that extractable from the posterior lobe. This is a pressor substance used to produce certain physiologic effects, such as elevation of the blood pressure, contraction of uterine muscle, and increase in intestinal peristalsis, and is commonly designated as *pituitrin*. It is not a pure hormone, however, since two (or more) products (e.g., *pitressin*, having pressor and antidiuretic properties, and *pitocin*, having oxytocic properties, stimulating uterine contraction) with separate physiologic effects have been isolated from posterior pituitary extracts.

PITUITARY INSUFFICIENCY, PITUITARY CACHEXIA, SIMMONDS' DISEASE

The symptoms of adult general pituitary insufficiency were described by Simmonds (57). If the hypofunction develops in childhood before normal stature is attained, dwarfism will result. The bones fail to grow, and ossification of the epiphyseal cartilages is delayed. Normal sexual development does not take place in either sex (sexual infantilism). The skin remains smooth and of a fine texture. There may be retardation in mental development. If the disease occurs in childhood before puberty, the male skeleton may assume a feminine appearance, with a broad pelvis and genu valgum; the fingers are apt to be *narrow and tapering*. Hair on the face, pubis and axillae is scanty or absent.

If the disease develops after puberty, there will usually be a gradual diminution of sexual activity with impotence. In women, sterility and amenorrhea are quite constantly observed. Drowsiness and somnolence are common manifestations. Polyuria and a high carbohydrate tolerance are not uncommon. The body temperature may be lowered considerably, as is also the basal metabolism.

In complete pituitary failure there is the appearance of premature senility, with loss of hair, emaciation, wrinkling of the skin, and progressive severe cachexia. The pathologic processes responsible for the development of pituitary cachexia are extremely varied and include such lesions as carcinoma, cysts, syphilis, tuberculosis, and embolism involving the anterior lobe of the pituitary.

From the surgical standpoint, the most important feature in therapy is the determination as to whether or not a tumor is present. Removal of a tumor compressing the pitui-

Fig. 23. X-ray of skull showing marked enlargement of the sella turcica in a patient aged 19, with a chromophobe adenoma of the pituitary. There is mild thinning and erosion of the posterior clinoid process. The patient had poor vision and headaches of six months' and four months' duration respectively. He also complained of a poor memory during the past few months. Visual fields revealed a *bitemporal hemianopsia*. (*Courtesy*, Dr. Ernest Sachs.)

noted by the patient until they are far advanced. Examination by perimetry will reveal variable defects but usually bitemporal hemianopsia.

The treatment of acromegaly may or may not be surgical. If the adenomatous growth is so large as to produce an impairment of vision by pressure against the optic chiasm, removal of at least a part of the tumor is indicated. Even in the absence of visual impairment, operation may be advisable because of prominent symptoms, especially headache. Resection of a large part of the tumor usually relieves the symptoms, but no improvement in the bony changes can be expected. X-ray therapy frequently will be found helpful as a substitute for operation in many cases, and should be given postoperatively, especially if symptoms recur.

Basophilic Adenoma. This type of tumor is usually nothing more than an abnormally large collection of basophilic cells and is spoken of as *pituitary basophilism*. Since this syndrome was originally described by Cushing (1932), it is now known as Cushing's disease, which has already been discussed in this chapter. Neighborhood or pressure symptoms are rarely produced by basophil adenomata, which are usually small. The clinical picture produced is that of hyperadrenocorticism.

Chromophobe Adenoma. This type of tumor is more common than the chromophil adenoma which causes acromegaly and attains a much larger size, usually breaking through upward toward the brain. For this reason "neighborhood" symptoms are more common than in acromegaly. The most frequent and significant of these neighborhood symptoms is defective vision, of the same type encountered in acromegaly, and is produced by pressure on the optic chiasm by the tumor (Fig. 23). Headaches are common. Adults are afflicted much more often than children. There is usually a diminished sexual power and desire, beginning shortly after onset of growth of the tumor, produced perhaps by pressure of the tumor on the basophilic cells. In women, amenorrhea is usually present. The patients are usually sluggish physically and a tendency toward somnolence is not uncommon. The basal metabolic rate

Fig. 21. Acromegaly. A, photograph of patient before development of the disease. B, patient is 23 years of age; three years before this photograph was taken patient noted beginning thickening of the lips and coarseness of facial features. Recently, her hands and feet have enlarged; headaches are very troublesome, and amenorrhea has been present for the past nine months. During the past several months, vision has become blurred. Visual fields reveal a bitemporal hemianopsia. See Figure 22. (Courtesy, Dr. Ernest Sachs.)

ening, of its bony wall. The hands are broad and roentgenograms reveal a thickening of the phalanges with prominent exostoses. The bones of the head are likewise thickened and massive.

Subjective symptoms may be slight. Headaches, however, are common. At first there may be an actual increase in sexual power and desire, but usually these characteristics are gradually lost. There may be secondary changes in other endocrine glands. The thyroid may be enlarged and hyperthyroidism, as evinced by an increase in the basal metabolic rate, may be present. Polyuria and mild glycosuria are not uncommon. True diabetes occurs in about 25 per cent of cases. Occasionally, the tumor may progress upward so that there is compression of the optic chiasm, thereby producing defects in the visual fields (Fig. 22). These defects are usually not

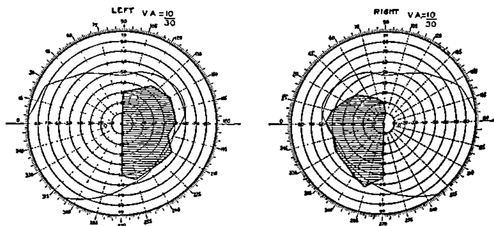

Fig. 22. Visual field revealing a bitemporal hemianopsia (same patient as in Figure 21.). The fields for a normal individual are outlined on the charts with a continuous line.

with neoplasms of the adrenal cortex but differ chiefly in the absence of obesity, hypertension, and hyperglycemia, which are apt to occur in the latter. Surgical removal will lead to complete cure. *Follicle cysts* occur because of failure of ovarian follicles to rupture and may result in prolonged absorption of large amounts of estrogenic hormones, leading to menorrhagia and metrorrhagia. When hormone therapy is unsuccessful in such patients, removal of the cyst or the whole offending ovary may prove necessary.

TESTES

Certain tumors of the testes, particularly the group called teratoma, may secrete hormones, curiously enough, which are similar to the chorionic gonadotropins produced in the placenta of the pregnant female. Most of these patients exhibit positive tests for gonadotropin. Other endocrine disturbances in the male associated with the sex hormones such as gynecomastia have been discussed elsewhere in the text. Testosterone is valuable in treating male hypogonadism. In females, it is useful in treating menorrhagia. In elderly patients, the anabolic effects of estrogens and androgens are employed in promoting protein and calcium storage. In the treatment of tumors, gonadal hormones are clinically highly useful. Estrogens inhibit cancer of the prostate. Androgens inhibit mammary cancer.

is frequently low and the temperature subnormal. There may be a high carbohydrate tolerance. Examination reveals a soft, pale, smooth skin with loss of hair, particularly in the pubic and axillary region. In men, the hair on the face becomes finer and grows slowly so that shaving is necessary only at infrequent intervals. Many patients become obese. Affected males develop feminine characteristics, with fat pads in the breast regions and mons veneris, knock knees, tapering fingers, and soft, smooth, hairless skin. The genitals are atrophic. The x-ray usually reveals a greatly enlarged sella turcica.

With few exceptions, treatment is surgical only when the eyesight is threatened. Under this circumstance, the removal of the greater part of the tumor prevents progression of the visual defect and in many instances results in restoration of vision. Since many of the manifestations of the disease are in reality a hypofunction of the gland, surgical removal of the pituitary would obviously exert an unfavorable effect except for the relief of symptoms caused by local or general pressure of the tumor.

CYSTIC TUMORS

Several types of cysts are encountered about the pituitary, only a few of which are actually intrasellar. Most of them are suprasellar or retrosellar. They are thought to be of congenital origin, arising in "cell rests," misplaced during the neurobuccal development of the pituitary gland. A variable amount of solid tumor tissue may accompany the cyst. Many of the symptoms, as in chromophobe adenomas, are referable to pituitary hypofunction. Such cysts develop early in life and usually are recognizable in childhood by the manifestations produced. However, many are present for years without producing symptoms.

Dwarfism or stunted growth is usually the first feature noted. The genitals remain infantile. The skin is soft and pale and there is a slight tendency toward obesity. The child may develop mentally in a normal manner unless pressure manifestations occur. These pressure symptoms are extremely variable in type and may be either local or general; they are similar to those encountered in chromophobe adenomas. If the cyst encroaches upon the third ventricle, compression of vital centers in this region may lead to a fatal outcome. The foramen of Monro is occasionally blocked resulting in hydrocephalus. After the tumor has been present for many years, calcium becomes deposited in the wall of the cyst, thus making diagnosis by x-ray possible.

Unless symptoms are absent or mild, the treatment is obviously surgical. On account of the extreme variability in the location of the tumor and its attachment, operation in these cases is not only difficult but accompanied by a high mortality. After exposure of the cyst through a transfrontal approach by removing an osteoplastic flap, aspiration of its contents usually relieves the pressure symptoms but is not curative since the cyst refills.

THE GONADS

Although detailed discussion of the ovaries and testes will be found in the chapters on Gynecology and Genitourinary Diseases, respectively, certain features of these organs which are primarily of endocrine importance are considered here.

OVARIES

Certain ovarian disorders may result in endocrine abnormalities and require surgical attention. *Granulosa cell neoplasms* are composed of cells which secrete large amounts of estrogenic hormone. When they occur in young girls they produce precocious puberty with development of breasts, hair growth, and other adult secondary sex characteristics, including menstruation, either cyclic or irregular. When such tumors appear in women past the menopause, there is a return of menstruation, which is apt to be irregular and excessive. The treatment is surgical removal of the neoplasm. *Arrhenoblastoma* is an ovarian neoplasm composed of testicular type cells developing from embryonic rests within the ovary. A male type hormone similar to or identical with testosterone is secreted, and masculinizing effects are produced. Menstruation ceases, the face becomes bearded and body hair becomes more abundant and changes to the male type. The breasts atrophy and body contours become masculine. These symptoms resemble those associated

GYNECOLOGY

Malformations and Malpositions
Injuries of Childbirth
Infections
Neoplasms
Miscellaneous Conditions
Endocrine Disturbances
Diseases of the Vulva and Vagina

As a branch of medicine dealing with the female genital tract, gynecology has contributed significantly to the development of surgery. The first successful abdominal operation was performed for the removal of an ovarian cyst. This milestone in the history of surgery is all the more remarkable because it is dated 1809, nearly 50 years before the introduction of anesthesia and asepsis. Moreover, the scene was set in the frontier town of Danville, Kentucky. The patient was Mrs. Jane Todd Crawford, the surgeon, Dr. Ephraim McDowell, the place, a kitchen table in a small farmhouse. To be sure, it was not a true intraabdominal procedure, for the large cystic mass was merely delivered through a small incision and amputated at the stump. Nevertheless, the patient was up and about on the sixth postoperative day and lived several decades to tell her story.

Gynecology developed rapidly as a specialty, particularly through the work of J. Marion Sims, and of Howard A. Kelly. Despite its increasing limitations as a separate specialty, the female genital organs are frequently the site of disease which has general medical and specific surgical interest. This is particularly true of lesions in the pelvis, which, after all, is but a part of the general peritoneal cavity. Moreover, through the vagina one may by examination gain much information of lower abdominal disease, even when there is no pelvic lesion. The more external and obvious manifestations of gynecological disease, finally, are so common that a fundamental knowledge of them should be possessed by all practitioners whether or not they specialize in surgery, obstetrics, or gynecology. No attempt is made in this chapter to cover the field of gynecology, but only to call attention to the aspects of more general interest. The following single volume works on gynecology can be recommended: Curtis and Huffman (1), Crossen (2), Novak and Novak (3) and Meigs and Sturgis (4).

Definitions. *Normal menstruation* (catamenia, monthly flow, monthly sickness, period, menses, being "unwell") begins at puberty, which occurs usually about the fourteenth year, but varies between the eleventh and sixteenth year (5, 6). Its onset is accompanied by other manifestations of sexual maturity, both external (growth of pubic hair, breasts, and external genitalia) and internal (growth of ovaries, uterus, and vagina). Although normal menstruation varies, the average flow lasts three to five days and consists of 40 to 50 ml. of fluid blood mixed with cervical secretion and uterine debris. The length of the cycle varies somewhat between 27 and 31 days, the average being 28 days or one lunar month. Normally there is hardly any pain associated with menstruation. Changes in the breasts, external genitalia, uterus, and ovaries occur and are often noticed by the patient; other symptoms of a neurovascular nature are also present in some individuals. Menstruation occurs normally (except during pregnancy) from puberty to the *menopause* (climacteric, "change of life"). The menopause may be sudden, but is usually gradual, taking several months to years, and normally develops at about the age

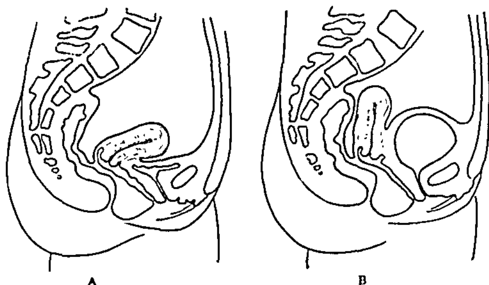

Fig. 1. Longitudinal section of the adult female pelvis. A, the normal relative positions of the various organs. B, the effect of a distended bladder.

tions, alone or in combination, and direct inspection of the cervix represent the essential minima. On special occasions other examinations are indicated. These include cystoscopic and proctoscopic study, x-ray visualization of the uterus and tubes by iodized oils, determination of their patency by injection of air, and finally, examination of urine and blood for chronic gonadotropins, which are virtually diagnostic of pregnancy (Aschheim-Zondek, Friedman, male frog tests). In some patients biopsy of cervical tissue or of endometrium (after curettage) may be necessary to arrive at a proper diagnosis.

Adult females should, if possible, be examined in the presence of a nurse or other witness whether or not the pelvis is included. *Abdominal examination* will frequently reveal much information by excluding disease outside the pelvis. However, acute pelvic inflammation often produces abdominal tenderness, rigidity, and muscle spasm which is usually bilateral but may also be located in the mid-line if an endometritis is present. A mass is rarely palpable. A full bladder is often a source of confusion and should be avoided as a possible explanation of pelvic tumor, of lower abdominal dullness, and even distention by asking the patient to void and occasionally by catherization of the bladder. Any tumor mass arising from the pelvis can be palpated abdominally after it attains a certain size (2 to 4 inches in diameter, depending on location and attachments). Thus, a pregnant uterus or large myoma can be felt as a prominent suprapubic enlargement. Ovarian cysts are often detected on examination of either or both sides of the abdomen. *Inspection of the external* genitalia will often reveal evidence of inflammation, ulcers, chancre, condyloma, cystic or other swelling, congestion, and redness about the opening of the urethra. Other abnormalities to be searched for include cystocele, rectocele, uterine prolapse, vaginal discharge, congenital malformations, and so forth. The presence of a hymen may at times be an important factor in eliminating certain types of pelvic disease.

Digital vaginal examination (Fig. 2) is ordinarily not performed during menstruation or at any time on virgins. During late pregnancy vaginal examinations are done only when necessary and with special precautions in order to avoid the danger of infection. Much information as to form and consistency of the cervix is obtainable by palpation with the tips of the fingers. The direction in which the cervix points indicates the position of the uterus; its shape and consistency is noted; tenderness on manipulation of the cervix is often significant. A soft mass or bulging behind the cervix is frequently an important indication of fluid or inflammation in the cul-de-sac. The cul-de-sac is the peri-

of 45, although great variations exist; in 68 per cent of women it occurs between the fortieth and fiftieth year. Symptoms may be absent, but are frequently severe enough to demand medical aid. Functional disturbances, such as nervousness, "hot flashes," and general irritability may hardly be classed as pathologic unless very pronounced and persistent. These functional disturbances are apt to be more severe when an *artificial menopause* has been produced by bilateral oophorectomy (excision of ovaries) and may require substitution therapy, by either oral or parenteral administration of sex hormones.

Dysmenorrhea indicates the presence of severe pain during the menstrual period. Though definitely an abnormal manifestation, it is so frequent among many otherwise normal women that the cause is often difficult to determine. In the severe cases medical aid is sought; in such patients a cause should be detected if at all possible by thorough investigation. Inflammatory, mechanical, neoplastic, neurogenic, allergic, and other factors have been described. *Amenorrhea,* or absence of menstruation, is normal before puberty, during pregnancy, and after the menopause. Otherwise, it may be due to maldevelopment, inflammatory or neoplastic disease, operations, irradiation, or ovarian dysfunction.

Oligomenorrhea, or scanty menstruation, is normal preceding menopause. *Menorrhagia* refers to an excessive amount or duration of the menstrual flow. Since individual variations are great, menorrhagia is said to be present only when a change develops which is greater than normal for the particular patient. *Metrorrhagia* indicates the presence of bleeding between menstrual periods. Although spotting may occur with ovulation, metrorrhagia is nearly always abnormal and even if slight demands investigation, particularly with the possibility of malignant disease in mind.

Normally there is a slight mucoserous discharge at the vaginal opening which keeps the parts moist. It is increased in amount during sexual excitement. It is also apt to be prominent for a few days after menstruation. When the discharge is profuse and continuous, or is of an abnormal character, it is generally an indication of inflammatory or other disease and is called *leukorrhea.* Leukorrhea usually consists of a whitish, colorless, or yellowish vaginal discharge. If brownish, the presence of blood is almost certain. Often the discharge is definitely purulent in nature or thick and mucinous. It may be profuse and cause intense irritation to the surrounding skin. *Dyspareunia* refers to painful sexual intercourse. It may be due to anatomic causes but is much more frequently due to psychic incompatibility.

Methods of Diagnosis. As a rule, gynecological diseases do not offer as much difficulty in diagnosis as many other surgical conditions, except for the group of diseases involving disturbed ovarian secretion. As in other fields, a good history and careful examination, though often neglected, are primary prerequisites for an accurate diagnosis. Special features thereof may be emphasized.

History. A good history is especially important in gynecology because the symptoms are frequently characteristic. Inquiry into the menstrual and marital history is essential and should be detailed. Urinary symptoms, such as frequency, burning, and pain on urination, are present in many gynecologic diseases. The number of complaints referable to disease of the genital organs is relatively few, but the degree of disability or the severity of the pain, especially of backache or other symptoms, may be either exaggerated or minimized. Careful evaluation of social, personal, and sexual factors is often of great significance. Care and tact are necessary in eliciting such personal information, which is often of decisive importance. It can be readily obtained by a show of interest and by the establishment of complete candor and confidence.

Examination. A routine physical examination should always include the genital tract (Fig. 1) lest the diagnosis be missed and ineffective therapy recommended. It is clear, of course, that gentleness and avoidance of pain are necessary in order to obtain as much information as possible. Judicious persistence, however, in accordance with a minimum routine, is often necessary in order to make sufficiently complete observations without which a correct diagnosis may be impossible.

Abdominal, pelvic, and rectal examina-

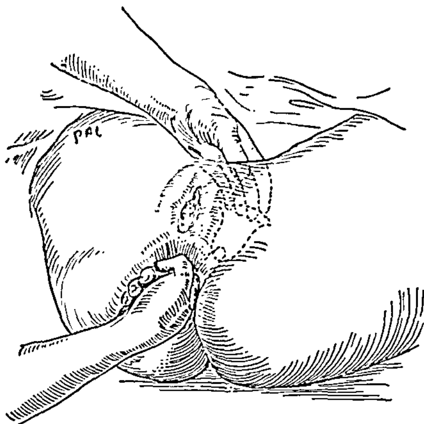

Fig. 3. Bimanual examination of the pelvis when a vaginal examination is not carried out. With the index finger in the rectum, gross abnormalities can usually be made out with a fair degree of accuracy. This method of palpating pelvic and lower abdominal structures is used in virgins and in children.

strong light to visualize the cervix (Fig. 4). The dorsal position is usually advisable. The patient is sometimes placed on her side with the knees flexed (Sims' position). In young girls and adult virgins the cervix may be visualized with a tiny speculum without injuring the hymen.

MALFORMATIONS AND MALPOSITIONS

Malformations. Defects in embryonic development produce congenital malformations of the genital tract, which though present at birth, may not produce symptoms until puberty or later during active sex life. In the external genitalia there may be enlargement of the clitoris and a rudimentary scrotum and vagina, which are characteristic of a hermaphrodite. In some cases it may be difficult to tell whether a child is male or female unless the gonads are examined histologically. Such abnormalities are extremely rare. Exstrophy of the bladder and epispadias are analogous in development to similar anomalies in the male.

Imperforate hymen produces no symptoms until puberty when menstruation begins. The uterine blood accumulates and distends the vagina (hematocolpos) which produces definite symptoms. No menstrual blood appears, but each month there occur the other manifestations of menstruation, called molimina, which consist of pelvic heaviness, engorgement of the breasts, and so forth. Since no blood can escape, the discomfort and pain in the lower abdomen becomes more and more marked as more blood accumulates, until the uterus becomes distended (hematometra) and a tender mass appears above the symphysis pubis. On examination there is no vaginal opening, but merely a distended, fluctuating membrane. Rectal examination reveals the extent of the mass. Treatment consists of adequate incision or excision of the hymen and evacuation of the old blood

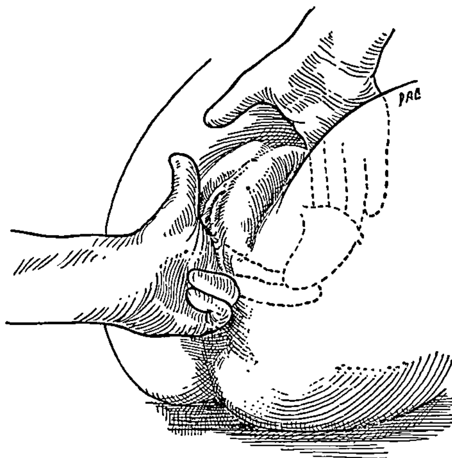

Fig. 2. Digital examination of the vagina and cervix. Note also the manner in which a bimanual palpation of the uterus, tubes and other pelvic structures may be carried out. The term pelvic examination is also applied to the bimanual technic.

toneal reflection between the posterior wall of the uterus and the anterior wall of the rectum, often called Douglas' pouch. Digital pressure over the urethra when applied from above downward may reveal on inspection a purulent discharge emerging from the urethral orifice, or from Skene's ducts.

Bimanual examination (Fig. 3) is probably the most important method of pelvic examination, because with two fingers in the vagina and the other hand on the lower abdomen, the entire pelvis can ordinarily be palpated and much information obtained. In normal sized women the tip of the examining finger reaches well up on the wall of the uterus and broad ligaments. The ovaries are usually palpable, but the tubes are not normally felt except in small, thin women. Complete relaxation of the patient is obviously necessary. For this, gentleness, cooperation, and reassurance are essential. In obese patients, satisfactory examination is often impossible. The dorsal position is usually used, but in some cases the knee-chest posture is useful. In special cases, examination under anesthesia may be indicated. The size and position of the uterus, the condition of the adnexal structure (ovaries and tubes), and the existence of masses, tenderness, and induration are especially noted.

The routine gynecologic examination should include a rectal examination. In virgins the latter is used in place of the digital vaginal examination in order to palpate the pelvis bimanually. In children especially, the entire pelvis can be palpated with great facility by bimanual rectoabdominal examination. In the later stages of pregnancy or during menstruation, a rectal replaces vaginal examination. The cervix can easily be felt through the thin rectovaginal wall.

Inspection of the cervix is very important and requires the introduction of a speculum to separate the walls of the vagina and a

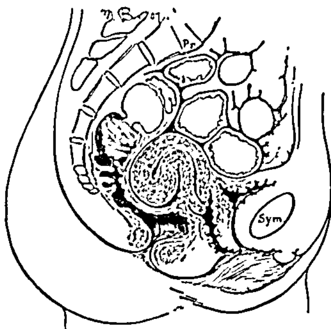

Fig. 5. Acute retroflexion of the uterus. (After Kelly.)

displacement are various and include backache, pain and discomfort in the pelvis aggravated by exercise, constipation by rectal pressure, sterility, and repeated miscarriage, particularly at the fourth month. In many cases these symptoms are due to associated lesions. Diagnosis is made by vaginal or rectal examination combined with abdominal examination (bimanual palpation).

Treatment of retrodisplacement depends on many factors, particularly its cause. In many patients in whom symptoms are not due to the malposition, no treatment may be indicated. The use of pessaries is indicated in some patients, not to correct a malposition, but to maintain the normal position which has been achieved by manual manipulation; its use, however, is contraindicated in many individuals. The operative procedures for the correction of retrodisplacement are described under treatment of childbirth injuries.

ANTEFLEXION. This is uncommon and rarely produces symptoms, except when the lumen of the uterus is kinked by the malposition. It is usually congenital. Symptoms include dysmenorrhea, especially cramplike pain during menstruation, sterility, and dyspareunia. Treatment consists of eradication of other associated lesions and of dilatation of the cervical canal to overcome the uterine stenosis. Pessaries are sometimes useful.

INJURIES OF CHILDBIRTH

Childbirth, though a normal physiologic process, is probably the most frequent cause of gynecologic disease. However, under the above heading only those will be discussed which are produced mechanically by the tearing or permanent stretching of the pelvic structures during passage of the fetus. Infections due to pregnancy are considered separately.

Relaxation and Laceration of the Perineum. The mechanical changes produced during labor vary from a simple dilatation of the vaginal opening to complete tearing of the perineum into the rectum (third degree tear). Various types of fistulas may be produced by childbirth (e.g., rectovaginal and vesicovaginal). In most patients, the external laceration is the most common injury, but is often associated with tearing of the deep pelvic muscles and fascia, particularly the levator ani, so that there is a marked weakness and relaxation of the pelvic floor (Fig. 6). Through the wide vaginal opening the posterior vaginal wall with the adjacent rectal wall may bulge (*rectocele*); the anterior wall with the adjacent urinary bladder may also protrude (*cystocele*). Frequently, the uterus itself may slip down into the dilated vagina so that the cervix presents at the out-

under scrupulous aseptic precautions to avoid infection.

Atresia of the vagina (*gynatresia*) is most commonly due to an imperforate hymen (see above), but may be due to a thin septum in the canal or to a congenital absence of more or less of the entire vagina. There is in such patients an associated malformation of uterus, tubes, and ovaries, which can often be determined by rectoabdominal examination. Many instances of atresia are acquired and are really due to a stenosis produced by injury or infection. The clinical manifestations of atresia are rarely due to hematocolpos, but usually are produced because of the associated lack of development of the uterus (amenorrhea) or because of the obstacle offered to normal sexual intercourse. Treatment depends on the local conditions present and on the problem presented by the individual case. When indicated, an epithelial lined vagina may be fashioned, utilizing skin from the adjacent thigh.

Double vagina is due to the presence of a longitudinal septum which divides the vagina into two canals. Symptoms may be absent. Dyspareunia may be produced by the lesion and interference with normal labor may occur. Division of the septum is easily per-

vious symptoms of disease ar tected accidentally, especiall nancy or during x-ray study af lipiodol. When one horn is as stenosis at the cervix, hematom due to accumulation of mens

the menopause. It is called the interposition operation and is associated with the name of Watkins.

Laceration of the Cervix. A cervical laceration is of significance only when it does not heal, leading thus to erosion of the cervical mucosa, hypertrophy, cyst formation, and ulceration, all of which are manifestations of chronic infection (chronic cervicitis). Diagnosis may be suspected on palpation but is made certain only by inspection of the cervix with a vaginal speculum. Clinically, the patient may suffer only from a profuse vaginal discharge originating in the inflamed cervix. Treatment is often indicated to relieve this leukorrhea or because the lesion suggests cancer. Moreover, chronic infections of this sort are believed to encourage the development of malignant disease. Electrocoagulation or actual excision of the diseased tissue is the most effective treatment. The latter method permits microscopic study of the tissue. Simple care, notably frequent vaginal douches and topical applications to the cervix, is sometimes effective in allowing healing to occur (see Chronic Cervicitis).

Fistula. Childbirth injury may produce a communication between the rectum and vagina (rectovaginal fistula) or between the bladder or urethra and vagina (vesicovaginal fistula). The opening may, on rare occasions, be into the uterus itself or into the cervix, rather than into the vagina. Unfortunately, these lesions sometimes occur after vaginal operations or application of radium; malignant neoplasms are occasionally the cause. The distressing lack of control of feces and urine may lead to serious invalidism. Operative repair is difficult. Though silver wire is seldom used now, its introduction by Marion Sims in the middle of the last century for the operative cure of these lesions was an important step in the development of surgical technic. Each case requires its own type of operation.

INFECTIONS

Infections of the female genital tract may be classified into four groups: those due to the gonococcus, tubercle bacillus, spirochete pallida, and the pyogenic group. The first and last mentioned organisms are the most important. The manifestations of each, however, vary according to which of the several

ig. 6. Method of demonstrating relaxed vaginal outlet. The fingers are hooked in the vagina on both
s and pulled outward and backward. Note the protrusion of the anterior vaginal wall (cystocele).
er Kelly.)

(*prolapse*). If the prolapse is extreme, so the entire uterus protrudes outside the ina (Fig. 7), which is thus really turned de out, the term *procidentia* is used. ugh prolapse and procidentia are nearly ays the result of injuries sustained during dbirth, they have been known to occur in cases in women who have not borne chil-1.

LINICAL MANIFESTATIONS. Cystocele, ocele, and prolapse are accompanied by ptoms generally described by the patient sense of "bearing down" or pelvic pres-, associated with considerable fatigue r standing or walking. Backache and drag- pain are often frequent complaints, blad- symptoms, such as frequency, burning, the like, less so. In many cases, the rated cervix may become reddened and ımed and occasionally ulcerated. In se- cases (prolapse), a satisfactory position he uterus can be maintained with difficulty all.

REATMENT. Careful supervision of the ond stage of labor, the performance of a simple episiotomy, and adequate postnatal rest and care will lessen remarkably the incidence of relaxation of the pelvic floor and its various complications. Simple therapy such as the use of pessaries, rest, vaginal douches, may lead to adequate relief of symptoms. In the severe cases, however, operation is frequently indicated and may be abdominal, vaginal, or both. Abdominal operation has as its object the support of the uterus, thus preventing its descent into the vagina. The procedures consist of shortening the round or uterosacral ligaments. These suspension operations are numerous and are associated with the names of Baldy, Webster, Crossen, and a great many others. Vaginal operations are particularly indicated for rectocele and cystocele and consist of repair of the pelvic floor (colporrhaphy) through posterior (and often anterior) vaginal incisions. Repair of the lacerated cervix is often done at the same time. Fixation of the uterus may also be achieved through the vaginal route by interposing it below the bladder and is sometimes useful in older women well past

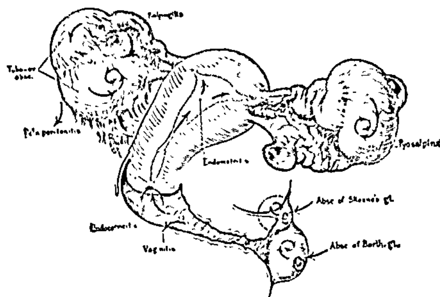

Fig. 8. Chief lesions of gonorrhea. The whorled arrows mark the common sites of infection. All lesions are those of adult women, except the vagina which is infected primarily only in childhood (juvenile vaginitis). (After Kelly.)

If a mistaken diagnosis is nevertheless made and the patient is operated upon, it is important that no operative procedures be carried out on the acutely inflamed organs in order to insure against extension of the infection. Other diseases which may offer diagnostic difficulty include tubal pregnancy, and infected dermoid cyst, and ovarian cyst with a twisted pedicle. These conditions are discussed later.

Pelvic cellulitis may be accompanied by distention, tenderness, pain in the entire abdomen, and may produce vomiting, simulating the picture of general peritonitis or intestinal obstruction. In spite of these abdominal manifestations, the absence of "toxicity" and the detection of pelvic cellulitis on palpation generally give the true clue to the diagnosis. The abdominal signs may be due to invasion of the general peritoneal cavity by the gonococcus, but are most likely due to an extension of the pelvic edema to the parietal peritoneum, or perhaps to a partial intestinal obstruction produced by adhesion of a loop of intestine to the inflammatory mass; spontaneous subsidence in a few days is the rule. On rare occasions the inflammatory mass becomes sufficiently adherent to such a loop of intestine as to produce complete occlusion.

Treatment of acute gonorrhea in the female, as in the male, has been completely revolutionized by the advent of chemotherapy, particularly penicillin (7). The sulfonamides were first used and proved fairly effective. However, the proportion of patients resistant to sulfonamide therapy has been gradually increasing ever since the introduction of these drugs. Penicillin, on the other hand, is effective against practically all strains of the gonococcus in all patients in relatively small doses, even when given in as short a period as 24 to 48 hours. In many instances 50,000 units of penicillin will completely eradicate the infection, although in most cases 100,000 to 200,000 units are necessary. This remarkable sensitivity of the gonococcus to penicillin has permitted effective treatment in many cases with a single injection. Because of the small dose required, moreover, the oral route has proved practical and relatively inexpensive. The striking and persistent sensitivity of the gonococcus to penicillin is in marked contrast to the changes in the staphylococcus. However, there are signs that even the gonococcus may be changing in that penicillin is becoming increasingly ineffective.

Complications of acute gonorrhea are generally included under the term chronic gonorrhea, although the dividing line may be difficult to draw. Complications may be en-

organs are primarily invaded. In many instances, however, all the pelvic structures are obviously the site of an infective process and the term "pelvic inflammatory disease" is used. In the acute stage, diagnosis may be easy, but when chronic infection is present, differentiation on the basis of the causative organism may be fairly difficult. Since the chronic manifestations produced by the various organisms are so similar, they will be considered together in more detail under the heading of chronic pelvic inflammation (p. 1098).

Gonorrhea. A veneral disease transmitted only by coitus (except in juvenile vaginitis), gonorrhea in the female is a prevalent disease largely because of sexual promiscuity, transmission being especially common by prostitutes. In this way innocent women are infected by their husbands who at the time of marriage consider themselves free of the disease which may have been contracted months previously. It may require six months or years after a male acquires gonorrhea before such a danger is past. Moreover, infectivity in women may last for several years. The disease in the female is serious not only because of its duration and infectivity, but also because of the frequency and ease with which it produces complete disability of the procreative and even the endocrine function of the genital organs. General disability due to chronic or recurrent infection is also common. The gonococcus, though a fragile organism, once it gains a foothold spreads rapidly, usually along the surface and between the cells of the mucous membranes; it soon reaches all the pelvic structures and sets up a severe, acute, inflammatory process. Extreme variations of severity exist. The acute manifestations usually last from one to several weeks and are followed by the chronic stage which often lasts indefinitely and is subject to recurrent exacerbations of acute nature from time to time. Fortunately the scourge of this disease has been all but eliminated by chemotherapy (see Chap. 5).

Acute Gonorrhea. Within a few days after intercourse, the disease becomes evident as a dry, burning pain in the external genitalia, followed by a yellowish vaginal discharge, frequency of, and pain and burning on, urination. These initial symptoms may be severe or may be so mild as to escape the patient's notice. The urinary symptoms are due to associated urethritis, the leukorrhea to the presence of vulvovaginitis and endocervicitis. Other lesions are frequently present or develop during the course of several days or weeks (Fig. 8). Thus, infection of the Bartholin's glands on either side of the vaginal opening often leads to abscess or cyst formation. Skene's glands, which are located on each side of the urethral meatus, are also infected and may lead to periurethral or suburethral abscesses. The inguinal lymph nodes are usually enlarged. In most patients the process sooner or later extends into the pelvis, producing an acute salpingitis or commonly an extensive inflammatory reaction of all pelvic structures. The terms pelvic cellulitis, pelvic peritonitis or acute pelvic inflammatory disease are often used to describe the extensive nature of the swelling, edema, and tenderness. Such an extension is particularly prone to develop when the infection takes place during or near the menstrual period. Of special importance to the surgeon is the fact that the lower abdominal pain, fever, and leukocytosis which accompany pelvic cellulitis may lead to a mistaken diagnosis of perforated acute appendicitis. Important in the diagnostic differentiation is the absence of toxic symptoms such as prostration, even when the fever is high. The bilateral localization of the tenderness and muscle spasm, particularly when located in the lower abdomen over the adnexal regions, is characteristic of gonorrhea. The presence of vaginal and urethral discharge is, of course, important and should be looked for. Palpation of tender masses on both sides of the pelvis on bimanual examination, and tenderness on manipulation of the cervix are nearly always noted. Occasionally, however, only one tube is affected, at least for a short time during the course of the disease. If the affected tube is on the right side, extreme difficulty in the differential diagnosis from appendicitis may be experienced. The demonstration of gonococci (intracellular, gram-negative diplococci) in stained smears of material obtained from the cervix is of obvious significance. Unlike acute appendicitis, gastrointestinal symotoms such as nausea and vomiting are generally absent.

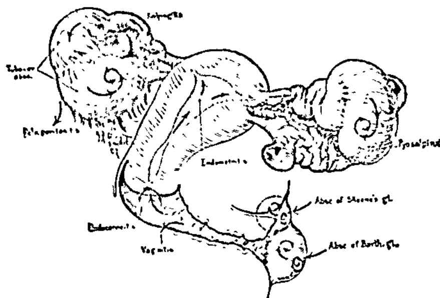

Fig. 8. Chief lesions of gonorrhea. The whorled arrows mark the common sites of infection. All lesions are those of adult women, except the vagina which is infected primarily only in childhood (juvenile vaginitis). (After Kelly.)

If a mistaken diagnosis is nevertheless made and the patient is operated upon, it is important that no operative procedures be carried out on the acutely inflamed organs in order to insure against extension of the infection. Other diseases which may offer diagnostic difficulty include tubal pregnancy, and infected dermoid cyst, and ovarian cyst with a twisted pedicle. These conditions are discussed later.

Pelvic cellulitis may be accompanied by distention, tenderness, pain in the entire abdomen, and may produce vomiting, simulating the picture of general peritonitis or intestinal obstruction. In spite of these abdominal manifestations, the absence of "toxicity" and the detection of pelvic cellulitis on palpation generally give the true clue to the diagnosis. The abdominal signs may be due to invasion of the general peritoneal cavity by the gonococcus, but are most likely due to an extension of the pelvic edema to the parietal peritoneum, or perhaps to a partial intestinal obstruction produced by adhesion of a loop of intestine to the inflammatory mass; spontaneous subsidence in a few days is the rule. On rare occasions the inflammatory mass becomes sufficiently adherent to such a loop of intestine as to produce complete occlusion.

Treatment of acute gonorrhea in the female, as in the male, has been completely revolutionized by the advent of chemotherapy, particularly penicillin (7). The sulfonamides were first used and proved fairly effective. However, the proportion of patients resistant to sulfonamide therapy has been gradually increasing ever since the introduction of these drugs. Penicillin, on the other hand, is effective against practically all strains of the gonococcus in all patients in relatively small doses, even when given in as short a period as 24 to 48 hours. This remarkable sensitivity of the gonococcus to penicillin has permitted effective treatment in many cases with a single injection. Because of the small dose required, moreover, the oral route has proved practical and relatively inexpensive. The striking and persistent sensitivity of the gonococcus to penicillin is in marked contrast to the changes in the staphylococcus. However, there are signs that even the gonococcus may be changing in that penicillin is becoming increasingly ineffective.

Complications of acute gonorrhea are generally included under the term chronic gonorrhea, although the dividing line may be difficult to draw. Complications may be en-

organs are primarily invaded. In many instances, however, all the pelvic structures are obviously the site of an infective process and the term "pelvic inflammatory disease" is used. In the acute stage, diagnosis may be easy, but when chronic infection is present, differentiation on the basis of the causative organism may be fairly difficult. Since the chronic manifestations produced by the various organisms are so similar, they will be considered together in more detail under the heading of chronic pelvic inflammation (p. 1098).

Gonorrhea. A veneral disease transmitted only by coitus (except in juvenile vaginitis), gonorrhea in the female is a prevalent disease largely because of sexual promiscuity, transmission being especially common by prostitutes. In this way innocent women are infected by their husbands who at the time of marriage consider themselves free of the disease which may have been contracted months previously. It may require six months or years after a male acquires gonorrhea before such a danger is past. Moreover, infectivity in women may last for several years. The disease in the female is serious not only because of its duration and infectivity, but also because of the frequency and ease with which it produces complete disability of the procreative and even the endocrine function of the genital organs. General disability due to chronic or recurrent infection is also common. The gonococcus, though a fragile organism, once it gains a foothold spreads rapidly, usually along the surface and between the cells of the mucous membranes; it soon reaches all the pelvic structures and sets up a severe, acute, inflammatory process. Extreme variations of severity exist. The acute manifestations usually last from one to several weeks and are followed by the chronic stage which often lasts indefinitely and is subject to recurrent exacerbations of acute nature from time to time. Fortunately the scourge of this disease has been all but eliminated by chemotherapy (see Chap. 5).

Acute Gonorrhea. Within a few days after intercourse, the disease becomes evident as a dry, burning pain in the external genitalia, followed by a yellowish vaginal discharge, frequency of, and pain and burning on, urination. These initial symptoms may be severe or may be so mild as to escape the patient's notice. The urinary symptoms are due to associated urethritis, the leukorrhea to the presence of vulvovaginitis and endocervicitis. Other lesions are frequently present or develop during the course of several days or weeks (Fig. 8). Thus, infection of the Bartholin's glands on either side of the vaginal opening often leads to abscess or cyst formation. Skene's glands, which are located on each side of the urethral meatus, are also infected and may lead to periurethral or suburethral abscesses. The inguinal lymph nodes are usually enlarged. In most patients the process sooner or later extends into the pelvis, producing an acute salpingitis or commonly an extensive inflammatory reaction of all pelvic structures. The terms pelvic cellulitis, pelvic peritonitis or acute pelvic inflammatory disease are often used to describe the extensive nature of the swelling, edema, and tenderness. Such an extension is particularly prone to develop when the infection takes place during or near the menstrual period. Of special importance to the surgeon is the fact that the lower abdominal pain, fever, and leukocytosis which accompany pelvic cellulitis may lead to a mistaken diagnosis of perforated acute appendicitis. Important in the diagnostic differentiation is the absence of toxic symptoms such as prostration, even when the fever is high. The bilateral localization of the tenderness and muscle spasm, particularly when located in the lower abdomen over the adnexal regions, is characteristic of gonorrhea. The presence of vaginal and urethral discharge is, of course, important and should be looked for. Palpation of tender masses on both sides of the pelvis on bimanual examination, and tenderness on manipulation of the cervix are nearly always noted. Occasionally, however, only one tube is affected, at least for a short time during the course of the disease. If the affected tube is on the right side, extreme difficulty in the differential diagnosis from appendicitis may be experienced. The demonstration of gonococci (intracellular, gram-negative diplococci) in stained smears of material obtained from the cervix is of obvious significance. Unlike acute appendicitis, gastrointestinal symptoms such as nausea and vomiting are generally absent.

Acute Gonorrheal Vaginitis of Children. This is a clinical entity which follows inoculation of fresh gonococci on the external genitalia, usually by contact or contamination from an infected adult or another child with the disease. It is seen most commonly among children living in squalid, unhygienic, and crowded quarters. Its contagiousness makes it an especially dangerous disease in institutions caring for large numbers of little girls. The symptoms produced are usually confined to the development of a persistent, profuse, creamy, vaginal discharge which contains the organisms and often irritates the vulva and skin of the thigh. It differs from adult gonorrhea in the absence of inguinal adenitis, gonorrheal arthritis, and the rarity of salpingitis. Occasionally, however, the abdominal signs seen in adults are produced, simulating closely the picture of general peritonitis from a ruptured appendix. These abdominal manifestations subside rapidly, however, without any special treatment and are not accompanied by the severe nausea and vomiting and prostration which are so characteristic of an *E. coli* peritonitis, and therefore offer no serious diagnostic problem, provided the vaginitis is noted.

Gonorrheal vaginitis demands isolation from other children until the discharge shows an absence of the organisms on three successive examinations. Various types of douches and antiseptics have been advocated, but it is probable that simple cleanliness is all that can be achieved by such local treatment. Chemotherapy has completely eliminated most of the older methods of therapy, including the use of estrogens. The sulfonamides were first used, but penicillin is so much more effective that it is now the method of choice.

Tuberculosis. The Fallopian tubes are most frequently the primary site and though relatively rare, it is found most commonly in younger women. It is believed to originate either as a hematogenous infection or by extension from an adjacent tuberculous peritonitis. The latter lesion was present in two thirds of the 200 cases reported from the Johns Hopkins Hospital. The uterus and ovaries are secondarily involved, but the cervix is seldom, and the vagina rarely, affected.

The *clinical manifestations* develop insidiously and vary remarkably, resembling in this respect tuberculosis of the peritoneum (see Ch. 32). Abdominal pain, fever, gastrointestinal symptoms, disturbed menstruation and urination, leukorrhea, backache, and sterility have been described as important symptoms. Bimanual examination reveals only the evidences of chronic pelvic inflammation, indistinguishable from those produced by chronic gonorrhea which, when it can be excluded, especially by the history, helps in establishing the diagnosis of tuberculosis. Often, however, the diagnosis is first made at celiotomy.

Treatment consists of general and hygienic care with plenty of good food and sunshine; surgical excision of the diseased tissue may be advisable. As in the case of tuberculous peritonitis, many patients seem to improve after celiotomy alone without drainage.

Syphilis. Syphilis produces local lesions in the female external genitalia, which are similar to the primary and secondary lesions in the male, though more often occult, because they are hidden in the vagina, and hence not easily seen without careful inspection. The chancre, inguinal adenitis, mucous patch, and condyloma latum are usually similar, but may be overshadowed by a coincident gonorrheal invasion. The vulva is, however, the site of other lesions which are not syphilitic and are discussed in this chapter. Syphilitic disease of the uterus, tubes, and ovaries is rare and of no special significance, except that the cervix is reported to be frequently the site of the chancre; however, it is probably often overlooked. Syphilis is also a common cause of spontaneous abortion.

The appearance of the local lesions, the visualization of the treponema by darkfield illumination, the manifestations of the disease elsewhere, and the Wassermann or Kahn reaction make the diagnosis.

Pyogenic Infections. Pyogenic bacteria produce a great variety of pelvic disease. By excluding the gonococcus which has already been considered, nearly all of the acute infections are of puerperal origin and follow pregnancy or abortion. Chronic inflammatory disease may follow such an acute invasion; more commonly, however, the chronic lesions develop insidiously, presumably through portals of entry created or induced by childbirth injury. Other less obvious factors also

tirely absent; occasionally the infection subsides without leaving any residual pathologic changes. More commonly, the acute invasion leaves permanent and *serious disease* as an aftermath. In some patients these after-effects seem to develop insidiously with few or slight clinical manifestations at the time of invasion. Recurrent attacks of acute infection are not uncommon during the chronic stage. Other complications such as gonorrheal arthritis are discussed elsewhere.

Chronic Gonorrhea. This term is applied to such lesions as persistent infection of the cervix (endocervicitis), a localized abscess in the uterus (pyometra) and tubes (pyosalpinx), a pelvic abscess in the pouch of Douglas, a tubo-ovarian abscess, or to extensive adhesions and scar tissue in and about the various pelvic organs. Other lesions include chronic infection of Skene's and Bartholin's glands.

Bartholin's gland abscess is obvious on inspection of a rounded tender mass in the posterior portion of the labia. Pain is severe, especially on walking. It usually demands incision and drainage to relieve pain. The pus usually fails to show gonococci. *Infection of Skene's glands* generally subsides spontaneously or responds to simple local treatment. Occasionally they form tiny abscesses which may have to be incised for adequate drainage. Excision is sometimes necessary.

Endocervicitis is diagnosed with certainty only on inspection. Swelling of the cervix with ulceration and erosion of the os are typical findings. The causative organisms, however, can rarely be found in the discharge except during the acute stage. However, the presence of a tenacious, mucopurulent exudate is said to be characteristic. It presents the same therapeutic features as chronic cervicitis due to other causes and is discussed in detail separately on page 1100.

Chronic pelvic infection due to gonococcus comprises a variety of lesions, particularly chronic salpingitis and ovaritis, and is manifested by such various symptoms as bearing down pains, especially during the menstrual periods, backache, menorrhagia, dysmenorrhea, and general malaise. The diagnosis depends on thorough physical and particularly bimanual pelvic examination. On palpation, the uterus is often in a retroverted position and adnexal masses or an abscess in the cul-de-sac are demonstrable. The findings depend on the stage and extension of the disease. Great variations exist. The entire pelvis may be the site of a solid mass of granulation tissue and adhesions, in the midst of which may be an abscess. Frequently the tubes alone are involved, either as dilated structures containing pus (pyosalpinx) or in the latter stages as sterile cysts due to the disappearance of the organisms (hydrosalpinx).

Chronic pelvic infection due to gonorrhea may be of diffuse nature and can be distinguished with difficulty from the disease produced by pyogenic infections. The latter type of infection may be quite disabling, resist conservative therapy, and thereby require surgical treatment; it is described on page 1100 with similar infections not due to the gonococcus.

The *treatment* of chronic gonorrhea is at first nonoperative except for the incision and drainage of superficial abscesses as already mentioned and consists of hot douches, rest, and general hygiene. Although penicillin has revolutionized the treatment of chronic gonorrhea just as it has the acute infection, chemotherapy cannot undo damage by the gonococcus, and this includes all of the lesions included under the term "chronic pelvic inflammation" for which operation is sometimes necessary, as discussed elsewhere. Nevertheless, bacteriologic study of tissue removed in 65 patients given adequate preoperative chemotherapy revealed no growth in all but four cases. In younger women operated on, important structures are conserved, but in older women radical excision of diseased tissue is often indicated. Cul-de-sac abscesses, though not common, are usually due to secondary infection, e.g., anaerobic streptococcus and *E. coli;* they may frequently be drained by a vaginal incision posterior to the cervix.

These chronic lesions, even when the patients have no symptoms, are still a source of infection. A large percentage of prostitutes are thus permanent carriers of gonococci which remain hidden in the various occult lesions about the cervix, vagina, and urethral glands and are difficult to detect even on careful examination. This explains the constant dissemination of the disease.

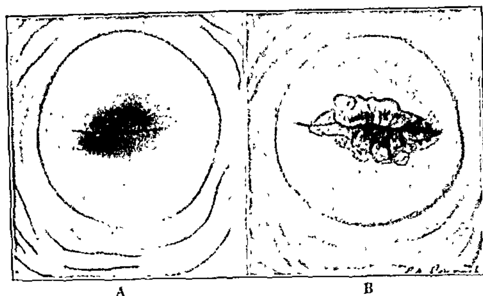

Fig. 9. Chronic cervicitis as viewed through a vaginal speculum. A, mild type, consisting of slight erosion, associated with a linear laceration. B, more severe type, consisting of definite ulceration and cyst formation. This type, if present for years, is believed to be a lesion which is a precursor of cancer.

CHRONIC PELVIC INFLAMMATORY DISEASE (CHRONIC PELVIC CELLULITIS, PARAMETRITIS). A specific diagnosis is difficult because of the variety of infective agents (gonococcus, tuberculosis, puerperal infections) and because other lesions are often confused with it, such as myoma of the uterus and other tumors, tubal pregnancy, and ovarian cysts. Moreover, the pathology is variable and may be confined to a diffuse fibrosis or induration, or it may consist of the presence of one or more abscesses, small or large, located in various parts of the pelvis. Malposition of the uterus is often associated. On pelvic examination, induration or extreme hardness is felt very low in the pelvis, especially on either side of the cervix. A mass may be made out and, if tender and fluctuant, suggests an abscess.

The *clinical manifestations* as well as the physical findings often give no clue as to the etiology. Such nonspecific symptoms as backache, pain in the lower abdomen, tenderness in the pelvis, and various menstrual disturbances are common.

Leukorrhea alone may bring the patient to the physician. The disability, however, may occasionally be severe enough to provoke rest in bed. Frequently, no symptoms are produced except that the patient comes to the doctor because of sterility. In other patients, evidence of chronic, long standing infection may be present, such as fever, emaciation, and anemia.

Differential diagnosis is of special importance in order to carry out effective therapy. There are seven diseases (modified from Crossen, 2) to be considered. 1. *Chronic endometritis* is rare except when due to polyps, abortion, functional bleeding, or malignancy. It is a cause of leukorrhea (when the cervix is normal), and of vaginal bleeding; it can often be diagnosed only by the examination of endometrial tissue obtained by curettage. The lesion is sometimes due to abnormal hyperplasia (fungous or polypoid endometritis). Treatment consists of removal of the primary lesion. 2. *Myoma of the uterus* produces symptoms of gradual onset; there is no fever or history of pelvic peritonitis; the mass is hard and not tender or fixed, and is a part of the uterus (see p. 1103). 3. *Tuberculosis* is of gradual onset and there is no history of acute infection. The presence of tuberculosis elsewhere as well as general malaise and loss of weight is often suggestive. Encysted ascites is sometimes detected. 4. *Syphilis,* though rare, is suspected when syphilis is present elsewhere and the Wassermann reaction is positive. Occasionally, gonorrhea may also be present in these patients as an associated disease. 5. *Ovarian and broad ligament tu-*

play a role; in general, therefore, chronic pyogenic infection offers a difficult problem in diagnosis, in determination of the causative organism as well as the portal of entry.

ACUTE INFECTIONS. Puerperal infections may follow either a presumably normal delivery or a criminal abortion. Before the days of chemotherapy this serious group of acute pelvic infections annually caused thousands of fatalities. They were of two types, exogenous and endogenous. The former were due to contamination, usually of *E. coli*, streptococci, and staphylococci, and represent infections which should be almost entirely avoidable. Endogenous infection, due to various types of anaerobic streptococci (Schottmueller) which the patient harbors herself, presented a more difficult problem. Even when the infection was not fatal it often resulted in complications which were the cause of serious and persistent disability. Puerperal infections are also of surgical interest because of their historical association with the development of aseptic technic (see Ch. 4) and are just as clearly due to contamination as in the time of Oliver Wendell Holmes. While the principles of aseptic technic in the prevention of infection are still basic, it must be admitted serious puerperal infection has virtually disappeared only since the advent of routine modern chemotherapy in all patients with significant postpartum fever.

When a criminal abortion leads to general septicemia, acute abdominal signs and symptoms are often mistaken for a general peritonitis from a ruptured appendix, especially since a correct history is often difficult to obtain. A foul bloody discharge, the profound toxic appearance of the patient, and evidence of extensive pelvic inflammation on bimanual palpation are usually sufficient to make the diagnosis.

CHRONIC PYOGENIC INFECTION. Even if gonorrhea is excluded, chronic infections of the genital tract in general are frequent. Although acute pelvic cellulitis of puerperal origin is often responsible, many cases result from obstetrical injury which has permitted an insidious secondary invasion. In many patients the source of infection may be difficult to determine and is entirely unrelated to puerperal infection. Invasion of this type may be classified into infection of the cervix (chronic cervicitis) and infection of the pelvis (chronic pelvic inflammatory disease).

Chronic cervicitis (*endocervicitis*) produces symptoms largely of leukorrhea which may become irritating to the patient (Fig. 9). Such symptoms as backache, dragging pelvic discomfort, and pain over the sacrum are frequently due to associated lesions, particularly chronic pelvic inflammation and various pelvic lacerations and uterine malpositions which have already been described. Regardless, however, of whether the disease has been produced by gonorrhea, unhealed lacerations, or other causes, the symptomatology, pathology, and treatment are similar.

Through the vaginal speculum the hypertrophies, erosions, or ulcerations may be shown with many cysts and polyps, particularly in the canal from which a mucopurulent discharge appears. Various terms, such as cervical catarrh, glandular endocervicitis, cystic disease, inflammatory hypertrophy, are used to describe the lesion. Chronic cervicitis especially in older women may be a precursor of cancer. The chronicity is due to the presence of the organisms deep within the mucous glands adjacent to the cervical canal and of obstruction to the glands producing cysts. In a few women, polyps are present in the cervical canal and become infected, leading to exudation which contributes to the chronic irritation. Chronic purulent discharge from deeply infected cysts also plays a similar role. Only rarely is bacteriologic study of any value since secondary invaders nearly always predominate. Even if the primary organism is present, mixed flora is therefore found.

Treatment in chronic cervicitis depends on the age of the patient and the amount of discharge and the presence of other disease. The various methods may be listed as: 1. vaginal douches, cleanliness and topical applications; 2. electrocoagulation of the diseased tissue; or 3. excision and plastic repair of the cervical canal which contains the cystic infected glands and crypts (trachelorrhaphy). One type of operation, conical excision, is usually associated with the name of Sturmdorf. More recently, excision (conization) is carried out with a cautery wire so that bleeding is minimized, and yet the coagulation is so slight that sufficient tissue is obtained for microscopic study.

months or years, and even then only when the mass is clearly the source of symptoms which have not been relieved by other care. On the other hand, if the infection has followed a pregnancy, it is often due to the streptococcus, which in general contraindicates abdominal operation, even after the lapse of some time, unless specific lesions are mechanically producing the symptoms. Careful history and study of each patient should be carried out to determine the etiologic organism if possible. In any case, the avoidance of radical pelvic operations should be emphasized, particularly in younger women in whom sufficient ovarian tissue should be preserved to maintain its endocrine function, and enough of the Fallopian tube to make pregnancy possible. For the same reason the uterus should not be removed unless absolutely necessary. Promiscuous pelvic evisceration, particularly in younger women, is to be seriously condemned; plastic operations are often sufficient to relieve symptoms. In most cases, nonoperative care is frequently satisfactory.

NEOPLASMS

Both benign and malignant tumors occur in the female genital organs, and are best classified as they affect the various organs, uterus, ovaries, Fallopian tubes, and vagina. Detailed discussion of pelvic tumors may be found in the texts already referred to.

UTERUS

Myoma is by far the most common benign tumor. (Endometriosis is described here since it may start in the uterus.) The malignant tumors are carcinoma, which is common, and chorioepithelioma and sarcoma, both of which are rare.

Myoma (Fibroid Tumor, Fibromyoma). This is the most common pelvic tumor (Fig. 11). Essentially a benign neoplasm of the smooth muscle of the uterine wall, fibromyoma nearly always contains a variable amount of fibrous tissue; hence its name. In some patients endometrial cells are found scattered through the tumor; the term adenomyoma is used in these cases (see also Endometriosis).

Myomas may be single or multiple; they are nearly always encapsulated and can be easily shelled out when in the uterine wall, where they begin their growth as interstitial or intramural myoma. Their growth is slow and progressive, requiring years before they reach an appreciable size; 20 to 30 per cent grow toward the peritoneal surface and are called subperitoneal myomas. If they grow out still farther, they may become pedunculated or even attached to other structures and lose their connection with the uterus (wandering or parasitic myoma). If the tumor grows inward toward the lumen of the uterus, it is called a submucous myoma, which also may become pedunculated; if it pushes into the broad ligament, it becomes an intraligamentary tumor. Only rarely is myoma located in the cervix. Secondary changes which may occur in large myomas are necrosis, due to inadequate blood supply, hyaline changes and liquefaction, hemorrhage into the mass, sarcomatous degeneration, infection, suppuration, and calcification. Associated effects are due to attachments with or pressure on neighboring structures. In this way the ureters may be occluded, thereby producing urinary obstruction; the vessels or nerves to the lower legs may be compressed, producing various effects; attachment by adhesions may lead to intestinal obstruction.

Clinical manifestations may be absent when the tumor is small or may be confined to menorrhagia, dysmenorrhea, and slight leukorrhea. However, bleeding may be profuse and lead to secondary anemia. As the tumor grows, pressure symptoms develop which are often indefinite at first. Bladder irritability is common. Pain is a late symptom, but pelvic discomfort and backache, particularly on exertion, is not uncommon. Some women with the complaint of sterility are found to harbor a myoma. In a great many patients, however, the myoma is first detected as a firm lower abdominal mass presenting usually just above the symphysis.

Diagnosis is made fairly easily by bimanual palpation of the pelvis. Examination should reveal not only the existence of the tumor, but also its location, extent and type. Differential diagnosis includes a normal pregnancy, cyst of the broad ligament, ovarian tumors, pelvic inflammatory disease, and malposition of the uterus. Repeated examinations at

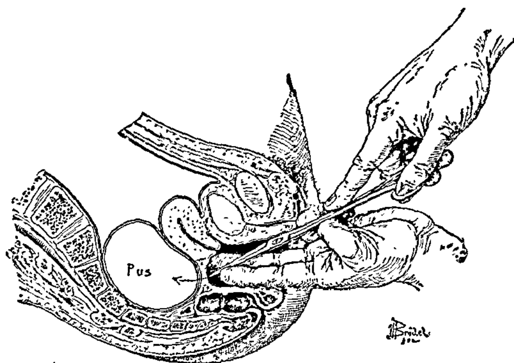

Fig. 10. Pelvic abscess; a common location in the cul-de-sac. The drawing also shows the manner by which such an abscess may be drained. (After Kelly.)

mors produce symptoms of gradual onset; there is no fever or much menstrual disturbance or history of pelvic infection. The mass is lateral and while fluctuant is not tender. 6. *Tubal pregnancy* besides its other features (see p. 1110) is associated with a positive test for pregnancy; however, this is true in only 50 per cent of cases. 7. *Other conditions,* such as chronic appendicitis and diseases of the bladder, colon, and rectum, nearly always can be excluded by the absence of tenderness and other local signs and by the manifestations characteristic of these conditions as noted elsewhere in the text.

Treatment of chronic pelvic inflammation, whatever the cause, may be either operative or nonoperative. Satisfactory relief of symptoms may be achieved by the latter, which consists of chemotherapy, psychotherapy, and other measures, such as bed rest, local applications of heat, and general hygiene, including good food, plenty of fluids, and care of fecal stasis. In some patients the presence of pus low in the pelvis, especially in the cul-de-sac, will necessitate incision and drainage through the vagina (Fig. 10).

Abdominal operation may be indicated in the presence of a tender mass obviously containing pus. Transperitoneal drainage is especially important in certain patients with puerperal infections in whom a general septicemia from absorption is feared and in whom vaginal drainage is impossible or inadequate. The danger of inducing a general peritonitis was greatly feared in the past but has all but disappeared with the use of well selected chemotherapy. On the other hand, if abdominal operation is carried out for a tubo-ovarian abscess of nonpuerperal origin, complete removal of the inflammatory mass is preferred to incision and drainage. Each patient, however, must be considered individually in making a decision as to the time for and the type of operation with special reference to the influence of chemotherapy. The indications for abdominal operation in chronic pelvic inflammation are especially difficult in the absence of clinically detectable suppuration. A few general principles may be mentioned. If the infection is due to the gonococcus, nonoperative treatment is generally advisable, especially with chemotherapy which has supplanted most of the older methods and minimized the need for operation. Operation for removal of diseased tissue is indicated only after the lapse of several

known until the brilliant observations of Sampson (9) revealed its true mechanism, at least in those implantations occurring in the ovary and pelvic peritoneum. Endometrial tissue may penetrate the wall of the uterus by direct extension (adenomyosis) or may escape through the tubes and become implanted anywhere in the pelvis or peritoneum; it may likewise spread by mechanical (operative) means, or by way of lymphatics and veins, or be displaced during embryonic life. The process of endometrial transplantation is often called endometriosis. The most frequent site of endometrioma is the ovary, but it has been found in the tubes, rectovaginal septum, rectum, sigmoid, broad ligament, round ligament, appendix, and even in the wall of the small intestine. It occurs most frequently between the age of 25 and menopause.

Clinical manifestations depend somewhat on the site of the cyst but in most cases consist of pain during and after menstruation. Atypical pain which occurs only during the menstrual period should always excite a suspicion of endometriosis, which actually is more common than is generally supposed. Other manifestations include abnormal menstruation, dyspareunia, intermenstrual abdominal pain, sterility, sacral backache, and pain in the rectum or bladder related to menstruation. Many cysts which are located on the right side are operated on with a diagnosis of acute appendicitis. Sudden rupture of the cyst into the peritoneal cavity may occur with transient collapse. Adhesions from partial rupture may produce intestinal obstruction. A correct diagnosis, however, is usually made only at operation, but even then only if the surgeon is aware of the possibility or notes the characteristic chocolate colored or bloody contents of the tumors. In some cases only on microscopic study is the true nature of the lesion revealed.

Treatment consists of excision, taking precaution to prevent further implantation. Effort should be made to preserve at least part of one ovary unless the patient is past menopause. Radium and x-ray therapy are rarely indicated.

Carcinoma of the Uterus. Uterine cancer is common formerly comprising 14 per cent of the deaths due to malignant disease. It occurs more commonly in the cervix than in the body or fundus (5:1). In the cervix it was formerly more frequent, now is less frequent than mammary cancer.

In the *cervix*, carcinoma produces ulceration and destruction of tissue, forming a fungating growth (Fig. 12) which invades by direct extension into the parametrium, and through the lymphatics into the iliac nodes, and through the blood stream to distant organs, including the lungs. There are two types, the squamous cell and the adenocarcinoma. The former arises from the vaginal portion of the cervix or the extension of the squamous epithelium just inside the external os; the latter arises from the cylindrical cells lining the glands in the cervical canal. Squamous-cell carcinoma is far more frequent (8:1).

The first and most important clinical manifestation is abnormal bleeding. The vaginal hemorrhage may be small in amount, not more than a mere "spotting," occurring between periods or it may be present as a menorrhagia. Recurrence of menstruation in women after the menopause is always suspicious and demands examination. Next in importance is leukorrhea, which may be overlooked by the patient until it becomes foul, profuse, or blood-tinged, which occurs later. As indicated above, leukorrhea is most often due to chronic cervicitis; the role of such chronic irritation in the etiology of cancer, particularly of the squamous cell type, must be considered at least in older women in whom cancer of the cervix is common. Pain and other local manifestations of malignant disease of the cervix are usually present only in the terminal stages.

Diagnosis depends upon a careful direct visualization of the cervix by means of a vaginal speculum. Lesions which are not cancer usually respond rapidly to treatment. Chronicity, persistence, and failure to heal should arouse a suspicion of cancer. However, delay in diagnosis is unjustified because an adequate biopsy is so easy and will lead to a definite diagnosis. The danger of spreading the malignant cells by biopsy is remote. Hyperplastic or deeply ulcerating lesions, particularly those which bleed easily when touched with an applicator and are associated with induration, are considered cancerous.

Fig. 11. Large globular myoma choking pelvis, compressing rectum and bladder and forcing bladder up into the abdomen. Note the retroflexion of the uterus. (After Kelly.)

reasonable intervals may furnish evidence as to the rate of growth and the development of secondary changes.

Treatment may not be necessary if the tumor is not producing symptoms. The diagnosis in these cases is usually made accidentally. However, if the tumor is in the cervix, removal is indicated for prophylactic reasons (Crossen). When the tumor is producing definite symptoms, removal by abdominal operation is the procedure of choice and is curative. Palliation for temporary relief of symptoms, or when curative procedures are refused or impossible, consists of uterine astringents (ergot, and so forth), vaginal douches which, however, are seldom effective. A thorough study has been reported by Corscaden (8), who achieved satisfactory results in over 95 per cent of a series of cases comprising 30 per cent of his patients with myoma. In general, radiotherapy may be used but only for the control of bleeding in patients at or near the menopause, when the tumor is not too large, when there is no adnexal disease. It should be emphasized, however, that in the presence of bleeding a diagnostic curettage must precede therapy in order to rule out malignancy.

Endometriosis (Endometrial Cyst). The tumor in this disease is not a neoplasm at all but a cystic swelling which forms because endometrial tissue is implanted, misplaced, or develops (by metaplasia) at various sites outside the uterus; secretions are formed at each menstrual period and may accumulate with a resultant gradual increase in size of the cyst. The bloody contents of the cyst change with time to a brownish color, giving rise to the term *chocolate cyst.* For a long time the pathogenesis of this tumor was un-

ectomy preceded and/or followed by radiotherapy with a likelihood of 70 per cent five-year survival. Excellent results have been obtained by radiotherapy alone in patients who are poor operative risks.

Chorioepithelioma (Deciduoma Malignum). A rare but exceedingly rapid-growing and fatal tumor of the uterus, it arises from the fetal cells covering the chorionic villi, and hence may occur weeks or months after normal delivery or miscarriage. It is especially likely to follow hydatidiform mole, a degenerative neoplasm related to the growth of the placenta which is well described in obstetrical texts (Williams). It produces persistent bleeding and early pain. Diagnosis is made only after curettage. Practically all chorioepitheliomas produce chorionic gonadotrophin in sufficient quantity to give a positive pregnancy test by any of the methods in routine use. Treatment is unsatisfactory where metastases are present. When the lesion is presumably confined to the uterus, hysterectomy should be done.

Sarcoma. Sarcoma of the uterus may occur spontaneously but usually forms at the site of a myoma. Rapid growth in a myoma should always suggest the development of malignant change, although sarcoma sometimes grows slowly. Diagnosis is often made only on section of the tumor. Treatment is surgical excision.

THE OVARIES

The ovaries are the site of a great variety of tumors, 95 per cent of which are cystic. A complete but brief classification is that reported by Gardner and Trout. Besides the true neoplasms (both epithelial and mesodermal) which include benign and malignant groups, retention cysts occur commonly, and teratomas uncommonly, in the ovary. Inflammatory cysts (abscesses) have already been considered under chronic pelvic inflammatory disease. The pathology and clinical course vary in each type of cyst; but there are two complications which may occur in many of them: rupture of the cyst and rotation (torsion or twisting) of the pedicle.

Simple Retention Cysts. These nonproliferating cysts comprise a variety of types. Among them are Graafian follicle cyst (due to failure of the follicle to rupture), corpus luteum cyst (due to failure of normal luteal absorption), and tubo-ovarian cyst (union of ovarian cyst and tube, usually of inflammatory origin). These cysts are small, rarely larger than an egg, and produce no special symptoms, except, on occasion, abnormal bleeding. They are noted during celiotomy most commonly, and are frequently resected, leaving as much normal tissue as possible.

Cystadenoma (Ovarian Cyst, Proliferating Cyst). Cystadenoma represents a benign epithelial neoplasm which is the most common of the true ovarian tumors. There are several types. The small unilocular type is called simple serous cystoma, which is rarely larger than an infant's head. The larger multilocular type is called pseudomucinous cystadenoma and represents the classical ovarian tumor whose removal really established gynecology as a specialty and paved the way for other abdominal operations. Many cysts contain proliferating epithelial masses, and represent a special group which are called papillary tumors or papillomata. Some are pedunculated; a few are located in the broad ligament. Paraovarian cysts originate in the tubular remains of the embryonic Wolffian body and account for 10 per cent of excised cystic tumors of the ovary. Most cysts of the broad ligament are paraovarian in origin. The pathology of the various tumors is fairly complex and a great many variations have been described. Many grow to a large size if untreated, because of the accumulation of serous or pseudomucinous fluid within the cystic areas. They occur at any age but are most common between the twentieth and fiftieth year. The small serous cysts are usually bilateral.

Clinical manifestations consist of mild symptoms of pelvic discomfort which brings the patient to the doctor for examination. The small serous cyst may remain stationary and silent; the proliferating cysts grow slowly, usually taking several years to reach an appreciable size, but never cease growing. In the late stages the large amount of fluid contained in the cyst may be mistaken for ascites (Fig. 13). The growth of the tumor may simulate a normal pregnancy since menstrual disturbances are not infrequent. Bimanual pelvic examination usually suffices to make the diagnosis. The pedunculated cysts, how-

Fig. 12. Squamous cell carcinoma of the cervix. Photograph of the view obtained by retracing the vaginal walls. The cervix is entirely replaced by malignant disease. The patient, aged 32, had had leukorrhea for some time but only for a few months had it become, first brownish, and later red, in color. Biopsy confirmed the clinical diagnosis. Radiotherapy was instituted with satisfactory conversion of the diseased tissue to extensive scar. Complete destruction of the tumor, however, was probably not achieved. (St. Louis City Hospital.)

Examination of the vaginal smear for malignant cells is becoming popular because of its simplicity and promises to yield earlier diagnoses. However, suspicious smears must be confirmed by a biopsy before a positive diagnosis is made.

Radical excision (panhysterectomy) was formerly the recommended procedure but was abandoned because of the high mortality *and because radiotherapy proved so effective.* Extensive resection was reintroduced because it is now followed by a low operative mortality. Recent study indicates that properly used radiotherapy still achieves as good results. The percentage of five-year cures varies between 70 per cent in the very early cases to 50 per cent in the slightly advanced cases. Radical surgery (pelvic evisceration) is now reserved for the few patients who do not respond to, or recur after, radiotherapy. Since cervical cancer tends to remain localized, such a sequence is justified.

In the *body of the uterus,* adenocarcinoma is fairly common. At or before the menopause cervical carcinoma is more frequent, but after the cessation of menstruation the incidence is about equally divided. Any vaginal bleeding after the menopause is always suggestive of malignant disease of the uterus. Diagnosis, *however, depends on microscopic* examination of tissue obtained by curettage. In the presence of a normal cervix (myoma and periuterine disease being excluded by palpation), chronic endometritis may produce bleeding and discharge which may be mistaken for carcinoma. This lesion, however, responds rapidly to conservative treatment in most cases. If bleeding persists, curettage should be performed for the purpose of diagnosis. Treatment consists of complete hyster-

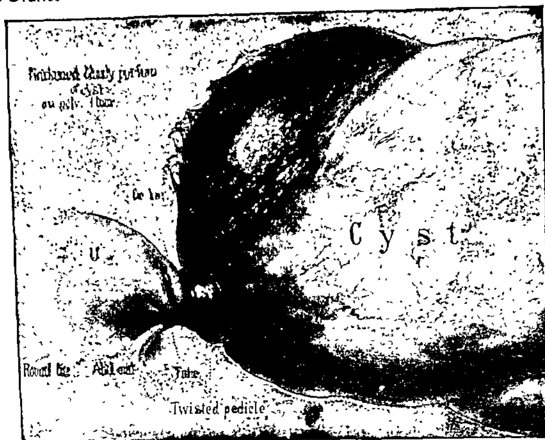

Fig. 14. Acute torsion of an ovarian cyst. The pedicle includes also the uterine tube, ovarian and round ligaments. (After Kelly.)

sected, all of the remaining normal ovary should be left, particularly in younger individuals.

Dermoid Cysts. Dermoid cysts may produce symptoms similar to those already mentioned but are quite different pathologically. They occur at any age and are in reality *teratomas* in which the skin elements predominate. They are more likely to become infected than other cysts and being more adherent are often more difficult to excise. They seldom undergo malignant change. Treatment consists of excision of the tumor, preserving ovarian tissue if possible.

Solid Tumors. Solid tumors of the ovary are somewhat rare, comprising but 5 per cent of all neoplastic diseases of the ovary which come to operation (Crossen). The benign growths are the *fibroma* and *myoma*, which are usually small and are diagnosed only at operation or by microscopic section. *Granulosa cell tumors*, because of their endocrine effects, are discussed in Chapter 39.

Carcinoma of the ovaries may rarely develop as a primary solid tumor, usually of the medullary type. Most frequent is the carcinoma which forms in a cystadenoma possessing papillary ingrowths. This type is called malignant papillary cyst and presents the same clinical manifestations as a cystic tumor of the ovary. The true diagnosis is often made only on microscopic study of the excised cyst. A third group comprises tumors which occur in both ovaries, but which are secondary to cancer elsewhere in the peritoneal cavity, most commonly the stomach or colon. When they assume a scirrhous form, they are associated with the name of Krukenberg. Sarcoma has also been observed in the ovary and is important in children, in that it comprises nearly one half of ovarian neoplasms in early life.

Early diagnosis in malignant disease of the ovaries is nearly always difficult, if not impossible, on clinical grounds alone, unless operation is performed, at which time the

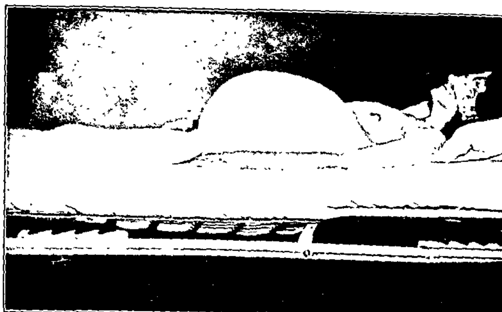

Fig. 13. Ovarian cyst. Note the characteristic manner in which the swelling rises sharply symphysis; this is not true of abdominal distention and ascites. The patient, a 48-year-old eight months previously, noted a small tumor just above the pubis; it grew steadily to its pr Edema of the feet and ankles developed more recently. At operation a large cystadenoma of th cular pseudomucinous type was removed as well as a myomatous uterus and the opposite ad covery was uneventful. (Gynecological Service, Barnes Hospital.)

ever, are so freely movable that their origin from the pelvis may be difficult to demonstrate except at operation. On rare occasions gradual rupture of a cyst may result in adhesions to neighboring structures. An acute abdominal emergency may be precipitated by sudden rupture; more commonly such a picture is due to *torsion of the pedicle,* which is more common in the smaller cysts, including the retention and simple serous cysts. Severe lower abdominal pain, nausea, vomiting, and leukocytosis follow provided the twist is sufficient to interfere with the blood supply. If gangrene occurs, the patient may become prostrated and go into shock. In a few instances the twisted pedicle involves the gut, producing the manifestations of acute intestinal obstruction. The palpation of the mass may be sufficient to make the diagnosis.

Differential diagnosis in the small ovarian cysts includes consideration of tubal swellings which are due to inflammatory disease (salpingitis, pyo- and hydro-salpinx), tubal pregnancy, myoma, retroverted pregnant uterus, and broad ligament cyst. In the larger cysts, such conditions as abdominal distention (paralytic ileus), obesity, ascites, pregnancy, degenerated cystic myoma, and ab tumors (hydronephrosis, hydrops of bladder, and so forth) are to be cor Ascites, however, is often associat malignant ovarian tumors which scribed on page 1109. In a few c nature of the tumor will not be rec until laparotomy.

When acute torsion of the pedicl ovarian cyst occurs (Fig. 14), the dif diagnosis demands consideration of a pendicitis, rupture of ovarian cyst or p renal or gallstone colic, acute intesti struction with strangulation, ruptured pregnancy, mesenteric thrombosis, deed all of the other acute abdominal already discussed elsewhere (see Ch. 3

Treatment of ovarian cyst is urgen torsion of the pedicle or acute rupture and it consists of immediate celiotom excision of the tumor. Under ordina cumstances removal of the smaller c cysts is indicated in order to prevent growth or torsion and because of the of malignant regeneration. The small bi cysts which produce little or no sym rarely justify operation, but if they a

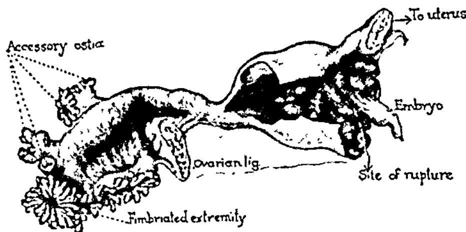

Fig. 15. Ectopic (tubal) pregnancy; specimen removed at operation. Inside the ruptured blood clot, the tiny embryo could be made out on careful gross inspection. The patient, aged 15, was suddenly seized with acute abdominal pain in the right lower quadrant, 30 hours before admission. The pain remained severe and was referred to the upper abdomen and under the shoulder blades; prostration, shock and pallor developed rapidly. The erythrocyte count was 1,500,000. At operation the peritoneal cavity contained a great deal of clotted blood.

infrequently, rupture into the peritoneal cavity produces a sudden intraabdominal hemorrhage with collapse and manifestations of surgical shock. If the patient recovers, or the bleeding is slow, a marked secondary anemia develops. It is rare for ectopic pregnancy to proceed to term without rupture, but when this occurs, it is usually an abdominal pregnancy.

Clinical Manifestations. Before rupture occurs, the patient may be asymptomatic, or note only the signs and symptoms of early pregnancy, i.e., amenorrhea, slight pelvic pain, increasing nausea, pain in the breasts, or general malaise. In some patients there will be a history of previous pelvic inflammatory disease. Bimanual examination will often be diagnostic, not only in detecting a mass, but also in revealing a soft, succulent cervix and a uterus which is slightly enlarged. However, because of the paucity of symptoms, it is rare for a patient to consult a physician with an unruptured tubal pregnancy. In most instances acute rupture of the growing ovum produces sudden and severe manifestations which are the first indication of disease; the diagnostic accuracy of a pregnancy test is unfortunately of little practical value in such cases because it requires too much time to carry out when an immediate diagnosis is necessary.

Acute rupture often follows exertion, but may be spontaneous. The clinical manifestations in the severe cases are of dramatic suddenness, the patient falling to the ground in profound collapse. Unlike the collapse following rupture of a peptic ulcer, there is evidence of circulatory shock of the type due to severe hemorrhage. The pulse is rapid and weak, the blood pressure low, the extremities are cold and moist, the skin extremely pale, and air hunger is present. Nausea and vomiting are frequent because of the peritoneal stimulation by the blood. The abdomen is tender to palpation and may be distended with fluid. Pain is, of course, severe, but usually unilateral. Pelvic examination reveals the presence of a bulging, boggy mass in the cul-de-sac; an adnexal tumor may also be palpable. A bloody vaginal discharge is often present. Aspiration of pure blood from the cul-de-sac is often of considerable diagnostic aid.

The patient may recover rapidly from the initial collapse because of cessation of bleeding and efficient encapsulation of the blood clot. In many patients recovery is slow and accompanied by signs of marked secondary anemia. Occasionally there may be no acute manifestations of rupture, the patient gradually becoming weaker and more anemic. The pregnancy test is of especial value in this type of patient, provided that the fetus is still viable.

true nature of the tumor can often be ascertained by gross inspection. Frequently, however, the existence of malignant disease becomes evident only after study of the microscopic sections, especially in the case of cystic tumors which have become malignant. In the late cases the presence of severe pain, extensive masses, or ascites is frequently noted. Treatment consists of excision; radiotherapy is also used, especially in the form of colloidal gold left in the peritoneal cavity in extensive disease.

THE FALLOPIAN TUBES

Tumors in this location are exceedingly rare and are usually mistaken for the various neoplasms which originate in the ovaries, uterus, or broad ligaments. The small cysts or hydatids of Morgagni are seen at the fimbriated end of the tube but have no clinical significance.

THE VAGINA

Solid tumors are so rare as to require no special consideration. Malignant disease is usually secondary to that of the cervix, although primary carcinoma occurs, usually on the posterior wall. Squamous cell carcinoma is seen in the vulva (see p. 1115). Cystic tumors are not so rare and comprise epithelial inclusion (epidermoid) cysts which form in the scar following lacerations or perineal operations; cysts arising in the glands of the vaginal wall which are rare; congenital cysts due to embryonic inclusions, which are likewise uncommon. Bartholin's gland cyst at the vaginal outlet is not infrequent and is described under diseases of the vulva.

MISCELLANEOUS CONDITIONS

Normal Pregnancy. Normal pregnancy not infrequently simulates acute abdominal disease. In some instances the patient may not herself be aware of the true diagnosis; in a few women, such knowledge is withheld in the hope that an operation may be performed which will result in abortion. Abdominal pain, vomiting, local tenderness, muscle spasm, and leukocytosis may lead to a diagnosis of acute appendicitis. Even if the history is unreliable, bimanual examination will rarely fail to establish the true state of affairs.

If the diagnosis is not urgent, any doubt may be dispelled by the Aschheim-Zondek test which consists of the injection of the patient's urine (or blood) into a young immature female rat, which is killed 18 to 48 hours afterwards. If the patient is pregnant, characteristic changes will be seen in the ovaries. In the Friedman test, a modified Aschheim-Zondek procedure, a rabbit is utilized. The male frog test is also useful (Haskins, 10). The test is positive even in the early weeks of pregnancy. A negative test (especially when repeated) rules out pregnancy in 85 per cent of cases.

The coexistence of a normal pregnancy with other surgical disease may present problems particularly in the case of suspected intraabdominal disease. In general, the pregnancy is no contraindication to needed operation provided adequate care is taken to minimize a miscarriage. In the case of carcinoma of the breast, other considerations apply.

Ectopic (Extra-Uterine) Pregnancy. When a fertilized ovum lodges and grows outside the uterine cavity, the patient suffers from an ectopic pregnancy (Fig. 15) which obviously cannot result in a normal delivery. In nearly every instance serious symptoms develop within a few weeks or months after conception because of local bleeding which arises from erosion of the vessels by the trophoblast or from rupture of the tube due to distention. The hemorrhage may be either sudden and profuse, slow and persistent, or encapsulated. The ovum is most commonly lodged in the Fallopian tube (tubal pregnancy) but may develop in the peritoneal cavity (abdominal pregnancy) or in the broad ligament. The etiology of ectopic pregnancy is nearly always a mechanical interference with the passage of the fertilized ovum through the tube into the uterus. Inflammatory adhesions are often thought to be the most common cause, though careful work has shown that various malformations (diverticula) play the most important role. The pathology varies with the location of the fetus as well as its viability. When the mass ruptures but remains encapsulated in the tube, the sudden symptoms will subside, and a local mass will form (tubal abortion). A localized hematoma in the broad ligament or cul-de-sac or a tubo-ovarian hematoma may form in a similar manner. Not

"motor of the ovary." A delicate balance exists between the hormones of the ovary and pituitary which is described below. Other endocrine glands, such as the thyroid and adrenal, also exert important, though lesser, influences on the ovary and pituitary. Indeed, there is growing evidence that a balance exists between many if not all endocrine glands —an interesting general phenomenon which is made still more complicated by the influences exerted on them by the autonomic nervous system.

The cyclic production of ovarian hormones, controlled in turn by the pituitary, is responsible for the periodic changes in the uterus and breast. The mechanism is somewhat complicated but fairly well understood. Before explaining this mechanism, it may be useful to enumerate a few of the hormones, many of which have been isolated in crystalline form and, indeed, synthesized. The pituitary hormones affecting the ovary are a follicle-stimulating hormone (FSH), a luteinizing hormone (LH), and luteotropin (probably the same as lactogenic hormone), which maintains the functional state of the corpus luteum. The ovaries produce two hormones, one group called estrogens, which originate from the Graafian follicles and the corpus luteum, the other progesterone, which originates in the corpus luteum alone. Progesterone (formerly called progestin) was first isolated in pure crystalline form in 1934 by Wintersteiner and Allen (11). The important part of the mechanism of these two groups of hormones, as far as their cyclic behavior is concerned, is the reciprocal relationship they bear to each other by which the pituitary stimulates the ovary to produce hormones which in turn inhibit the pituitary, thus setting at rest (for a while) the stimulus to ovarian activity. The consequent fall in the production of ovarian hormones then removes the inhibition from the pituitary, which begins to act again; the ovary is then stimulated, completing the cycle.

The cyclic changes in the uterus and breast are, therefore, due to the periodic increase and decrease of the ovarian hormones, governed in turn by the reciprocal stimulation and suppression of pituitary activity. Of the changes in the uterus, vascularization and hyperplasia are stimulated by the estrogens whereas secretion of the uterine glands is due to the presence of progesterone. These changes cease with the fall in the hormone concentration, which also corresponds with the appearance of the menstrual flow; the onset of menstruation has been shown to coincide with the diminution of the ovarian hormones. The ebb and flow of the ovarian and pituitary hormones thus accounts for the regular cycles which occur in normal females. It is obvious that with this cycle, the hyperplastic changes in the uterus and breast are succeeded by involution or regression back to the resting stage. In the breast, absence of this regression or hypoplasia may result in a nodular condition of the parenchyma, usually called chronic cystic mastitis (see Ch. 35). When pregnancy occurs, the cycle is temporarily upset and under these conditions the large amounts of gonadotropic hormone are produced by the placenta. This hormone is called human chorionic gonadotrophin (HCG). This secretion begins soon after conception and makes possible the early detection of pregnancy by injecting blood or urine into laboratory animals. Many such tests for pregnancy are in general use. Some tests utilize the effect of chorionic gonadotrophin on the ovaries of rodents (Aschheim-Zondek), others the effects in the ovaries of rabbits (Friedman), and still others the capacity of this hormone to induce ovulation or to release sperm in amphibians (*Xenopus laevis* test; male frog test). As pregnancy proceeds, the amount of chorionic gonadotrophin rapidly increases, reaching a maximum at about two months of pregnancy. The amount then decreases but remains sufficiently great to give a positive test throughout pregnancy.

The difficulties in applying this knowledge to gynecologic disturbances are due not only to the number of hormones involved, but particularly to their balanced relationship. Thus we may consider not only the effects of overactivity and underactivity of the ovaries, but also an imbalance between the pituitary and ovaries. These factors make diagnosis more difficult. Therapy is complicated, too, by the delicacy of the threshold for these hormones; a certain dose will produce one effect whereas a larger dose quite a different one, dependent partly upon the stage of the cycle in which they are given, but also on other factors, such

Differential diagnosis in acute rupture rests between the following five diseases. 1. Perforated peptic ulcer, which is extremely rare in women and is not accompanied by circulatory shock. 2. Abortion has a similar history, but the pain which consists of intermittent cramps is localized to the region of the uterus and gradually increases in intensity. Vaginal bleeding may be present in either abortion or ectopic pregnancy, but is much more profuse in the former condition. Pelvic examination is obviously important. 3. Acute exacerbation of chronic salpingitis is accompanied by little or no prostration and no circulatory collapse; the pain is usually bilateral. 4. Acute appendicitis is accompanied by no pelvic signs and produces characteristic gastrointestinal symptoms and signs. 5. Torsion of an ovarian cyst is apt to be confusing, but the history is different; there is no anemia, and pelvic examination reveals a normal cervix and uterus, as well as the location of the mass, which is higher in the pelvis than is an ectopic pregnancy.

TREATMENT. Patients with an unruptured tubal pregnancy should be subjected to celiotomy and the mass excised. In this way the almost certain danger of rupture is avoided. When rupture has resulted in an encapsulated hematoma, further bleeding may stop provided the embryo has ceased growing. Even so, operation is usually necessary in order to remove the placenta and other tissue so as to prevent hemorrhage later. In the acute cases operation is an urgent emergency in order to prevent death from shock. Treatment of the shock is carried out at once and is continued during and after the operation; the intraperitoneal blood may be used as soon as it is obtained (autotransfusion), provided, of course, it is not clotted. The most difficult cases technically are those in which the placenta is attached to the peritoneum rather than to the tube. However, it is advisable and usually possible to conserve the ovary on the affected side.

ENDOCRINE DISTURBANCES

The most important advance in gynecology in recent years has been the investigations of the hormones which govern the activities of the genital organs. These studies, which were to a large extent initiated by Born, Fraenkel and Leo Loeb, and recently developed by Edgar Allen, Willard Allen, Doisy, Corner, Evans and others, have explained much regarding the mechanism of menstruation and the changes following conception and pregnancy. Moreover, it is now recognized that many conditions, previously ill understood or attributed to organic disease and uterine malposition, are in reality due to endocrine disturbances. Many of these patients with endocrine deficiencies can be satisfactorily treated by administering the hormone which is absent. Diagnosis is obviously important but extremely difficult in most instances. Direct analysis of blood or urine to determine the amount of hormones is possible but laborious. There is no test as simple as the basal metabolism test which determines the presence of hypofunction and hyperfunction of the thyroid. Great strides in the identification of conditions caused by ovarian dysfunction will no doubt be made within the next few years. The clinical evidences of abnormal endocrine function are only partly useful. The menstrual flow itself is only one manifestation of ovarian hormone activity. Changes in the endometrium are useful but are detectable only by curettage. In the mammary gland, endocrine effects can be determined only to a slight extent by palpation; accurately, only by biopsy. Thus, much of the status of our knowledge of endocrine disturbances is incomplete and complicated, because of intrinsic difficulties in measuring their clinical manifestations. A few general principles, however, have been established, and these will be briefly described. Further details may be found in publications by others (6). The chapter on endocrines in this volume should also be consulted.

As the female gonad, the ovary has two functions, the maturation of the germ or ovum (ovulation) and the production of hormones. The latter function is responsible for the development of secondary sex characteristics and governs the periodic changes in the uterus (menstruation), in the mammary glands and other organs. This periodicity (roughly 28 days) is one of the important features of ovarian activity. The stimulus to the ovary is the presence of gonadotropic hormones produced periodically by the pituitary which is thus often referred to as the

ciently large amounts, and this is now possible by giving them in relatively pure form. In treating menopausal symptoms the estrogens are most useful and are widely employed. Stilbesterol, a new compound, synthesized by Dodds and his co-workers, has also been found to exert therapeutic estrogenic effects.

Functional Uterine Bleeding. Abnormal bleeding from the endometrium, due to disturbances in ovarian function, occurs frequently during adolescence and the climacteric. The bleeding may be prolonged and profuse. The endometrium usually shows no progestational change. In most instances the ovaries contain numerous Graafian follicles but no corpora lutea, indicating that the abnormal bleeding is associated with a failure of regular periodic ovulation and corpus luteum formation. The bleeding, which is almost invariably painless, especially in young individuals, can be interrupted and the cycle restored to normal by the use of progesterone. On rare occasions, excessive production of estrin may be due to *granulosa cell tumors* of the ovary which is discussed on page 1084.

DISEASES OF THE VULVA AND VAGINA

The vagina and vulva are the site of disease which should offer no diagnostic difficulty, chiefly because the lesions are external and are easily examined by direct inspection. Many have already been considered in detail.

Vulvovaginitis. Primary inflammation is rare, secondary lesions frequent. Redness of the external genitalia, edema, pain, and heat are similar to the cardinal signs of acute inflammation anywhere in the body, although the signs are more superficial, rarely involving the deeper structures. Pain and burning, when present, are usually aggravated by walking. Such manifestations may indicate the onset of a *gonorrheal infection* as already described. The inflammation is due to invasion by the gonococcus only in the primary stages of the disease; in the later stages the irritant vaginal discharge which originates in most instances not from the vagina but from the cervix is responsible. Indeed, any irritating vaginal discharge, whether of gonorrheal origin or not, leads to vulvitis. In some cases, irritating urine is apt to be an important cause. Vulvitis may also be secondary to other factors, such as pediculosis, masturbation, chafing, or uncleanliness. Skin lesions of various sorts may be present in the external genitalia and set up an acute inflammatory reaction; some are secondary to the acute exanthemata. Treatment consists of local care, but particularly removal of the cause.

Simple vaginitis describes a primary inflammation of the vaginal mucosa and is actually a rather rare disease. Inspection reveals the reddened, inflamed vaginal wall; the etiology may be apparent, such as an injury, a foreign body, or irritating douches. When a flagellated protozoa (*Trichomonas vaginalis*) has been found in the discharge, the term *trichomonas vaginitis* is used. The etiologic role of this organism has not been scientifically established; while many observers attribute to it a primary etiologic importance, others claim that it is a secondary invader. The vaginal discharge in these cases is particularly profuse and is thin and watery in character. Various forms of local therapy (cleanliness, vaginal douches, antiseptics) are advocated; chemotherapy is effective, although persistence and a long period of time are necessary before the organism can be permanently eradicated. As in every disease, the exciting factor in the production of the lesion should be searched for and eradicated when possible.

In older women the vagina becomes atrophic. Occasionally the walls adhere to each other; the term adhesive vaginitis is applied to this condition.

Injuries. Trauma due to childbirth has already been described. In the vulva, lacerations are nearly always located in the perineal body or located in the posterior part of the vaginal outlet. Other injuries are encountered following rape or from penetrating or lacerating wounds which children sustain in climbing trees and fences. They present the same problems of treatment as wounds sustained in other parts of the body.

Ulcers. Ulcers are found in and about the vulva just as they are elsewhere and present a similar and often a complicated diagnostic problem, except that significant circulatory factors are generally absent. *Simple ulcers* are usually due to trauma or pyogenic infection, and heal rapidly on removal of any irri-

as their effect on the activity of other organs. By analyzing the urine and blood for the content of ovarian and pituitary hormones over a long period of time, Frank and his coworkers have produced evidence of overfunctions and underfunction of the ovaries which seems of definite value in correlation with the clinical symptoms present.

Ovarian Underfunction. Ovarian function may be reduced by x-ray or radium therapy to the pelvis or by diseases such as chronic infections or undernutrition. It may likewise be due to congenital underdevelopment. Ovarian activity is abolished, of course, after surgical extirpation (artificial menopause) and normally tapers off during the normal menopause. Underfunction may be due to primary pituitary disease. The important clinical manifestations of ovarian underfunction are sterility (including certain types of miscarriage), amenorrhea (including oligomenorrhea), dysmenorrhea, and the menopause.

STERILITY. Underfunction of the ovulating mechanism may be responsible for sterility in that mature ova are not produced; if produced, they may not be discharged because of failure of the Graafian follicle to rupture. These patients may present no other clinical evidence of underfunction and menstruation may be normal. Hypofunction of the thyroid may be the cause of insufficient pituitary stimulation; the latter, however, is difficult if not impossible to determine.

In 50 per cent of sterile matings, defects in the male are responsible. Thus all factors must be considered and evaluated by thorough study, before diagnosis and treatment are possible. In many cases, sterility is less a complaint than miscarriage which may be due to progesterone deficiency readily corrected by daily administration of the hormone. Since the placenta produces considerable quantities of progesterone after the third month, such therapy is not necessary after this time.

DYSMENORRHEA. Irregular, especially painful menstruation may be produced by any of several causes. Stenosis of the cervix and malposition of the uterus are important factors. In other instances it may be due to ovarian underfunction; if this is definitely determined, treatment with the missing hormone, ovarian, or pituitary, is indicated. Dysmenorrhea, however, may be present with excessive menstruation which is usually considered to be due to abnormal function of the ovaries (see below). In a number of patients with dysmenorrhea the etiologic factor has been allergic; relief has followed elimination of substances to which the patient is sensitive.

AMENORRHEA. Failure of menstruation is a symptom which, in itself, should produce no disability. It occurs normally during pregnancy and in many nonpregnant women, without interfering with general health. Similarly, oligomenorrhea or scanty menstruation may be present without clinical significance unless the patient is concerned about it psychologically; in sterility, of course, it assumes considerable importance. Amenorrhea may be due to ovarian insufficiency of ovarian origin (maldevelopment), debilitating systemic disease, or to the absence of pituitary hormone; however, other causes, inflammatory, neoplastic, and operative (hysterectomy), must obviously be excluded before a diagnosis of endocrinopathy can be considered. Treatment depends upon the cause, detection of which should be established, if possible, by thorough study. Clinical manifestations of ovarian activity, occurring in spite of complete amenorrhea, are grouped together and called *molimina;* they consist of engorgement of the breasts, pelvic heaviness, and periodic leukorrhea. Evidence of the cyclic production of ovarian hormones has been found in these patients.

Amenorrhea at the menopause may lead to disturbing symptoms, especially when an artificial menopause has been tragically and often needlessly produced in young women by gynecologic *furor operativus*. These clinical manifestations consist of a variety of neurovascular, psychic, and other disturbances which are frequently severe enough to demand therapy. True substitution organotherapy was attempted decades ago by H. A. Kelly, who gave such unfortunate young women sandwiches spread with minced hog ovaries obtained from an abbatoir close to the Johns Hopkins Hospital. It is now known, of course, that such attempts at replacement therapy were entirely useless because the dose was completely inadequate. To be effective, ovarian hormones must be given in suffi-

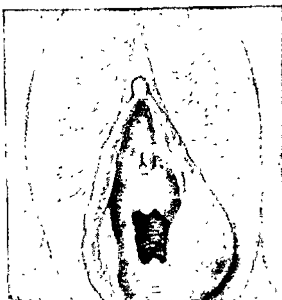

Fig. 17. Bartholin's gland abscess. Note the characteristic location. The patient, a 23-year-old housemaid, contracted gonorrhea several weeks previously, but suffered very little disability until severe pain, aggravated by walking, developed with the appearance of a tender mass in her vulva several days before. Incision and drainage resulted in immediate relief; the causative organisms were found in the pus

of the vulva is thus advisable in all cases of leukoplakia or kraurosis in order to eradicate the lesion before it undergoes malignant change (Taussig). Treatment of the lesion when definitely carcinomatous should include excision of the regional lymph nodes, as well as radiotherapy.

Cysts are nearly always confined to Bartholin's glands which are located on either side, just inside the posterior portion of the labia (Fig. 17). Bartholin's glands normally produce a mucoid secretion which lubricates the inner labial surfaces; they are not infrequently the site of infection, forming abscesses which produce the usual acute manifestations and often require incision or open spontaneously. These abscesses are nearly always associated with acute gonorrheal infections. If the opening of one of Bartholin's glands becomes occluded because of inflammation, or if an acute abscess subsides without drainage, a Bartholin cyst may develop. Such a tumor is rarely of large size but may cause sufficient discomfort to demand excision.

A soft swelling which is present in the labia may really be due to a *pudendal hernia* or to a hydrocele of the canal of Nuck. These lesions have been described elsewhere (see Ch. 34). Swellings due to varicose veins are also seen, particularly during pregnancy.

Pruritus Vulvae. The severity varies greatly, but may become a serious cause of disability. Detection of the cause is obviously important, and a thorough history and physical examination is a *sine qua non*. Pruritus is not a disease, but only a manifestation of a disease, the nature of which may require much study before it is detected. In many patients, the cause will be found in the presence of irritating vaginal discharge or of irritating urine, *especially in diabetics*. *Skin diseases* of various types, such as eczema, leukoplakia, or kraurosis may be present. Lack of cleanliness, foreign bodies, fungus infection, and many other factors are sometimes of importance. Psychogenic factors may be prominent. Treatment consists of the eradication of the cause and the application of soothing lotions and cleanliness; fungicides may be indicated in some cases.

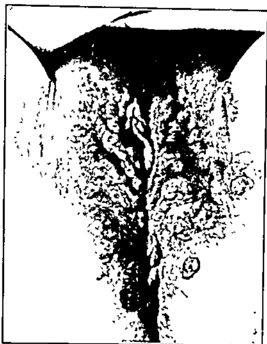

Fig. 16. Condyloma latum. Secondary luetic lesions of five weeks' duration, around the vulva, in a 35-year-old housewife followed a definite history of exposure; severe itching was the only complaint. The Wassermann reaction was positive. The lesions disappeared within a few days after intensive antiluetic therapy. (St. Louis City Hospital.)

tating factors. Frequently, simple ulcers are produced at the vaginal outlet because of excessive and irritating vaginal discharge. Ulcerations due to *chancroidal* infection, have been described elsewhere (Ch. 7). Ulcers due to syphilis may be primary or secondary, i.e., the *chancre* and *flat condyloma*. In both, the causative organism may be demonstrated in dark field illumination of the discharge from the lesion. The chancre has a hard indurated base and is single. The flat condyloma (condyloma latum, Fig. 16) represents multiple rounded elevations with a flat plateau surface, grayish and moist. When in the vagina, it is called a mucous patch, similar to the lesion of the mouth in secondary syphilis. The Wassermann and Kahn reaction is positive at this stage. It is easily distinguished from the condyloma acuminatum, which is described below. It should be emphasized, however, that most of the perineal lesions which are called condylomas (except the flat, syphilitic type described above, and the venereal warts described below) are in reality due to *lymphogranuloma venereum*, which has been described in Chapter 7.

Chronic hypertrophic ulcerative vulvitis is a type of chronic ulceration which is associated with an overgrowth of skin and subcutaneous tissue. It is probably due to chronic lymphangitis and is therefore a type of *elephantiasis*, a term, however, which is used only when the overgrowth of tissue becomes tremendous. Treatment depends on the symptoms produced by its size; surgical excision may be indicated. *Granuloma inguinale* also occurs about the vulva and is considered in Chapter 7.

Condyloma acuminatum (venereal wart) is a papillary and hence conical (rather than flat) skin lesion which is single or multiple, and consists of an overgrowth of the epithelial layer of the skin; unlike the true wart or verruca vulgaris, it does not penetrate the layers of the skin, but extends out from its surface. It is usually associated with lack of cleanliness and the presence of an irritating leukorrhea, especially that due to gonorrhea. Superficial ulcers may form which cause some discomfort; otherwise the warty overgrowths produce no symptoms. Local cleanliness and care of the discharge is all that is needed in the way of treatment in many cases. Others, however, are more resistant and require local excision, electrocoagulation, or chemical cauterization.

Kraurosis is a term frequently used to describe a lesion in the vulva which in reality should be called *leukoplakic vulvitis*, which has a definite histology and clinical appearance (Taussig). As mentioned below it is to be considered as a definite precursor of carcinoma. Hyperplasia of the outer skin layers is supplanted later by atrophy. Most of these patients suffer from pruritus; dyspareunia also occurs. Treatment consists of excision of the diseased skin (vulvectomy) in order to prevent the development of carcinoma.

Neoplasms and Cysts. Most benign tumors, such as fibroma, lipoma, and hemangioma, have been found in the vulva and even in the vagina. Malignant disease is confined to squamous cell carcinoma.

Carcinoma of the vulva is an important though rare type of squamous cell tumor and occurs usually only in older women; occasionally it is of the adenocarcinoma type. It is so often preceded by leukoplakia, that early diagnosis should be relatively easy. Excision

thra whereas the second glass contains only bladder urine (plus any excessive amount of urethral pus); a comparison of the two glasses often enables a differentiation between urethritis and cystitis and the degree of each. If urinalysis is necessary in an acute emergency and the patient cannot void, catheterization may be justified. In the female, catheterization is always indicated for microscopic examination, especially in the adult; otherwise a voided specimen may be used for routine urinalysis.

Unless urine is examined when fresh, inaccurate and often misleading results may be obtained, particularly in the search for bacteria, because many types of organisms may multiply sufficiently in an hour or two to give the erroneous impression of a massive bacteriuria. The routine urinalysis includes the staining of sediment with methylene blue for bacteria, determination of pH (i.e., acid or alkaline), search for pus cells, albumin, and the like.

3. Rectal examination. The tone of the sphincter is estimated in male or female. In the male, the size and shape of the prostrate and seminal vesicles are noted and prostatic fluid is expressed and examined at this time. If the rectal examination precedes the routine urinalysis, microscopic blood may be found in the urine and prove confusing.

4. Measurement of residual urine. In certain cases it is necessary to know how much urine is left in the bladder after voiding. This is known as "residual" and is drawn off by catheterization which, however, must be done within a minute or two of voiding, particularly if the patient has recently drunk considerable fluids.

5. Cystoscopic examination. The introduction of cystoscopic (retrograde) pyelography, consisting of the passage of small catheters through the cystoscope (Fig. 1) into the ureter and kidney followed by the injection of radiopaque solutions (Voelcker and Lichtenberg, 1), and an x-ray film (Fig. 2), has

THE GENITOURINARY SYSTEM

Kidney
Bladder
Prostate
Seminal Vesicles
Urethra
Epididymis
Testicle
Penis
Miscellaneous Lesions

The early use of operative procedures (cystostomy for stone) and mechanical instruments (crude sounds and catheters for urinary obstruction) in ancient times represented greater accomplishment in the treatment of surgical diseases of the genitourinary organs than of any other organ. However, the physician's ignorance of physiologic principles and the poor results obtained allowed even the sound principles to be discarded. Without special instruments, the inaccessibility of the urinary organs naturally made progress slow. However, the invention of the cystoscope (Fig. 1) by Nitze (1899), and the perfection of the technic of ureteral catheterization by Albarran (1897), as introduced a few years previously by numerous independent workers, were the means of instigating rapid development in the knowledge o diseases of the urinary system and their t ment.

Methods of Examination. Because of cessibility of the organs of the genitourin system and their simplicity of function, merous procedures for examination ha been devised. These methods of examinati have been largely responsible for the exac ness of diagnosis which exists in genitourina surgery to a greater degree, perhaps, than i most other specialties. A definite routine however, should be adopted and carried ou methodically in steps as follows:

1. History and physical examination.
2. Urinalysis. In the male the "two glass" test is made. The first glass contains enough urine to wash accumulated pus from the ure-

Fig. 5. Aortography revealing kidney cyst on right (C—cyst).

outline of the kidney and adrenals. A needle is inserted just anterior to the coccyx and 400 to 800 ml. of oxygen or air is injected. The air collects on the side uppermost (Fig. 6), but both sides may be visualized by shifting the patient from side to side following the injection. This procedure is fairly safe, although years ago with deficient technic fatalities with air embolism occurred.

KIDNEY

In general, there is a clearer understanding of the surgical diseases caused primarily by the kidney than those caused by practically any other organ, because the function of the kidney is limited to one important process, namely, excretion of urine. The amount of kidney tissue necessary to carry on the normal excretory function is no greater than one half of one kidney, but the reserve amount of renal tissue is of extreme importance in combating the effects of disease. The amount of urine excreted depends upon the amount of fluid ingested, but on certain occasions a diminution of the amount excreted may definitely signify acute renal impairment. Especially is this true when comparisons of the amount secreted by each kidney are made by ureteral catheterization. The phenolsulphonphthalein excretion test (Rowntree and Geraghty) may be of great value in detecting certain types of disease. Normally the two kidneys should excrete 40 per cent of 1 ml. of a 6 per cent solution of phenolsulphonphthalein within an hour after intramuscular injection. This test is of even greater value in determining the extent of renal damage when the dye is given intravenously with ureteral catheters in place. Normally the dye should appear in the urine from each kidney two to six minutes after injection; at the end of 15 minutes about 15 per cent of the total amount should have been excreted by each kidney. The 15-minute test is more accurate than the hour test.

When renal insufficiency exists in each kidney, there may be a sufficient retention of nitrogenous compounds (urea, creatinin, uric acid) to produce a demonstrable increase in the blood stream. An elevation of the nonprotein nitrogen in the blood (normal of 35 to 45 mg. per 100 ml. of blood) is an accurate method of detecting bilateral renal damage, or a urinary retention, especially the common type produced by prostatic hypertrophy. The nitrogen retention in such instances may be merely an expression of urinary retention in the absence of permanent

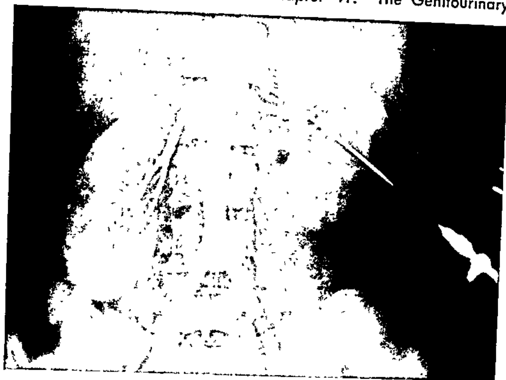

Fig. 4. Kidneys outlined by aortography. Any one of two or three opaque materials mentioned in the text may be used. The kidneys are outlined satisfactorily; no deformities are noted, but right nephroptosis is present.

been very helpful in the diagnosis of renal lesions. Sodium iodide and bromide (Cameron, 1) were originally used but have been largely supplanted by organic compounds of iodine, e.g. hippuran.

Cystoscopic examination includes the visual inspection of the bladder and ureteral orifices, collection of fractional urines, excretory (phenol red) tests, and a variety of roentgenograms in different positions.

6. Intravenous pyelography. The discovery by Von Lichtenberg and Swick (2) that uroselectan (a compound containing 42 per cent iodine by weight), when injected intravenously, is secreted so rapidly by the kidney as to make the urine impervious to the x-ray (Fig. 3) has to a great extent displaced cystoscopic pyelography, because it avoids pain and the occasional reaction (fever, chills) produced by instrumentation of cystoscopy. Various types of organic compounds of iodine, including Diodrast, Hypaque (sodium amedotrizoate), and Urokon (sodium acetrizoate), are used for intravenous pyelography. The adult dose of the three drugs is 7, 15, and 7.5 grams respectively. After a detailed study of the latter two drugs, Jones and associates (Ann. Surg., 73:99, 1956) conclude Hypaque is superior. Although the intravenous method is used as a routine, the retrograde method may be necessary when accurate detail in the pyelogram is needed, e.g., the early stages of tuberculosis and neoplasms of the kidney.

7. Aortography. This procedure was described by Dos Santos (1929) but not popularized then because of the potential dangers associated with it. Injection of 20 ml. of 70 per cent Neo-iopax or 70 per cent Urokon is made directly into the abdominal aorta just above the origin of the renal arteries (Figs. 4, 5). A general or spinal anesthetic is required. X-rays taken after injection are particularly useful in detecting aberrant renal vessels, cysts, and tumors. Evans (3) reports a series of over 1,200 aortograms without a fatality, but renal damage (4) and deaths (5) have been reported. In view of the possibility of complication, most urologists rely upon intravenous or retrograde pyelography and use aortography only on rare occasions (6).

8. Presacral Pneumography. This procedure is particularly useful in revealing the

renal damage, but it is a good criterion for the determination of operability.

Anomalies. Congenital anomalies of the kidney are very common and often produce symptoms. Occasionally the two kidneys are fused together, forming a horseshoe kidney, most often united at the lower pole. One kidney may be small or rudimentary, is frequently displaced (downward) and anomalous in shape (round or mushroom shape). Double ureter and congenital stricture of the ureter are not uncommon. The latter condition is, of course, serious because of its complications (pain, infection, and so forth). On rare occasions, an aberrant artery may be present and by pressure produce a kink of the ureter. Frequently nephroptosis (movable kidney) is present at birth; on other occasions there is apparently sufficient deficiency in the structures supporting the kidney to displace the organ downward later in life. Many of these anomalies produce few or no symptoms and may therefore not be detected except at autopsy or at operation performed for other conditions. Of the manifestations produced by anomalies, pain and urinary infection are perhaps most frequently encountered. Treatment is therefore determined by the symptoms produced; on rare occasions conservative measures fail, and it may be necessary to resort to such radical procedures as nephrectomy. Obviously, nephrectomy should never be performed until it has been established definitely that another kidney is present and is functioning adequately.

Injuries of the Kidney. Although the kidney lies in a protected position adjacent to the vertebral column and above the margin of the lower ribs, it is injured frequently. On most occasions the injury is of a crushing type, although not infrequently it is of a penetrating type (e.g., gunshot injury). There may be no external evidence of injury in the former case, but a history of a blow over the region of the kidney can usually be elicited. The type of injury sustained by the kidney varies from a microscopic tear in the organ to complete division, laceration, or maceration. Degree of destruction, subsequent scar, and urinary leakage are the important points.

The *clinical manifestations* are dependent upon the extent of the injury and upon whether the peritoneal cavity has been entered. Hematuria is the most constant symptom. Microscopic tears may produce no manifestations except hematuria and slight tenderness over the kidney. When the injury is extensive, the patient may present all the manifestations of shock, including tachycardia, low blood pressure, pallor, and weakness. Hemorrhage is no doubt the most important factor in the production of these symptoms. Extravasation of urine of significant amount occurs rather infrequently and adds to the severity of the early symptoms. If the injury to the kidney is associated with a tear through the posterior peritoneum, the symptoms and signs are apt to be more acute because of the increased amount of hemorrhage and the peritoneal irritation. On most occasions, even in the absence of a rupture of the peritoneum, there will be definite manifestations of early peritonitis, including localized abdominal tenderness, muscle spasm, nausea, vomiting, and leukocytosis. These manifestations appear to be caused primarily by direct irritation of important nerves by the retroperitoneal hemorrhage, and not because of the urinary extravasation, because identical findings are encountered frequently in hemorrhage associated with fracture of the spine.

X-ray examination after the intravenous injection of one of the organic iodine compounds mentioned on page 1120 will frequently be of value in revealing the site and extent of injury provided significant escape of urine is taking place.

The *treatment* is likewise dependent upon the extent of the injury. In the absence of severe manifestations, operation is not necessary; the patient may be treated by bed rest, antibiotics, and supportive therapy even though considerable hematuria is present. The spontaneous reparative process in the kidney is considerable, provided the injury is not too severe and has not involved the peritoneum. However, if hematuria is accompanied by marked signs of peritoneal irritation or by a progressive development of shock, it is safe to assume considerable injury to the kidney has been sustained; an operation will therefore be indicated to prevent further bleeding and serious peritoneal extravasation, as well as to repair anatomic de-

Fig. 6. Presacral pneumography following injection of 600 ml. of oxygen. Above, no abnormal findings; K—kidneys and S—spleen. Below, adrenal tumor on right; P—pheochromocytoma, K—kidneys, and S—spleen.

domonas aeruginosa (pyocyaneus) are becoming more frequent (8). Mixed infection is present in 10 to 15 per cent of cases.

Infection may gain access to the kidney in *one of three* ways: 1. the blood stream, 2. by ascending infection, or 3. by way of the lymphatics. Since many of the infections are produced by the colon bacillus, it would appear that on many occasions the organisms are carried to the kidney by the lymphatics which surround the ureter, or by anastomotic channels between the colon and kidney. However, it is probable that an additional factor, i.e., urinary stasis due to obstruction, is necessary before an actual infection develops.

Urinary obstruction, thus, may be responsible for the development of the three main types of infection. Obstruction may be produced in various ways: 1. Calculous obstruction of the ureter (usually at the ureterovesical orifice), or of a calix in the pelvis of the kidney, is one of the most common causes of obstruction. 2. Congenital stenosis at the ureterovesical orifice is a frequent anomaly. 3. A kink may be produced in the ureter by nephroptosis. 4. Anomalies such as double ureter, bifid pelvis, aberrant renal artery, etc., may result in obstruction to the normal flow of urine. 5. Abdominal masses including neoplasms, pregnant uteri, abscesses, etc., may press directly upon the ureter.

The experimental production of hypertension by renal ischemia by Goldblatt (9) and associates has placed an additional responsibility upon the urologists. Numerous clinical reports (Nesbit and Ratliff, 10) are available revealing cure of hypertension following removal of a kidney affected with chronic sclerosing pyelonephritis, proving that renal ischemia was undoubtedly produced by the lesion. Obviously, operative therapy is feasible in such cases only when examination reveals a normal kidney on the other side.

Clinical Manifestations. There is no uniformity in the early symptoms produced by the infections designated as *pyelitis, pyelonephritis,* and *pyonephrosis.* Frequently the onset is sudden, with a chill, fever, nausea, vomiting, and severe pain in the region of the kidney, but radiating downward to the thigh or genitals. On other occasions the onset is insidious, with fever, lassitude, weakness, anorexia, loss of weight, and so forth. In either case there is a tendency for the infection to persist along with the symptoms unless eliminated by proper therapy. The urine contains bacteria and pus cells, usually early in the disease and in large numbers. Frequently, red blood cells are found. Albumin is rarely present in more than slight amounts. Pyelitis is extremely common in young girls. When the infection involves the right kidney and is associated with pain, it may simulate appendicitis; extreme care must be exercised to arrive at a correct differential diagnosis. However, as stated in more detail below, the presence of pus cells in the urine and tenderness over the loin will usually lead to a correct decision. In most instances pyelitis subsides without the development of more than a trivial infection in the kidney parenchyma, and with very little residual change, particularly in young people.

If the infection persists, regardless of treatment, and a hydronephrosis occurs, the cortex gradually becomes destroyed and thinned out and very little urine is excreted. This process may continue until all function ceases and an *autonephrectomy* is established, i.e., the infected organ becomes encapsulated to a great extent by scar tissue and little absorption from the infection takes place. When the function is destroyed to the extent that little or no urine is excreted, pus cells but no bacteria may be found in the urine.

Diagnosis. Examination of the urine is perhaps the most reliable method of establishing a diagnosis. Bacteria and pus cells will be found except in the instances mentioned above. It must be remembered, however, that bacteria and pus cells may be found in various other diseases, including prostatitis, urethritis, etc. A leukocytosis is usually present. Tenderness and, in acute cases, muscle spasm will be demonstrable over the infected kidney. Cystoscopic examination, including inspection of the ureteral orifices, ureteral catheterization, and a search for bacteria in a stained smear of urinary sediment from each kidney obtained by centrifugation, may be of great value in establishing the diagnosis. The amount of urine obtained from the infected kidney and the excretion of phenolsulphonphthalein will be diminished late in the disease, when considerable renal damage is pres-

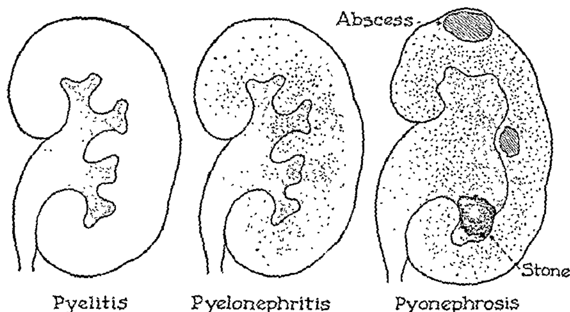

Fig. 7. Drawing to illustrate the three common types of nontuberculous infections of the kidney. From the drawing it appears that the three diseases represent increasingly severe grades of the same process; this, indeed, is true in a large percentage of cases. The term pyelitis is confusing because a certain degree of parenchymal infection undoubtedly exists in most instances of pyelitis, but is of insufficient degree to impair function. In pyelonephritis and pyonephrosis, infections in which the parenchyma is significantly damaged, function may be severely impaired. Stones may or may not be present. A variable amount of hydronephrosis accompanies pyonephrosis.

fects, i.e., lacerations. An incision through the anterior abdominal wall may be advisable because of the likelihood of simultaneous injury to other organs within the abdomen. *Simple lacerations should be repaired by interrupted sutures, whereas severely injured kidneys should be removed, provided the presence of the other kidney is established.* Drainage through a stab wound in the loin should be established to prevent accumulation of urine or bloody fluid. *Failure to operate in the serious cases may allow the development of a perinephric abscess, or if the peritoneum is ruptured, a fatal peritonitis.* For many years it has been known that in patients with a severely damaged kidney the mortality was remarkably lower in those operated upon than it was in those treated conservatively without operation. On the other hand, *in the lesser injuries the patient will recover completely with rest in bed alone.* Therefore, the decision as to operation depends on the extent of the injury as indicated by the manifestations presented by each individual patient.

Infections (Nontuberculous) of the Kidney. The various infections of the kidney may be classified into 1. *pyelitis* and *pyelonephritis;* 2. *pyonephrosis;* and 3. *carbuncle* of the kidney, but such a division is arbitrary and inaccurate since these diseases, with the exception of the latter, on most occasions merely represent various stages in one infectious process (Fig. 7) and are usually associated with obstruction to the urinary flow (7). For example, a persistent pyelitis practically never exists without also a pyelonephritis, except *on occasions when the infection is induced by ureteral catheterization.* The accompanying pyelonephritis may be slight and limited to the central portion of the kidney adjacent to the pelvis. The term pyonephrosis is applied to that type of infection associated with ulceration about the calices, abscesses in the parenchyma, and a thinning of the cortex due to hydronephrosis. *The function of the kidney is least disturbed if the infection is limited primarly to a pyelitis and impaired to the greatest extent in pyonephrosis, in which the loss of function may be complete and permanent.* Years ago the colon bacillus, streptococcus and staphylococcus were the most common causative organisms; however, of recent years, *Aerobacter aerogenes* and *Pseu-*

If no function remains, nephrectomy is performed after acute symptoms have subsided. If adequate drainage cannot be established by ureteral catheterization and the infection is so fulminating as to threaten destruction of the kidney, nephrostomy may be a wise procedure.

Carbuncle of the kidney is the third type of nontuberculous infection; it is commonly of hematogenous origin and pathologically resembles a cellulitis. There is usually a history of a furuncle or carbuncle on the skin several days preceding the onset of symptoms. As would be expected, the causative organism is usually the staphylococcus. The manifestations are much less variable than those of the other types of renal infection already mentioned. Symptoms are insidious and consist primarily of fever, malaise, anorexia, and mild, dull pain in the region of the kidney. Tenderness over the kidney posteriorly is a fairly constant finding and is therefore significant diagnostically. Leukocytosis is usually present. Urine examination may reveal pus cells and erythrocytes but is commonly negative at the onset. The absence of pus cells in the urine is frequently of considerable aid in differentiating this from other types of infections in which pyelitis is the predominating lesion. Treatment is limited to the nonoperative therapy as described above, except when a perinephric abscess is present. Exploration of the kidney may be justified when persistent chemotherapy fails to control the infection and an abscess in the carbuncular infection is suspected.

Perinephric (Perirenal) Abscess. Infection of the perirenal space may be produced by any of several mechanisms, but perhaps the most frequent source is a "carbuncle" of the kidney which in its invasion throughout the cortex finally breaks through the capsule. Frequently it appears that a small abscess, resulting from suppuration in a carbuncular infection, or from a tiny infected embolus, breaks through the cortex. Less commonly, the infection perhaps arises from infected emboli lodging initially in perirenal tissue or results from rupture of a pyonephrosis through the thinned cortex.

The pain associated with a perinephric abscess is variable, is usually located posteriorly in the region of the kidney, but may be so mild as to escape detection by the patient. The pain may be aggravated by bodily movements; the patient and even the physician may thus be led to interpret the pain as originating in the spine. Because of the muscle rigidity, a diagnosis of spinal arthritis or tuberculosis of the spine may erroneously be made. The tenderness posteriorly over the kidney associated with spasm of the lumbar muscles is quite constant, and is significant because of the lack of positive abdominal findings. Fever develops early, is variable in amount, but may be associated with a chill at the onset. Leukocytosis is usually pronounced. Examination of the urine rarely reveals any pathologic findings and is of no diagnostic aid. After the abscess has been present for some time, many systemic manifestations become prominent. Anorexia and nausea are usually present, but vomiting is not so common. The patient becomes weak and pallid, complains of lassitude, and rapidly loses weight. If the abscess increases in size, induration of the deep tissues over the kidney may be demonstrable. On rare occasions the abscess may eventually present anteriorly, thereby masquerading as an appendiceal or liver abscess. The pus may burrow through a small defect in the deep fascia posteriorly and present superficially as a bulging mass (Fig. 8). When this happens, fluctuation is demonstrable, but rarely before; in reality, such a superficial mass is a part of a collar button abscess.

The *treatment* of a perinephric abscess is drainage by operation posteriorly over the kidney as soon as the diagnosis can be made. One or two large cigarette drains are placed in the wound and left in place for five or six days until the abscess cavity is largely obliterated and drainage insignificant. Diagnostic aspiration, if carefully carried out, is occasionally justified in doubtful cases. If possible, the operator should explore for an associated renal carbuncle. Since staphylococcus is the usual organism, penicillin (locally as well as systemically) is a useful adjunct to operation.

Nephrolithiasis. Kidney stones may be composed of any of the urinary components; uric acid, calcium oxalate, and calcium phosphate are common, xanthine and cystine less so. Usually solitary and ovid, the stone, when large, tends to assume the shape of the pelvis

ent, for example, in pyonephrosis or severe pyelonephritis.

Occasionally when a complete block of the ureter occurs, the infected urine cannot enter the bladder; only the clear urine from the other kidney will then be voided. Sooner or later, however, the escape of pus will lead to its detection in the urine; repeated urinalaysis is often necessary, therefore, before making a negative diagnosis of infection.

When considerable pain is present, differential diagnosis between infections of the kidney and such intraabdominal lesions as appendicitis may be difficult. There are several features, however, which should allow one to make the correct diagnosis. For example, the pain associated with a renal lesion usually radiates downward toward the thigh or genitals and the tenderness is confined posteriorly. Fever is present much earlier in the onset of the disease than it is in appendicitis. The presence of fever alone, especially if associated with a chill, will rule out many of the intraabdominal lesions of alimentary tract origin, since they are usually associated with pain and few have chills.

Treatment. One of the most important features in the treatment of renal infections is *chemotherapy*, a procedure extremely valuable in the treatment of urinary infection of all types because these drugs are largely excreted by the urinary route. Numerous drugs are utilized, depending somewhat on the type of infection. The sulfonamides have a wide bacterial spectrum, rarely produce bacteria-resistant strains, and are effective for both bacillary and coccal organisms. The average dose of sulfadiazine is 1 gm. four times daily, and of gantrisin is 2 gm. four times daily.

If sulfadiazine is used, the patient should be given sodium bicarbonate and a copious amount of water, to prevent precipitation of the drug into the kidney. Penicillin is of little value in kidney infection, since its usefulness is limited to staphylococcal, streptococcal, and gonococcal infections (relatively uncommon) and because the majority of staphylococcal strains are becoming resistant to penicillin. Aureomycin is effective against many infections of the kidney, and particularly against *Aerobacter aerogenes*. Of all the chemotherapeutic agents being used at the present time to combat *Pseudomonas aeruginosa* (*pyocyaneus*), polymyxin appears to be most effective (11). However, it is slightly toxic and must be used with care. Terramycin, neomycin, or chloromycetin may be found effective, but tetracycline probably is somewhat more effective. It must be remembered that under therapy with mycin drugs serious micrococcal enteritis will occasionally develop. Again, the value of performing sensitization tests on the organism should be emphasized. On certain occasions when a gram-negative organism is present which resists the usual efforts to control it, sulfathaladine should be given for an interval of several days. Streptomycin and dihydrostreptomycin are useful in coliform and tubercle infections.

Occasionally changing the reaction of the urine appears to be effective in relieving bladder irritation. It may be made alkaline by small doses of sodium bicarbonate (1 to 3 gm. daily) or acid sodium phosphate (1 to 2 gm. daily) or ammonium chloride. In combination with either of the latter two drugs, methenamine in doses of 2 to 3 gm. daily is frequently given because of its effect as a urinary antiseptic. The degree of acidity or alkalinity of the urine can readily be determined by testing the color reaction with selected dyes (12).

When the infection is acute and associated with ureteral obstruction, the insertion of a ureteral catheter is extremely effective in its elimination by establishing drainage. It is frequently difficult to determine whether significant obstruction is present, yet its presence or absence must be determined since ureteral catheterization performed in the absence of obstruction may aggravate the symptoms as well as the infection. Sudden onset of fever and other symptoms, accompanied by severe pain, usually signifies the presence of a urinary obstruction at some point (usually in the ureter). Diagnosis is confirmed if ureteral catheterization reveals a retention of more than a few cubic centimeters of urine in the pelvis of the kidney. Occasionally, it will be advantageous to leave the ureteral catheter in place for two or three days. Bed rest, care of the bowels, and other symptomatic treatment are employed as indicated. Operative treatment is justified only when the function of the kidney is jeopardized or destroyed.

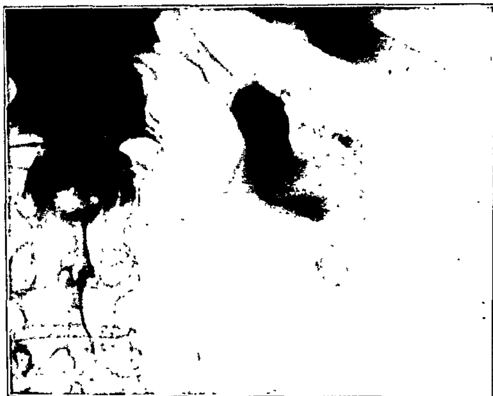

Fig. 9. Roentgenogram, revealing a renal calculus filling the entire pelvis. In this patient the finding was an incidental one; the film was taken only because of a supposed acute injury to the spine. Such stones produce variable manifestations; not infrequently no symptoms whatever are present. Hyperparathyroidism, though a rare disease, is frequently accompanied by stones of this type.

the bladder. The pain is most excruciating and usually radiates toward the thigh or genitals. The stone may pass rapidly into the bladder, often within a few hours, occasionally in two or three weeks, or become permanently lodged near the kidney or at the ureterovesical orifice. Hematuria is a constant finding and is an important sign but is not diagnostic because it is frequently present in such diseases as purpura, hemophilia, and vitamin C deficiency. If the stone is not passed rapidly, infection may develop and pus as well as bacteria will be found in the urine. At least a mild degree of frequency of urination and burning is present. Fever is absent except when obstruction has been present long enough to allow the development of infection. Regardless of the size of the stone, an obstruction to the flow of urine develops at the onset because the impaction produces a total ureteral occlusion. However, as the ureter dilates, the urine may pass around the stone, even though it remains lodged in the ureter. In either case, hydronephrosis develops almost invariably, and if the obstruction to the flow of urine is complete, may be serious because of infection, the development of which is encouraged by urinary stasis. If this condition is not relieved, the hydronephrosis and back pressure in themselves may become so marked as to destroy permanently the function of the kidney. On rare occasions the stone produces sufficient ulceration in the ureter during its passage to lead to stricture formation later on after healing takes place. Differentiation of renal colic from other acute abdominal conditions can usually be made readily by history, urine examination, and x-ray.

TREATMENT. Unless the renal stone is "silent," treatment should be directed toward its removal. Most stones which have entered the ureter will pass spontaneously into the bladder by the institution of conservative treatment such as forcing fluids, sedation, and the like. During severe attacks of colic larger doses of morphine may be required to control the pain, which is controlled most

Fig. 8. Perinephric abscess on the right. Note the bulging abscess which has perforated through the deep fascia and is "pointing" posteriorly. The patient, a 40-year-old male, complained of pain in the back, anorexia, fever, and increasing weakness of three months' duration. No urinary symptoms were present and urinalysis was persistently negative. Incision and drainage were carried out with uneventful recovery; the staphylococcus was isolated from the pus.

and calices. Small stones less than 1 cm. in diameter frequently find their way into the ureter and pass into the bladder.

Little is known of the actual cause of renal calculi, except that on most occasions stasis and infection appear to be important. One type, which is called a "primary stone" (commonly composed of uric acid, calcium oxalate, or urates) occurs in children or young people apparently in the absence of infection or stasis; they are perhaps of metabolic origin. Also metabolic are the large stones, which may be bilateral, seen in hyperparathyroidism (see p. 1069). The so-called "secondary stones," commonly composed of calcium phosphate, are apt to be associated with stasis or infection and may be deposited around a primary stone as a nucleus. Calcification of pre-existing lesions in the kidney has been mentioned as a possible cause (Randall). Prolonged recumbency of spinal cord injury results in stone formation in 25 to 35 per cent of cases (13). Baker and Connelly (14) have recently postulated that nephrolithiasis may be a "connective tissue collagen disease." In 356 cases studied, they noted that 8 per cent of patients with a stone in one kidney have a stone in the other kidney; there was evidence of infection in 43 per cent in patients with bilateral and recurrent calculi.

Clinical Manifestations. The manifestations of renal calculi are extremely variable. In many instances stones are carried in the kidneys for years without producing any symptoms (Fig. 9). More commonly, a mild infection develops in the pelvis about the stone and gradually involves the cortex of the kidney until a severe pyelonephritis develops. If the stone is large, or several are present, the infection may progress to a pyonephrosis, resulting in the ultimate destruction of the kidney. Mild fever, pain, malaise, and anorexia are usually present. Pus, casts, and a variable amount of albumin are present in the urine. Frequency of urination and mild burning pain usually accompany infection of this type. Diagnosis can almost invariably be made by a plain x-ray film since most renal stones contain sufficient calcium to be radiopaque.

The most dramatic manifestation of renal calculi is that spoken of as *renal colic*, which is brought about by the entrance of a stone into the ureter and its passage downward to

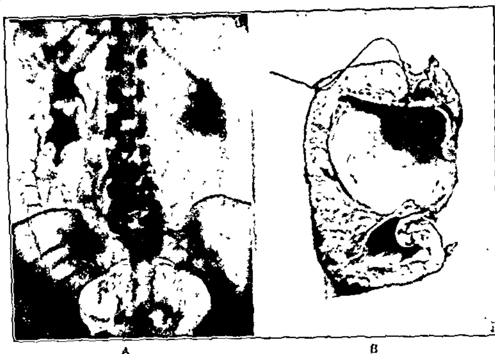

Fig. 10. Hydronephrosis. A, on the patient's right a dilated pelvis with double ureter is noted (after intravenous pyelography). On the left a shadow of a large mass may be observed, but none of the diodrast is passing through the kidney, thus indicating that the function on this side is almost, if not completely, destroyed. Lack of function was corroborated later by intravenous phenolsulphonphthalein with a uretral catheter in place. B, longitudinal section of the excised kidney. Note the thinned cortex and the hydronephrosis which was produced by a congenital stricture at the ureteropelvic juncture. (Courtesy, Dr. J. H. Sanford.)

should be carried out until the source of the obstruction is found.

Treatment should be directed to release of the obstruction which, if acute and complete, demands immediate relief. If the obstruction is produced by a stone in the ureter, such procedures as ureteral catheterization or actual operation are available to remove the calculus, if it is not dislodged spontaneously. Ureteral strictures may be kept open by such a simple procedure as *occasional dilatation* by ureteral catheterization and bougies. Kinks produced by nephroptosis may be *eliminated* by correction of the nephroptosis. Extrinsic pressure due to a tumor may be corrected by excision of the mass. When the hydronephrosis has progressed to the point that function of the kidney is destroyed, nephrectomy may be indicated, particularly if symptoms are manifested.

Nephroptosis. Ptosis of the kidney occurs most frequently in women, almost always on the right side and may be caused by a number of factors. Narrowness of the paravertebral niche, a decreased amount of perirenal fat, emaciation, weakness of the abdominal wall, and so forth, may be mentioned as prominent etiological factors. As stated previously, if the ptosis is sufficient to produce a kinking of the ureter, a hydronephrosis, perhaps with an associated infection, will develop.

Only a small percentage of patients with nephroptosis have symptoms of ureteral obstruction. The most common symptoms are those spoken of as renal colic, consisting of pain in the region of the kidney and perhaps *radiating down the ureter toward the thigh* or genitals. This pain may not be severe but is usually *aggravated by jolting as sustained by* riding in automobiles or streetcars. Frequent and painful urination is not uncommon. Palpation usually reveals tenderness over the kidney. When the patient changes from the recumbent to the sitting position, it is usually possible to demonstrate a shifting in position of the organ downward. If there is doubt about the demonstration of an abnormal *amount of mobility*, pyelographic examina-

promptly when the drug is given intravenously. If, after many days, there is no evidence of progression in the descent of the stone, ureteral catheterization may be instrumental in dislodging it. Occasionally, dilatation of the ureter with a bougie, or several ureteral catheterizations will result in spontaneous passage of the stone. On rare occasions an operation (usually extraperitoneal with incision into the ureter) will be necessary to remove the stone. Large stones in the kidney cannot be passed by way of the ureter and if symptoms are produced, may necessitate operation. This is best done by a posterior incision in the loin and removal of the stone by incision into the pelvis (pyelotomy). The opening in the pelvis is then repaired and the wound closed around a drain. If the function of the kidney is permanently destroyed, nephrectomy is usually indicated after acute infection has subsided. If the stones are present in both kidneys it is usually preferable to operate first on the kidney with the poorer function, since the operation may produce a temporary anuria; if the better kidney is the one operated on first, and this complication (i.e., temporary anuria) results, a fatal outcome may ensue. It has been shown experimentally by Vermeulen and associates (15) that diuresis will tend to dissolve bladder stones, although not enough clinical experience is available to determine how effective it would be in humans. Removal of stones by operation is effective in relieving the patient temporarily, but Abeshouse and Lerman (16) have reported a recurrence rate varying between 11 and 25 per cent in nearly 4,000 operations for stones. They report that when a stone forms in only one area of the kidney (indicating a local causative factor) removal of this area by *partial nephrectomy* reduces the recurrence rate to a very low figure, namely, 2 per cent. However, since the most common cause of renal stones is metabolic, this procedure will be practical in only a small percentage of cases. Baker and Connelly (14) report that treatment with the anti-inflammatory drugs (cortisone, butazolidin, and aspirin) has reduced the recurrence rate in their series by 50 per cent.

Hydronephrosis. Although the dilatation of the kidney pelvis or calices in hydronephrosis is usually caused by obstruction to the urinary flow, it is a fact that in many instances infection appears to be a responsible factor even in the absence of demonstrable obstruction. *Prostatic hypertrophy and stricture* of the urethra may produce hydronephrosis, but the damage inflicted by infection in these instances is more significant than the hydronephrosis. However, in ureteral obstruction "no distensible bladder intervenes to distribute the pressure, and infection is often entirely absent; so that the aseptic dilatation of kidney and ureter progresses rapidly and unobscured." The obstruction may be ureteral and be produced by a variety of causes: 1. stones, tumors, or trauma; 2. kink of the ureter due to nephroptosis, congenital malformation (megaureter with or without stricture); and 3. extrinsic pressure (aberrent vessels or tumors).

As the hydronephrosis progresses the cortex becomes thinned and function impaired (Fig. 10), but not to a degree proportionate to the thinning of the cortex. On many occasions the cortex may be nothing more than a mere shell; yet there may be few if any demonstrable manifestations of impairment of renal function. A sudden complete obstruction produced by a stone or by accidental ligation of the ureter may diminish the function to zero and produce irreparable damage in as short a time as one week, whereas a partial obstruction may exist for months with little impairment of function.

The *clinical manifestations* of hydronephrosis are variable. On many occasions a pronounced dilatation of the ureter and kidney pelvis may develop before sufficient symptoms are produced to bring the patient to a doctor. Mild pain in the region of the kidney, radiating downward along the ureter is a common complaint. Tenderness over the kidney posteriorly is usually present. The dilated kidney may or may not be palpable anteriorly. Fever may or may not be present, depending largely upon the amount of infection. If the obstruction is sudden and complete, or nearly so, acute symptoms (renal colic) as described previously in this chapter will be produced. Diligent effort must be made to find the cause of the hydronephrosis. Ureteral catheterization, pyelography, x-ray, or examination of the prostate and urethra,

such as frequency of urination and severe dysuria, are apt to develop. The urine becomes cloudy because of the pus contained in it, and frequently is smoky or red because of hemorrhage in the pelvis. Pain in the region of the kidney is not uncommon and is occasionally colicky, but never severe. Mild tenderness over the kidney may or may not be present. Examination of the urine reveals pus in large quantities, a variable amount of red blood cells, albumin, and casts. Cystoscopic findings, including ulcers in the bladder, reddening, ulceration, and retraction of the ureteral orifice, are fairly diagnostic of the disease. Pyelograms reveal irregularities in the shadows of the calices with narrowing, or clubbing, and a contraction of the pelvis with irregular constrictions and dilatation of the ureter. The excretion of phenolsulphonphthalein by the affected kidney is diminished, but not early in the disease. The diagnosis is confirmed by finding tubercle bacilli on smear or by culture, or by reproducing the disease by guinea pig inoculation.

TREATMENT. Since effective antibiotics have been found for tuberculosis, therapy has become much less radical. Nesbit and MacKinney (17) recommend complete rest in a sanitorium giving dihydrostreptomycin, 2 gm., and para-aminosalicylic acid (12 to 15 gm.) daily. Isoniazid is recommended in addition, if a second course is needed. In unilateral disease they recommend antibiotic therapy for 60 days. If improvement is not substantial, nephrectomy is performed and antibiotics continued for another 30 days. If the disease is advanced initially, they recommend nephrectomy after 10 days of antibiotic therapy. Before nephrectomy is done, it must be established (by pyelography and the like), that the opposite kidney is sufficiently healthy to sustain life. It is always important to examine the patient carefully for the possible existence of an active lesion elsewhere (particularly lung and bone). Nephrectomy should not be performed if such an active lesion is found. Removal of the kidney may be technically difficult because of the large amount of dense perirenal scar tissue. On account of the involvement of the ureter it is usually advisable to remove all of it, even though it may be necessary to do it through another incision at a later date. Partial nephrectomy is occasionally advisable. Ulcerations in the bladder heal rapidly following nephrectomy unless the remaining kidney is infected. Hygienic measures, such as rest, large amounts of wholesome food, and so forth, are important in the convalescence.

Tumors and Cysts. The great majority of the neoplasms in the kidney are malignant; few are benign. An enormous amount of confusion exists as to their classification. However, most authorities do not accept the hypothesis proposed by Grawitz in 1883 that clear cell carcinomas were adrenal rests, but prefer to classify renal tumors as 1. tumors of the adult renal parenchyma, 2. tumors of the renal pelvis, and 3. tumors of the kidney in childhood (Wilm's tumor). Adenocarcinomas are the most common renal tumors, constituting about 80 per cent of the total. Dodson (18) classifies these tumors as 1. papillary adenocarcinoma, (*a*) with clear cells, (*b*) with granular cells; 2. malignant cystadenoma; and 3. alveolar carcinoma.

ADENOCARCINOMA. Papillary adenocarcinomas with clear cells constitute the largest group. On cross section they have a yellowish appearance, often revealing hemorrhage and necrosis. On section the cells are large, cuboid, and clear, resembling carcinomas arising from the adrenal cortex (Fig. 12). In general, these tumors grow more slowly than other carcinomas of the kidney.

Hematuria, although not constant, is the most common symptom and is manifested early when present. It is usually sufficiently severe to be detected by the patient. The bleeding is painless unless it occurs in such large quantities as to form clots and produce renal colic. Mild pain in the region of the kidney may be present but is rarely noted before a tumor is palpable. The function of the kidney is rarely impaired until the terminal stage. Except in rare instances, pyelography reveals an abnormal "filling defect" in the x-ray. Occasionally the tumor remains small and produces such few symptoms that metastases (usually to the brain, lungs, or bone) may occur and produce symptoms before the local tumor does.

Nephrectomy is the treatment of choice unless metastases are present or the opposite kidney is severely diseased. The five-year sur-

tion should be resorted to, and roentgenograms of the kidney taken in the recumbent and standing position. If distention of the kidney pelvis by retrograde pyelography reproduces the pain complained of, it is reasonably presumptive that the kidney is the cause of the pain. Intravenous pyelograms during an attack of pain may reveal hydronephrosis although the pyelograms may be normal when the patient is having no pain. If replacement of the kidney to its normal position by recumbency and maintenance there by a "kidney belt" relieves the pain, the evidence is still more conclusive that renal ptosis is the cause of the patient's complaints.

Treatment should be directed toward improvement in the general health. It is important that the patient gain weight so as to increase the amount of perirenal fat. Frequently, correction of faulty posture will shift the abdominal organs so as to make more room for them in the upper abdomen. A wide abdominal support or elastic belt (with or without a "kidney pad") frequently relieves all symptoms, because of the support given the abdominal organs. Nephropexy, that is, fixation of the kidney in its normal position by operative means, is performed occasionally with variable success.

Fig. 11. Tuberculosis of the kidney (Longitudinal section after operative removal). Note the ulceration surrounding the calices. Abscess formation is common and may at times destroy practically the entire cortex. (Courtesy, Dr. D. K. Rose.)

Tuberculosis of the Kidney. Tuberculous infection of the kidney (Fig. 11) is a disease of early adult life and is primarily unilateral, but in 10 to 25 per cent of the cases both kidneys are affected. The organisms reach the kidneys by way of the blood stream. Usually a primary focus can be found elsewhere, most often in the lungs, but frequently no primary lesion can be demonstrated. The infection starts usually at the base of the papilla in the lower or upper pole of the kidney and may spread by the lymphatics so that several foci will be produced within the organ. A toxic nephritis of the parenchymatous type may develop in the opposite kidney as well as the diseased organ. The large amount of albumin and casts found so frequently in the urine collected from each ureter is explained by this complicating lesion. As the disease progresses and involves the bladder, the opposite kidney may become infected, usually by ascending infection.

The lesion progresses slowly, healing by scar tissue in isolated areas. This scarring gradually produces a shrinking of the kidney and a contraction of the pelvis. The infection may spread by caseation or cavitation until ulcers appear in the pelvis after which the ureter is obviously exposed to the disease. Sooner or later the infection becomes implanted in the ureter. Peristalsis is lost early. Ulceration leads to scarring of the wall of the ureter, thereby producing strictures at numerous points and a shortening of the ureter. If the fibrosis in the kidney progresses to the point that the arteries become obliterated, an autonephrectomy will be produced.

Clinical Manifestations. The symptoms produced by tuberculosis of the kidney are so insidious that the disease may be present for weeks or months before the patient is aware of it. Frequently, systemic symptoms, such as fever, malaise, anorexia, and loss of weight, are the first noted. On other occasions, frequency of urination caused by secondary invasion of the bladder is the first complaint. Sooner or later, in untreated cases the bladder becomes infected. When this occurs, troublesome symptoms,

of pain produced by the tumor is minimal, the tumor is usually very large before it is detected. If metastases have not taken place and the size of the tumor permits, nephrectomy should be performed. The tumor is so sensitive to x-ray therapy that many surgeons advise x-ray therapy preoperatively on the basis that a large inoperable tumor may be made operable. However, the authors agree with Gross (19), who advises against this, on the basis that metastases may take place while waiting for radiation effect. Prognosis is poor.

Polycystic Kidney. Multiple cysts of the kidney are usually bilateral and are presumably of congenital origin, although symptoms may not be produced until late in adult life. They appear to be hereditary as suggested by the fact that frequently more than one member of the family is affected. The cysts contain thin or gelatinous amber-colored fluid, not urine. There is usually a large amount of fatty tissue deposited about the organ. Surprisingly little renal tissue is demonstrable, even on cut section.

Except for hematuria, which may be present early in the disease, the symptoms are those of nephritis, although usually insidious; rarely do these patients live to be over 40 or 45 years of age. Albumin and casts are demonstrable in the urine. Polyuria may be present. One kidney usually increases in size faster than the other and may or may not be palpable. Diagnosis can be confirmed readily by pyelography because of the lengthening and distortion of the calices.

Since both kidneys are usually involved, treatment is rarely surgical. Occasionally, suppuration develops within the cysts, thereby demanding drainage or nephrectomy.

Solitary Cyst of the Kidney. Such cysts are practically always unilateral but may attain considerable size. The fluid within the cyst is clear and amber colored or hemorrhagic, but not urinous. Mild pain in the region of the kidney may be complained of when the cyst becomes large. Frequently they may attain a size large enough to be palpable through the abdominal wall without producing any symptoms. Treatment consists of excision of the cyst with repair of the defect; rarely is nephrectomy indicated. These cysts very frequently may be wiped out of the kidney with a gauze sponge.

BLADDER

Reference has already been made to surgical procedures performed upon the bladder (cystostomy for stone) in ancient times, but a clear understanding of the physiology of the bladder and the types of disease affecting it was not possible until the invention of the cystoscope. The bladder is innervated by autonomic fibers comprising two separate nerve tracts: 1. fibers from the second dorsal to the third lumbar anterior roots constitute the sympathetic innervation and permit filling of the bladder by maintaining contraction of bladder neck and relaxation of the wall; 2. pelvic nerve fibers arising from the second and third sacral roots constitute its parasympathetic innervation and are important in emptying the bladder since stimulation of this group of nerves causes contraction of the bladder wall and relaxation of the bladder neck. In 1927 Rose (20) introduced the use of the cystometer, an instrument designed to measure bladder pressure and capacity, and their relation to pain, desire to void, and so forth. This instrument opened up an entirely new field for the study of the physiology of the bladder and the diseases affecting it. A curve (cystometrogram) obtained by these studies is not specifically indicative of disease, but is in reality a graph of the individual patient's bladder muscle reaction when the bladder is filled with fluid (Fig. 13). Such data (i.e., the sensation produced by various amounts of fluid) allow the clinician to determine the cause of various types of frequency, urgency, and incontinence. Thus, treatment can be based on actual bladder physiology.

Congenital Anomalies. *Exstrophy of the bladder* is an exceedingly distressing congenital deformity in which exposed bladder mucosa lies open on the anterior abdominal wall. It occurs most often in males, but fortunately is rather rare. The defect is explained by a failure of the symphysis pubis and the abdominal wall just above it to unite in the midline. The roof of the bladder is absent; the floor of the bladder including the trigon protrudes outward. The penis and scrotum are small. The prostate and seminal vesicles are atrophic or absent. The escaping urine

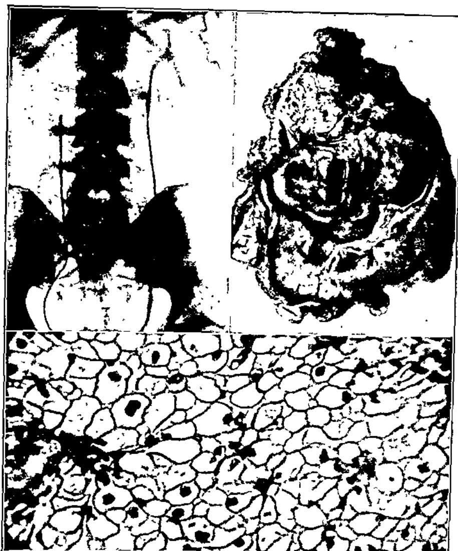

Fig. 12. Clear cell adenocarcinoma of the kidney (hypernephroma). Upper left, pyelogram (per ureter) of the left kidney shows elongation and narrowing of the upper calyx, thus indicating a tumor in this portion of the kidney. The patient had pain in the region of the left kidney, and hematuria of four months' duration. Upper right, photograph of a longitudinal section of the kidney after operation. The tumor involves the entire upper portion of the kidney and has filled the pelvis much more than the pyelogram indicates. Below, high power photomicrograph of the tumor, revealing the "foam" cells with very little connective tissue stroma. (Courtesy, Dr. J. H. Sanford.)

vival rate for adenocarcinoma of the kidney is about 30 per cent.

EPITHELIAL TUMORS OF THE RENAL PELVIS. These tumors are usually of papillary type and may be either benign or malignant. In either case the papillary or warty growth may grow profusely and completely fill the pelvis and even extend down into the ureter. Hematuria is the predominating symptom. Nephrectomy should be performed if possible.

EMBRYOMA OF THE KIDNEY (WILMS' TUMOR). This tumor is sarcomatous in type but contains many embryonal structures, including connective tissue, cartilage, muscle, and abortive renal elements. Spindle and polyhedral cells along with epithelial tubules usually constitute the major cellular elements. It is encountered only in children, rarely after the age of 10. The tumor attains a huge size, has a greater tendency to remain encapsulated than most malignant tumors, but may metastasize through lymphatics as well as the vascular system (including the wall of the renal vein). Like other renal tumors, the only early symptom is hematuria. Because the amount

fracture of the pelvis, the jagged bone edges may tear or perforate the bladder. A moderate blow over an overdistended bladder may cause a rupture, but spontaneous *rupture of the bladder* because of overdistention is exceedingly uncommon. Traumatic rupture is occasionally associated with fractures of the pelvis; it occurs most frequently when the bladder is full and therefore is relatively more common in drunken people. Unless the patient is drunk or unconscious, there is invariably considerable pain at the time of rupture. On the other hand, since sterile urine often excites only mild irritation of the peritoneum, very few symptoms and signs may be manifested, and the diagnosis will be missed. Peritonitis due to associated infection is apt to occur ultimately (unless prevented by early repair) and adds greatly to the seriousness of the situation. Mild shock may be present because of associated hemorrhage. Tenderness over the bladder is constant, but variable in intensity. Diffuse abdominal tenderness, muscle spasm, and other signs of peritoneal irritation, such as nausea and vomiting, may be present. Of most diagnostic importance is the inability to void. If rupture of the bladder is suspected, and the patient is unable to void, catheterization (using strict aseptic technic) should be performed; if perforation exists, rarely will more than a few cubic centimeters of bloody urine be obtained. Diagnosis is further confirmed by obtaining a cystogram using about 200 ml. of 15 per cent Urokon solution.

Treatment is obviously surgical, consisting of celiotomy with repair of the laceration as soon as the diagnosis is made. To prevent leakage at the suture line because of distention, it is necessary to insert a retention catheter and leave it in place for several days.

Rupture of the bladder is quite common in the explosions of war. Immediate operation is, of course, indicated, but performance of cystostomy is more imperative than in civilian injuries.

Cystitis. The term cystitis correctly used refers to an infection of the bladder, usually but not always accompanied by dysuria, i.e., frequency and pain on urination. On the other hand, the term cystitis is often used, perhaps incorrectly, in patients with the same symptoms, due not to infection of the bladder itself but to other causes, e.g., Hunner ulcer or urethritis.

Infection of the bladder occurs as a primary disease; also, it may be secondary to infections of the kidney. Of the other factors which may be responsible for cystitis, the following should be mentioned: prostatitis, residual urine, hyperplastic epithelial changes, tumors, and contamination from catheterization. The bacillus coli, tubercle bacillus, staphylococcus, streptococcus, and proteus bacillus are the organisms most commonly responsible for infection. The disease occurs in either the acute or the chronic form. The bladder mucosa is reddened and edematous. Ulcers are not uncommon.

Because of the danger of production of infection by catheterization, such a procedure should be performed only when necessary, and only with strict aseptic technic. Especially is this true when a residual urine, tumor of the bladder, hypertrophy of the prostate, calculus, or neurogenic lesion is present. Cystitis in the presence of such lesions is apt to be especially serious.

CLINICAL MANIFESTATIONS. The most significant symptoms are frequency and burning on urination. There may be severe pain at the end of urination because of the excessive contracting efforts of the bladder to empty itself. Pus cells are always found in the urine, frequently in such large quantities as to make the urine cloudy; red blood cells are not uncommon. Cystoscopy will reveal a reddened, edematous mucosa, perhaps with ulceration.

In tuberculous cystitis the depression of the ureteral orifice ("golf ball ureter") noted in cystoscopic examination may be the most diagnostic finding. The edema and redness are most commonly found in the trigon where the ulcerations produced by the miliary tubercles are likewise most frequently encountered. The symptoms and urinary findings in tuberculous cystitis are similar to those just mentioned except that with proper technic the tubercle bacillus can frequently be found in the urine.

The *treatment* of cystitis consists chiefly of elimination of the primary source of the infection, an achievement which often can be accomplished only when a urinary obstruction is relieved. Rarely does a cystitis fail to subside readily when the offending focus is

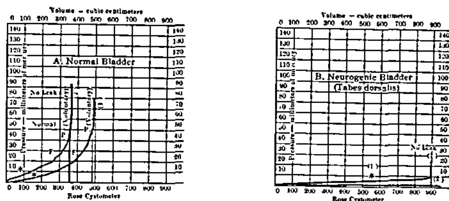

Fig. 13. Diagnostic charts obtained with the Rose cystometer. A cystometrogram is obtained by introducing sterile water through the cystometer into the bladder of the supine relaxed patient. The graphs, as exemplified above, record pressure changes against volume and also the sensations of the patient, e.g., first desire to void is indicated by an asterisk (*), a sense of fullness is shown at "F" and of pain at "P." Note that two consecutive superimposed graphs are obtained at each examination in order to stimulate the stretch reflex and to measure the strength of the bladder wall. (Modified from Rose, D. K. J. Urol.)

must be drained into a special type of cup or be absorbed by dressings. Sufficient urine escapes, however, to produce irritation and maceration of the skin about the defect. The floor of the bladder becomes infected and presents a red, beefy appearance. Infection ascends readily up the ureters and is instrumental in causing the death of two thirds or three fourths of these poor unfortunates before they attain the age of 18 or 20.

The most popular method of the past few years consists of the transplantation of the ureters into the sigmoid, preferably in two stages (one ureter at a time). This operation meets with the most success if not performed before the age of seven or eight. Transplantation of the ureters obliquely through the wall of the sigmoid, as originally suggested by Coffey to avoid ascending infection, is being abandoned because it appears that obstruction to urine flow into the sigmoid is more likely to cause renal infection than ascending infection (21, 22). A more direct anastomosis with as large a stoma as possible is, therefore, preferable to the Coffey technic. The bowel should be prepared a few days before operation by oral administration of sulfathalidine or streptomycin. Heavy chemotherapy with penicillin and streptomycin intramuscularly should be carried out for several days postoperatively. During the past few years the Bricker method (23) consisting of the construction of an artificial bladder from a segment of ileum is gaining favor; by this method the urine is drained continuously to the outside and is collected in a Rutzer bag or its equivalent.

A *diverticulum* is a common defect thought by some to be congenital in origin, but in reality it is usually associated with urethral obstruction (especially prostatic) of some type. Bladder diverticula may vary in size from a tiny saccule, which is not visible on the exterior of the bladder, to a defect which is larger than the bladder itself. They occur most often on the posterolateral wall, and as they increase in size may pull the trigon into the defect. There may be no symptoms of the diverticulum itself; however, frequency or burning on urination, difficulty in urination, etc., may be present because of the obstruction and infection. The infection may be secondary to stagnation of urine in the diverticulum or to the urinary (e.g., prostatic) obstruction. Treatment is directed toward eradication of the infection by irrigation of the bladder and relief of the urethral obstruction. If the diverticulum is large, it is usually advisable, however, to remove it surgically, because of the liability to reinfection. This is not a simple and innocuous procedure and should not be attempted by one not skilled in urologic surgery; postoperative care, including the use of a retention catheter, is likewise important.

Injuries of the Bladder. Because of the protected position of the bladder within the pelvis, injury is uncommon except when produced by fracture of the pelvis or penetration by bullets. When a patient sustains a severe

is more common in the malignant tumor, as is also cystitis and calcareous encrustation. Hematuria may be the only symptom except for burning and frequency of urination incited by infection. On rare occasions, bits of tumor break off and are passed in the urine or actually produce urethral obstruction. Fulguration, implantation of radium seeds or needles, and x-ray therapy constitute the chief procedures in the treatment, and are fairly efficient in effecting a local disappearance of the tumor. Because of the involvement in the base of the bladder, resection of the bladder is rarely indicated since transplantation of the ureters into the colon (a formidable procedure in these patients) must also be done.

CARCINOMA. In addition to the malignant papilloma there is another type of malignant growth designated as carcinoma, which is a squamous cell tumor, appearing as an ulcerating, elevated thickening of the bladder wall. The symptoms encountered are similar to those produced by the papillomatous tumors. For tumors in the dome of the bladder, local resection is appropriate. When the neoplasm is located near the trigone, total cystectomy with transplantation of the ureters will be necessary. However, Dean (24) has shown that in 40 per cent of cases the kidney shows damage (by pyelography) within six months following ureterosigmoidostomy. In view of this complication, which has been appreciated by most urologists, the operation is being modified by construction of an artificial bladder from the colon (25, 26) or ileum (23). However, the follow-ups in total cystectomy are disappointing; Marshall and Whitmore (27) noted that of 100 patients having ureterosigmoidostomy, only 37 were alive two years later.

Retention of Urine. Urinary retention occurs most commonly as a complication of operations, particularly those about the pelvis and perineum.

The difficulty in urination is made more acute by the recumbent position of the patient. Before resorting to catheterization, all possible effort should be made to assist the patient in voiding, particularly because repeated catheterizations may lead to cystitis. Such simple procedures as a warm water douche of the genitals and the psychic effect of turning on a water faucet in the patient's room may enable the patient to void. Enemas are frequently effective in inducing sufficient relaxation of the urinary sphincter to allow the patient to void. Now that we know that early ambulation is not only harmless, but is actually beneficial, whenever possible the patient may be allowed to sit or stand beside the bed to void, if unable to do so in bed. If retention is due to pain in a perineal wound, a small dose of morphine may be of aid in voiding. Carbachol (carbamylcholine chloride) in a dose of 0.25 mg., repeated in one-half hour if necessary, usually is effective in promoting urination. If the above measures fail, catheterization must then be done (Fig. 14). In general, catheterization should not be delayed until the bladder distention is pronounced, since only rarely is the patient able to void when distention with pain has been present longer than an hour or two. Moreover, a bladder which has been subjected to considerable distention is much more liable to become infected. In any event, extreme care, utilizing perfect aseptic technic, must be exercised during catheterization; no part of the catheter which is to be inserted beyond the meatus should be touched except with a sterile instrument or the sterile gloved hand. Gentleness is likewise important. Following catheterization the patient should be encouraged to void in a few hours, before sufficient urine has accumulated to produce pain. If difficulty is still experienced in voiding, catheterization should be repeated in eight or ten hours, because the normal mechanism is usually regained more rapidly than it is if one waits until distention develops to the point of pain. Intermittent catheterization is unwise when a definite obstruction is present and remains. Under such circumstances it is preferable to insert a retention catheter, although frequently suprapubic cystostomy may be indicated.

Following certain operations, e.g., resection of the rectum, retention of urine may persist for many days; it is assumed in such instances that the retention is not due to simple reflex spasm, but to actual division of the pudic nerve which supplies the bladder. Numerous other conditions produce retention of urine in addition to other disturbances in bladder function; the term neurogenic bladder is applied to such cases.

removed, regardless of whether or not the infection is tuberculous. Fluids should be given in large quantities. Sedatives may be necessary because of the pain, especially in tuberculosis. When the urine is highly acid, the burning and frequency on urination may sometimes be relieved by the administration of alkalis, such as sodium bicarbonate or citrate. Irrigation of the bladder once or twice daily with a 1:5000 solution of potassium permanganate, followed by instillation of a few cubic centimeters of 10 to 20 per cent solution of argyrol after irrigation of the bladder may be helpful. Chemotherapy is indicated, but only after the organism is isolated and its sensitivity to the various chemotherapeutic agents is determined.

Bladder Calculus. Stones in the bladder usually occur singly but may be multiple. Most of them are comprised chiefly of urates (descending from the kidney), but uric acid, phosphate, and oxalate stones are also encountered. There is usually sufficient calcium present to make the calculi impervious to the x-ray. Vesical stones are encountered most commonly in men, less frequently in children, but rarely in women except in hyperparathyroidism. The size is variable; on rare occasions they may be 2 inches or more in diameter. Frequently, stones originate from small calculi from the kidney and form primarily in the bladder; they may develop around a foreign body.

The *symptoms* include burning and frequency on urination, but the type of pain occurring in the perineum, radiating to the head of the penis and accentuated by activity of the patient, is more diagnostic. Pain is frequently severe at the end of urination when a few drops of bloody urine are occasionally observed. On rare occasions the stream is stopped suddenly by the stone lodging in the prostatic urethra. Infection is a frequent accompaniment of stones.

The *diagnosis* may frequently be made by contact of the stone with a sound, but the x-ray and cystoscope constitute much more reliable means of making a diagnosis. The urate stones, however, are occasionally radiotranslucent so that diagnosis cannot be confirmed by x-ray.

The *treatment*, of course, consists of removal of the stone. If the calculus is small, it may frequently be removed readily by litholapaxy; i.e., crushing with a lithotrite introduced through the urethra and removing the fragments by irrigation. If the stone is large or too hard to crush, or if obstruction due to urethral stricture or prostatic enlargement prevents the passage of the instrument, it will be necessary to open the bladder in order to remove the stone. The bladder is frequently left open to drain through the suprapubic opening, but rarely is it unsafe to close it, providing a retention catheter is placed in the urethra and allowed to remain for a few days.

Foreign Bodies in the Bladder. It is not uncommon to find foreign bodies, such as hair pins, pieces of rubber, and catheters, in the bladder, introduced by sexual perverts. Not only do these foreign bodies produce infection, but with few exceptions they act as the nucleus for the formation of stones.

Tumors. Neoplasms of the bladder may be either benign or malignant but with few exceptions can be classified into one of three types.

BENIGN PAPILLOMA. Benign papillomas are encountered most commonly in males, previous to the age of 45. They appear usually in the base of the bladder and may be single or multiple. The tumor grows insidiously and no doubt is commonly present months or years before symptoms are produced. Frequently, the growth is responsible for the development of an infection (cystitis). On rare occasions calcareous encrustations are found on the papillomatous strands. Ulceration is not common. Perhaps the most common manifestation is hematuria, occurring usually at the end of urination. Such tumors are best treated by fulguration through a cystoscope. On rare occasions it may be necessary to resort to excision by cystotomy.

MALIGNANT PAPILLOMA. This tumor is not unlike the benign papilloma in appearance but occurs, for the most part, in older people (usually males). It arises most commonly in the trigon, but there is a greater tendency toward multiplicity of foci or implantation of growth than in the benign tumor. The microscopic appearance of the base of the tumor is the determining factor in the differentiation between the benign and the malignant growths. Metastasis occurs slowly. Ulceration

is more common in the malignant tumor, as is also cystitis and calcareous encrustation. Hematuria may be the only symptom except for burning and frequency of urination incited by infection. On rare occasions, bits of tumor break off and are passed in the urine or actually produce urethral obstruction. Fulguration, implantation of radium seeds or needles, and x-ray therapy constitute the chief *procedures in the treatment, and are fairly* efficient in effecting a local disappearance of the tumor. Because of the involvement in the base of the bladder, resection of the bladder is rarely indicated since transplantation of the ureters into the colon (a formidable procedure in these patients) must also be done.

CARCINOMA. In addition to the malignant papilloma there is another type of malignant growth designated as carcinoma, which is a squamous cell tumor, appearing as an ulcerating, elevated thickening of the bladder wall. The symptoms encountered are similar to those produced by the papillomatous tumors. For tumors in the dome of the bladder, local resection is appropriate. When the neoplasm is located near the trigone, total cystectomy with transplantation of the ureters will be necessary. However, Dean (24) has shown that in 40 per cent of cases the kidney shows damage (by pyelography) within six months following ureterosigmoidostomy. In view of this complication, which has been appreciated by most urologists, the operation is being modified by construction of an artificial bladder from the colon (25, 26) or ileum (23). However, the follow-ups in total cystectomy are disappointing; Marshall and Whitmore (27) noted that of 100 patients having ureterosigmoidostomy, only 37 were alive two years later.

Retention of Urine. Urinary retention occurs most commonly as a complication of operations, particularly those about the pelvis and perineum.

The difficulty in urination is made more acute by the recumbent position of the patient. Before resorting to catheterization, all possible effort should be made to assist the patient in voiding, particularly because repeated catheterizations may lead to cystitis. Such simple procedures as a warm water douche of the genitals and the psychic effect of turning on a water faucet in the patient's room may enable the patient to void. Enemas are frequently effective in inducing sufficient relaxation of the urinary sphincter to allow the patient to void. Now that we know that early ambulation is not only harmless, but is actually beneficial, whenever possible the patient may be allowed to sit or stand beside the bed to void, if unable to do so in bed. If retention is due to pain in a perineal wound, a small dose of morphine may be of aid in voiding. Carbachol (carbamylcholine chloride) in a dose of 0.25 mg., repeated in one-half hour if necessary, usually is effective in promoting urination. If the above measures fail, catheterization must then be done (Fig. 14). In general, catheterization should not be delayed until the bladder distention is pronounced, since only rarely is the patient able to void when distention with pain has been present longer than an hour or two. Moreover, a bladder which has been subjected to considerable distention is much more liable to become infected. In any event, extreme care, utilizing perfect aseptic technic, must be exercised during catheterization; no part of the catheter which is to be inserted beyond the meatus should be touched except with a sterile instrument or the sterile gloved hand. Gentleness is likewise important. Following catheterization the patient should be encouraged to void in a few hours, before sufficient urine has accumulated to produce pain. If difficulty is still experienced in voiding, catheterization should be repeated in eight or ten hours, because the normal mechanism is usually regained more rapidly than it is if one waits until distention develops to the point of pain. Intermittent catheterization is unwise when a definite obstruction is present and remains. Under such circumstances it is preferable to insert a retention catheter, although frequently suprapubic cystostomy may be indicated.

Following certain operations, e.g., resection of the rectum, retention of urine may persist for many days; it is assumed in such instances that the retention is not due to simple reflex spasm, but to actual division of the pudic nerve which supplies the bladder. Numerous other conditions produce retention of urine in addition to other disturbances in bladder function; the term neurogenic bladder is applied to such cases.

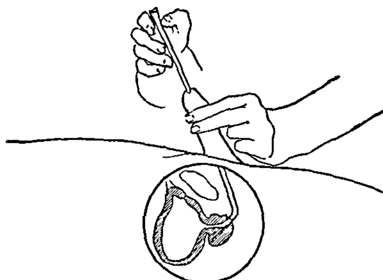

Fig. 14. Technic of catheterization in the male. Note the sharp curve made by the membranous and prostatic urethra; this angulation adds to the difficulties of catheterization, particularly when enlargement of the prostate is present.

Neurogenic Bladder. The term neurogenic bladder refers to disturbances in urinary function which are not due to disease of the urinary tract but to disease, injury, or abnormal function of the nerves supplying the bladder. The disturbances produced by neurogenic factors vary greatly and are often associated with or complicated by other lesions, inflammatory or neoplastic. Strictly speaking, any variation in bladder function from the normal is classified as neurogenic when the primary factor lies in the central nervous system. When the abnormal function is secondary to changes in the bladder wall, induced by trauma, prostatic or other obstruction, and the like, the term myogenic bladder is used.

The disturbances in bladder function which are of neurogenic origin may be either hypotonic or hypertonic. Of the first group, the etiologic factor is usually tabes, or occasionally trauma; reflex causes following rectal and pelvic operations especially are frequently responsible for a hypotonia bladder. In The hypertonic type, irritative lesions play a great role, such as neuritis, some spinal cord tumors, spinal meningitis, and so forth. To understand the mechanism of production of these types of bladder disturbances, it is necessary to have a clear understanding of the physiologic mechanism of the bladder.

The function of the bladder is divided into that exerted by the bladder wall (expulsive force) and that due to the sphincter control (the "lock"). The latter mechanism is made up of the internal sphincter, which is but a thickening of the circular muscle layer of the bladder wall, and the external sphincter, which consists of the muscle in the urogenital trigon and is influenced in its action by the anterior part of the levator ani. When the posterior roots of the spinal cord are diseased as in tabes dorsalis, an atonic bladder results; in diseases such as spina bifida, in which both anterior and posterior roots may be damaged, marked retention with low intravesical pressure and increased bladder capacity is apt to be present.

The autonomic nerve supply to the bladder contains both sympathetic and parasympathetic fibers from the standpoint of function; however, this is difficult to demonstrate anatomically. Actually, all three types of impulses (pain, stimulation, and inhibition) are carried by the autonomic nerves supplying the urinary bladder. These fibers are carried in the parasympathetics of the second and third sacral roots and in the sympathetics arising from the second dorsal to the fourth lumbar roots. This wide distribution explains the imperfect results when merely the presacral nerve is resected in attempt to relieve pain in the bladder and to decrease its capacity. The

occurrence of pain in itself may be primarily responsible for inhibition of normal contraction of the bladder wall, and thus produce retention of urine. Such cerebral inhibition is, of course, a normal impulse; in neurogenic bladders, however, it has a great clinical importance since suddenly impaired cerebration (organic or functional) may cause its release and thus produce incontinence. On the other hand, augmentation of this inhibitory influence as by fear, etc., may produce urinary retention (psychic retention). Postoperative retention is intimately tied up with inhibition, being partly due to the fear of initiating the act of voiding, particularly in pelvic and rectal operations; reflex spasm of the sphincter may also be important.

CLINICAL MANIFESTATIONS. The manifestations produced by a neurogenic bladder vary considerably with the type of disease responsible for it. As already indicated, two groups of disturbance are recognized, hypotonic and hypertonic; both types, however, may play a part in the symptomatology in a particular patient. *Incontinence* (involuntary urination) is an important clinical manifestation and implies an inability of the patient to control the voiding act. When it occurs during sleep, it is called enuresis. It may be associated with a retention of urine, i.e., the bladder may be dilated to capacity and small amounts of urine will dribble through the urethra constantly; this is an undesirable situation because of the increased danger of infection. *Frequency* of urination is most often due to organic disease (e.g., urethritis and cystitis) but may also be due to abnormal impulses carried by the autonomic nerves. *Pain* is present when retention is associated with a hypertonic state of the musculature. *Inability to void,* whether associated with pain or not, is likewise most often due to organic obstruction (enlarged prostate, and so forth); if due to neurogenic factors, it is produced by either a paralysis of the expulsive power of the bladder or a failure of the sphincters to relax. *Lack of desire to void* is distinctly a manifestation of a neurogenic bladder and is associated with marked *retention of urine*. Retention of urine is objectively manifested by the demonstration of increased bladder dullness but more certainly by catheterization. If other lesions are present or if catheterization has induced an infection, the manifestations due to neurogenic factors will obviously be complicated. The data furnished by the cystometer (Rose and others) give considerable information as to the type of neurogenic disturbance which is present; thorough physical and especially neurological examination will usually reveal the true nature of the disease responsible for the urinary abnormalities.

TREATMENT. Obviously, therapy depends on the type of disturbance present. Retention of urine due to reflex causes has already been considered. When tabes dorsalis is responsible for the retention, catheterization is used as necessary; on account of the low intravesical pressure, little damage to the kidney due to the pressure is sustained. Hence, bacterial contamination is less likely to lead to serious infection of the kidney. In the hypertonic bladder with retention, however, catheterization is less permissible because of the likelihood of the production of infection.

In the case of spinal cord injuries, the problem of treatment is more difficult because of the sudden development of the disturbance which is in most cases due to an inability to void, incontinence, or retention. It may be difficult, moreover, to estimate accurately the seriousness of the cord damage.

In general, there is much disagreement among urologists as to the treatment of this group of neurogenic bladders, sustained, for example, by injury to the spinal cord. It is agreed, however, that attempt should be made to produce an "automatic" bladder by effecting evacuation through the mechanism of massage of the bladder at regular intervals, four to eight times per day. In a large percentage of cases an automatic bladder, which will empty itself fairly completely with stimulation or effort on the part of the patient, will be developed. If this fails, tidal irrigation arranged in a manner similar to that described by Munro (28) may be instituted (Fig. 15). Less preferable is a retention catheter. Most urologists believe that a retention catheter or a suprapubic cystostomy is preferable to frequent catheterization.

If infection develops with the conservative methods and in spite of chemotherapy, a retention catheter or suprapubic cystostomy may be necessary. Transurethral resection of the vesical neck is often effective in eradicat-

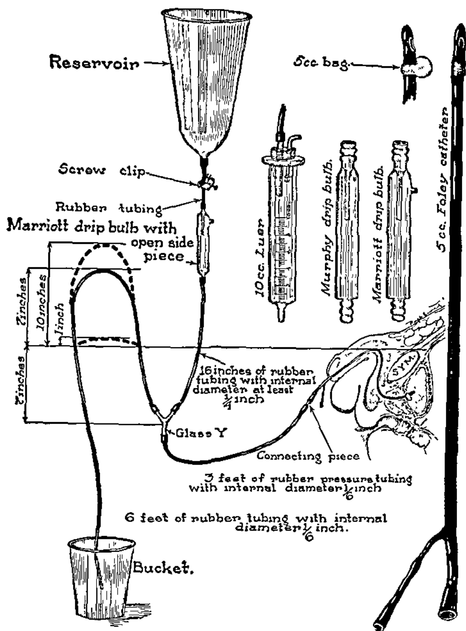

Fig. 15. Apparatus for continuous tidal irrigation. (Modified from Lawrie-Nathan, 1939.) Either a 10-cc. Luer syringe or a Murphy or Marriott drip bulb, as illustrated, may be used to provide a continuous drip. *An air vent is essential in this unit. 60 drops per minute is a suitable rate of flow from the antiseptic* solution, as regulated by the screw clip. The height of the overflow tube above the symphysis pubis is adjusted according to the state of the neurogenic bladder. A height of about 2 inches is recommended for the atonic stage with gradual elevation to 10 inches or more as the hypertonic stage is reached. It is important to exclude all air in assembling the apparatus. This can be accomplished by connecting the rubber tubing to the catheter after the air bubbles have been evacuated from the tubing and while fluid is still running through the system and at the same time escaping from the bladder through the catheter. The reservoir must always contain fluid, and the end of the drainage tube must always be kept above the level of the fluid in the drainage bucket. As the bladder fills, the intravesical pressure rises until it reaches *the level of the overflow tube, at which time siphonage takes place and the* bladder empties. The cycle then starts again. To maintain proper asepsis the reservoir hsould be a bottle with a small mouth which can be plugged *with sterile gauze. (From Military Surgical Manual III, National Research Council*, W. B. Saunders.)

ing the retention caused by a hypertonic neurogenic bladder; incontinence may follow this procedure, especially in the hypotonic bladder.

PROSTATE

The prostate is a gland composed of a framework of elastic and connective tissue in which are secreting glands which empty into the posterior urethra by many ducts.

Acute Prostatitis. Acute infection of this organ is due for the most part to gonorrheal infection arising from the urethra. Infection may likewise result from nonspecific urethritis, or from trauma due to instrumentation. The infection produces pain in the perineum which is accentuated by walking. Burning and frequency of urination and occasionally terminal dysuria are usual symptoms. The systemic reaction may be quite severe, consisting of fever and its allied symptoms. Rectal examination reveals a tender and swollen prostate. On rare occasions an abscess forms with accentuation of the manifestations just mentioned.

TREATMENT. Chemotherapy, rest in bed, application of local heat, and symptomatic care represents useful therapeutic agents. There must be complete abstinence from sexual excitement. Prostatic massage is strictly contraindicated. Any abscesses which form usually rupture into the urethra but may demand drainage through the perineum.

Chronic Prostatitis. A chronic infection of the prostate may develop insidiously or be the result of an acute prostatitis. Mild pain in the perineum and burning and frequency of urination are common symptoms. A mild urethral discharge containing shreds and pus cells is usually present; such shreds and pus cells are readily found in the urine. Rectal examination will reveal a large, boggy prostate, frequently with soft, fluctuant areas. Massage of the prostate expresses the purulent "shreddy" material into the urethra from which smears may be made for the establishment of the type and severity of the infection.

Treatment of prostatitis has been improved with chemotherapy. While on chemotherapy, prostates normal except for infection should be massaged only three to five times. Persistent massage may retain infection by attendant trauma. Only hyperplastic prostates should be massaged, along with antibiotics, until they are reduced in size. They cannot be cured of infection as their drainage mechanism is abnormal, but they can be materially benefited by this treatment.

Prostatic Hypertrophy. Prostatic hypertrophy is due to an endocrine abnormality. Lower and Johnston (1931) explain the mechanism of development of the disease by the fact that the testicular tubules which utilize anterior pituitary hormone become atrophied, thereby allowing an excess amount of hormone to accumulate and act upon the prostate and seminal vesicles, resulting in their enlargement. The hypertrophy is noted particularly in the lateral lobes, but on many occasions it appears to arise in submucosal glands of the prostatic urethra. The enlargement is due to an adenomatous hypertrophy, although at times there may be considerable fibrosis scattered throughout the gland. The disease occurs only in late adult life, rarely before the age of fifty or fifty-five, when poorly understood endocrinologic changes take place in the male.

CLINICAL MANIFESTATIONS. One of the first evidences of the disease is frequency of urination, particularly at night. The patient usually has difficulty in starting the stream and when through voiding frequently has the sensation that the bladder has been incompletely emptied. The stream is weak; dribbling at the end of urination is characteristic. As the hypertrophy increases, the amount of urinary retention in the bladder increases until even the patient may be aware of the mass produced by the distended bladder. The constant presence of a distended bladder produces deleterious effects upon the kidney, consisting primarily of hydronephrosis, atrophy of the cortex, and, if infection is present, pyelonephritis or pyonephrosis. The renal impairment may be serious, regardless of whether or not infection is present, resulting at times in uremia. Any or all of the symptoms of uremia, including a clouded sensorium, delirium, weakness, headache, anorexia, vomiting, etc., may be present. The nonprotein nitrogen content of the blood will be elevated. Acute retention of the urine is commonly experienced and frequently de-

mands catheterization before relief is obtained.

Infection (cystitis) may be present early in the disease but usually does not take place until catheterization has been instituted. With infection, other symptoms, including burning and pain upon urination, become prominent. Fever and its allied symptoms are apt to be present. The infection ascends readily to the kidney and may be instrumental in the development or exacerbation of the symptoms of uremia.

Examination of the patient will usually reveal a distended bladder. The amount of retention is useful in estimating the severity of the obstruction and may be determined by measuring the amount of urine obtained by catheterization immediately after voiding (residual urine). A rectal examination rarely fails to reveal a large prostate with firm lobes, but occasionally considerable obstruction may be present due to enlargement of the median lobe with only mild increase in size of the prostate itself. Cystoscopic examination is a reliable method of confirming the diagnosis. If infection is present, pus cells will obviously be found in the urine. If much renal damage is present, albumin will likewise be present. The degree of renal impairment may be estimated by the degree of elevation of the nonprotein nitrogen content of the blood.

TREATMENT. Unless the disease is severe enough to demand operative treatment, catheterization and cystoscopic examination should be avoided. When it becomes necessary to resort to the two latter procedures, extreme care as to aseptic technic and gentleness must be utilized. Large quantities of water should be taken at all times. Urinary antiseptics as mentioned previously will be helpful in minimizing infection. It is thought by many that a distended bladder of the type encountered in prostatic hypertrophy should not be decompressed (by catheter) suddenly, i.e., not all the urine should be removed at one time, on account of damage which may be inflicted upon the kidneys by the sudden change in the pressure against which the kidney is accustomed to excrete. However, this danger has no doubt been greatly exaggerated.

Although operative removal of the prostate offers great relief to patients afflicted with this disease, urologists have learned that such procedures cannot be done without adequate preoperative treatment. In addition to proper decompression of the bladder over the course of at least two or three days, the bladder must remain empty or nearly so for several more days, perhaps best accomplished by an indwelling catheter. Observations on the nonprotein nitrogen content of the blood and the phenolsulphonphthalein excretion of the kidneys must be made at intervals to determine the patient's progress; such tests should approach normal values before operation is resorted to. Fever is likewise a manifestation which strongly contraindicates operative procedures. It is of course essential that adequate caloric intake be maintained during the preoperative period. Fluids must be forced.

Prostatectomy may be performed by the 1. suprapubic, 2. retropubic, 3. perineal, or 4. transurethral method. The suprapubic method, which is carried out by a suprapubic cystostomy, was originally the most popular. It was originally performed in two stages, with an interval of several days for bladder drainage, but in patients who are good risks or have little urinary infection, may be performed in one stage. When supported with good preoperative and postoperative care including blood transfusions, a one-stage procedure will be safe in most patients except when severe infection, elevated blood nonprotein nitrogen, or other such complications exist. Transurethral resection is performed without a skin incision by passing a resectoscope through the urethra up to the prostate. It is most adaptable in patients with small bars, contractures, or small middle lobes but is used by some urologists in nearly all cases of prostatic hypertrophy. The relatively high recurrence rate (particularly in large prostates) and the high incidence of operative and postoperative hemorrhage represent disadvantages of the method of transurethral resection. However, Emmett (29) of the Mayo Clinic reports an incidence of only 4.4 per cent (over a three-year period) requiring a second operation, and a mortality rate of only 1.2 per cent over a nine-year period. However, it should be added that not all urologists report such good results; in the hands of many, 10 to 15 per cent of patients require

rehospitalization and reoperation. Perineal as well as retropubic prostatectomy requires a high degree of surgical skill.

Carcinoma. Malignant tumors of the prostate are commonly encountered, occurring as a rule, however, at a later age than does prostatic hypertrophy. Apparently the tumor originates in the posterior lobe, which is not as a rule affected by prostatic hypertrophy. Because metastases occur early, and patients come to the physician late, the prognosis is not good.

Frequency of urination is the most common early symptom. Hematuria may be present at times. After the growth has extended throughout the gland, acute retention is frequently encountered. Occasionally the first symptoms will be severe pain in the back and pelvis caused by metastases, although the original tumor in the prostate may be proved at autopsy to be confined to only a small nodule. Diagnosis can usually be made by rectal examination by the stony hard, nodular surface, except in those instances when the initial growth remains small. Cystoscopic examination may not be of much diagnostic aid, but portions of the gland removed by the "punch" may reveal malignant tissue. Elevation of acid phosphatase is of little value diagnostically unless the level exceeds 10 King-Armstrong units.

Treatment of carcinoma of the prostate is surgical removal, provided no metastases are demonstrable and the lesion remains within the prostatic capsule. In a series of 190 patients having no evidence of metastases, Jewett (30) reports radical perineal prostatectomy resulted in a five-year survival in 50 per cent of cases. Palliation with radiotherapy may relieve pain; transurethral resection relieves obstruction. Remarkably, Huggins (31) has found that castration is followed by recession of the growth (including metastases) in 75 per cent of the cases. Estrogen (stilbestrol) is likewise effective in controlling carcinoma of the prostate, but a combination of castration and stilbestrol appears preferable. Although stilbestrol therapy and castration are effective in prolonging life (for a year or two) and relieving symptoms, they are not curative. Adrenalectomy (Huggins, 32) and injection of radioactive gold (Flocks, 33) are likewise helpful as remedial procedures though not curative.

Prostatic Calculi. Calcareous deposits occasionally develop in the dilated prostatic alveoli and may produce the symptoms of prostatitis. Removal may be accomplished by the urethroscope or by prostatectomy.

SEMINAL VESICLES

Acute vesiculitis is no doubt a frequent disease, and in most instances is secondary to gonococcal infection of the posterior urethra. It is difficult to differentiate accurately the symptoms produced by acute prostatitis, acute posterior urethritis, and those manifested by acute vesiculitis. It is agreed, however, that the pain in the latter disease is frequently localized to the region of the rectum. Rectal examination reveals tender and distended vesicles, from which may be expressed a large amount of tenacious material containing large numbers of pus cells. It is probable that this suppurative process rarely progresses to the state of abscess formation. The treatment is symptomatic, but includes complete abstinence from sexual excitement. Expression of the purulent material by gentle massage rectally, followed by urination, is probably helpful but is dangerous because of the danger of production of acute epididymitis.

Chronic vesiculitis in most instances is the result of acute vesiculitis but may develop without any evidence of preëxisting acute infection. It is apparent that in the latter instance, the streptococcus on many occasions is the etiologic factor. Symptoms are extremely variable, consisting primarily of mild pain in the perineum and along the rectum, but may be absent altogether. Ejaculation may be painful. A mild urethral discharge may be present. The disease is occasionally discovered by rectal examination performed as a part of a complete examination made, perhaps, in an effort to discover a cause for a chronic arthritis. When chronically infected, the walls may be palpated as being thickened and roughened.

Careful massage of the vesicles every five or ten days may be an effective method of treatment. Chemotherapy, including particularly the use of penicillin or sulfathiazole, should be instituted. Injection of 5 to 10 per cent argyrol into the vesicle through the vas

deferens is considered by many urologists as being effective in relieving the pain of certain types of arthritis which are due to focal infection in the seminal vesicles. Vesiculectomy may be done but advisability is doubtful.

On rare occasions the seminal vesicles may be the seat of *tuberculosis*, in which instance vesiculectomy may be indicated providing the diagnosis can be made.

URETHRA

Wounds. Injury to the urethra is not uncommon and may be produced by direct laceration or by a crushing injury such as that sustained by falling astride a fence or similar object. When there is an obvious laceration of the urethra, repair should be performed by interrupted sutures over a soft rubber catheter.

Occasionally rough catheterization results in abrasion and even a complete tear through the wall. Although strictures may result from injuries as well as infections (gonorrheal), the immediate effect of rupture or laceration of the urethra is the escape of urine into the surrounding tissues.

EXTRAVASATION OF URINE. Leakage of urine takes place readily through tears in the urethra into adjacent tissue and, because of the concomitant infection associated perhaps with gangrene, may be so dangerous as to threaten life. It is now evident that the urine acts as a vehicle to disseminate infection; urine in itself, unless the extravasation is large and continuous, is not a necrotizing agent. With the advent of the antibiotics, extravasation of urine, therefore, carries less risk because the infection can be controlled. If the injury is located in the penile urethra, the extravasation will usually be limited to the shaft of the penis; if in the deeper part of the urethra, but still in front of the triangular ligament (urogenital diaphragm), the extravasation may extend into the scrotum and anterior abdominal wall. In lacerations behind or posterior to the triangular ligament, the urine may infiltrate into the posterior perineum around the neck of the bladder and the deeper portion of the anterior abdominal wall. The tissue affected by the extravasation rapidly becomes swollen and edematous. *Tenderness* is variable but is increased in the presence of infection which is prone to develop in the involved area. The skin may become reddened; if the condition is neglected, areas of gangrene may develop. Malaise, prostration, and fever, with its accompanying manifestations, are commonly observed. The toxemia resulting from extravasation of urine is profound; death is apt to ensue unless adequate and early treatment is resorted to.

Treatment consists of immediate and numerous incisions to prevent fatal spread of infection which is so prone to develop in the tissue where extravasation has occurred. It is usually necessary to perform a suprapubic cystostomy, unless a retention catheter can be inserted into the bladder through the urethra.

Foreign Bodies in the Urethra. Foreign bodies encountered in the urethra include objects inserted by the patient or stones arising usually in the kidney or bladder. The symptoms of pain and difficulty associated with urination usually disappear after removal of the foreign body.

Urethritis (Nonspecific). Mild acute urethritis not of gonorrheal origin caused by *E. coli*, streptococcus, *Micrococcus catarrhalis*, staphylococcus, and so forth, is relatively frequent and may cause the patient (male or female) considerable worry because of the similarity of the symptoms to gonorrhea in the early stages. It may also be produced by instrumentation or chemicals injected for prophylactic reasons. Mild frequency and burning on urination, and urethral discharge are common manifestations. Most of them subside spontaneously after a few days, especially if effort is made to drink a large amount of water and to void frequently. Unless the infection is of chemical or instrumental origin, chemotherapy or the injection of 1 per cent Protargol two or three times a day for two or three days is usually effective in eradicating the infection.

Gonococcal Urethritis (Gonorrhea). Gonorrhea* is a venereal disease contracted with few exceptions only by sexual contact and is first manifested as an anterior urethritis after an incubation period of four to six days. The first symptom is a burning or stinging pain in the anterior urethra upon urination. A

* Infection in the female is discussed in Chapter 40.

slight discharge of turbid, sticky secretion is noted which becomes thick, purulent, and profuse within a few days. The meatus is reddened and swollen. Frequency of urination is always present but is not severe during the four to eight days while the infection is limited to anterior urethritis. Unless effective treatment is instituted early, posterior urethritis develops in nearly all patients and is manifested by a pronounced exacerbation of symptoms. Mild fever is commonly present. The pain experienced during urination (especially at the beginning and end) becomes severe. The patient may be awakened frequently at night by a painful erection with curvature of the shaft (chordee). After six to eight weeks the symptoms, as a rule, decrease, the discharge lessens, and convalescence is well under way, although in the untreated case a cure is not expected for many months.

A mild chronic urethritis exists for a time, but on the average no manifestations remain after five or six months except perhaps the morning drop (slight urethral discharge noted in the morning upon arising). The chronic stage of the infection usually represents a residual infection of the mucous glands along the urethra or residual infection of the periurethral tissue. On many occasions, however, the chronic stage of the disease, as manifested by mild burning and frequency of urination and slight urethral discharge, are produced by complications such as prostatitis and seminal vesiculitis. The patient is usually infectious as long as a urethral discharge is present.

The *diagnosis* of the acute stage is readily made by examination of the urethral discharge. Gram-negative intracellular and extracellular diplococci are present in large numbers. The intracellular characteristic of the organisms is extremely important diagnostically because extracellular gram-negative diplococci are normal inhabitants of the urethra and may be found in nonspecific or chemical urethritis. Urinary shreds arising from the posterior urethra are diagnostic of the chronic disease. The two glass test (see p. 1118) may be helpful in determining the presence of posterior urethritis, since there will be no turbidity of the first glass if the bladder or kidney is the seat of the infection. The confirmation of the termination of the disease may be important, particularly from the standpoint of infectivity. If the disease is still present, though symptoms are few or absent, the inflammation can usually be relighted by strenuous exercise, sexual excitement, or insertion of a urethral sound.

COMPLICATIONS. The development of prostatitis and seminal vesiculitis in association with posterior urethritis is not uncommon. In the acute stage of gonorrhea, the symptoms are increased in severity by the development of prostatitis and seminal vesiculitis but can be differentiated only with difficulty from acute posterior urethritis. An acute epididymitis may be secondary to acute posterior urethritis and seminal vesiculitis and frequently results from errors in treatment such as instrumentation, excessive treatment, or strenuous exercise. The manifestations are described elsewhere. Acute balanoposthitis (inflammation of the glans penis and prepuce) is not a common complication; it occurs usually only in the presence of phimosis. Acute arthritis (see Ch. 24) occurring six to twelve weeks after the acute onset of the urethritis is not uncommon. Periurethral and prostatic abscesses are uncommon but may add considerably to the severity of the symptoms. They may break spontaneously in to the urethra but on many occasions require incision from the exterior. Acute lymphadenitis due to a Ducrey infection is not an uncommon complication of gonorrhea but is fortunately not a serious one although it may suppurate. Swelling and tenderness of the inguinal lymph nodes may also be produced by secondary pyogenic infection. The lymphadenitis due to the gonococcus does not suppurate, but if secondary pyogenic infection is present (e.g., balanoposthitis), the lymph nodes may become acutely inflamed and fluctuant and require incision.

Urethral stricture occurs usually in the bulbomembranous urethra, results from periurethral infection, but rarely develops earlier than 18 to 24 months following the acute gonorrheal infection. It is much more common in Negroes than whites, and is frequently multiple as contrasted to the solitary strictures which follow trauma. Early manifestations consist of the appearance of slight urethral discharge, mild burning upon urination,

and decrease in size of the stream. The stricture may progress to the point that the stream is reduced to a dribble. Acute retention may develop. Because of the ulceration which frequently develops proximal to the stricture, urinary extravasation or even fistulas may develop.

Treatment is most effective if started early before serious narrowing is produced, and it *consists of dilatation of the urethra every four to six days with as large a sound as possible.* No sounds smaller than 16F or 18F should be used because of the danger of injury to the urethral wall. The size of the sound should be increased at each successive treatment until a size 28F can be passed. Any dilatation which is followed by the escape of more than a small drop of blood is harmful in that it indicates injury; thus the deposition of more scar tissue is encouraged. Unfortunately, even this amount of dilatation is not permanent and the patient should be instructed to return every six months or year for further dilatation to prevent serious contraction. If the stricture is so pronounced as not to allow the passage of a size 18F sound, it is usually wise to pass a filiform bougie which is then threaded on to a small sound and pushed into the bladder ahead of the sound. In severe cases plastic operations may be indicated and are usually successful.

TREATMENT OF GONORRHEA. Since gonorrhea can be prevented, even after exposure, the most important feature in the treatment is prophylactic. Penicillin in a dosage of 50,000 units given every four hours for six to eight doses will rarely fail to prevent the disease. Likewise, sulfathiazole given in doses of 80 to 90 grains and continued in a dose of 60 grains per day for six to eight days will prevent the disease. Prophylaxis by local means was known to be effective long before the introduction of sulfonamides; distention of the urethra for five minutes with 2 per cent Protargol up to eight hours following exposure rarely failed to prevent the disease in men. It appears logical then that local treatment combined with chemotherapy might be advisable in the prophylactic treatment. In actual practice, however, prophylactic therapy is difficult to carry out, except in the Army and Navy where compulsion is effective.

Although sulfonamides offered a great improvement over local methods in the treatment of gonorrhea, penicillin is even more effective. In over 95 per cent of cases a cure will be obtained by 80,000 units of penicillin or less, given intramuscularly every two to four hours in individual doses of about 10,000 units. Such therapy with perhaps double the dose will cure even the sulfonamide-resistant cases. In a high percentage of cases a cure can even be expected with one 300,000-unit dose of penicillin in beeswax and peanut oil given by hypodermic. Therefore, most of the foregoing statements about chronicity and complications would in reality apply only to the untreated case. It must be emphasized, however, that occasionally patients may still harbor gonococci in their urethra for some time after symptoms have disappeared, thus indicating the importance of examination of urethral smears and urine sediment. In patients resistant to penicillin, aureomycin should be tried.

EPIDIDYMIS

Acute Epididymitis. Acute infection of the *epididymis is usually gonorrheal in origin* and is a common complication of untreated gonorrhea. Since it develops only in the presence of posterior urethritis, it rarely is encountered earlier than three weeks following onset of the infection. Ordinarily, abstinence from sexual excitement, limitation of exercise, and careful supervision of treatment will prevent acute epididymitis.

The most important manifestations are tenderness and pain which develop with swelling of the epididymis and are roughly proportionate to it. A moderate amount of fever may be produced by epididymitis, regardless of its cause, but is obviously more pronounced in the acute infections. The pain and tenderness may be so severe as to be completely disabling. Rarely does the process proceed to suppuration, regardless of the cause.

Aside from penicillin, the most important feature in the *treatment* is bed rest. However, if bed rest is impossible, the application of a suspensory for the scrotum will be very helpful. Even while in bed, the pain will be greatly relieved if some sort of suspensory is applied so as to prevent dependency of the scrotum. The application of heat or cold will aid in

relief of the pain. Ordinarily the pain disappears and the swelling recedes within a few days after institution of bed rest, but if the above treatment does not afford relief, a short incision into the distended epididymis is frequently efficient in eliminating the pain, although it may not shorten the convalescence to a very great extent. The fluid obtained by such a procedure may be turbid but is rarely thick and purulent. The disease subsides rapidly under penicillin therapy if the lesion is gonorrheal in origin.

On many occasions acute epididymitis is not of gonorrheal origin. Especially is this true in elderly men who may develop the disease in the absence of a significant posterior urethritis, which ordinarily must be present before acute epididymitis develops. Vigorous instrumentation such as that associated with frequent cystoscopic examinations is not infrequently followed by acute epididymitis. Ligation of the vas deferens prevents epididymitis, and for that reason is frequently done before urethral instrumentation is performed, especially in elderly men. The nonspecific type of epididymitis is more apt to suppurate than the gonorrheal type and may require incision. Otherwise the treatment of the two types is largely the same.

Chronic Epididymitis. Acute epididymitis if untreated usually resolves into chronic infection of the organ, which may remain enlarged permanently, though produce no symptoms. Recurrent attacks are not uncommon but may be prevented to a certain extent by treatment of any existing urethritis and by having the patient wear a suspensory. The amount of pain and tenderness is extremely variable. Sterility results much less often than would be expected. Occasionally it may be necessary to excise the epididymis.

Tuberculous Epididymitis. Tuberculous infection of the epididymis is usually secondary to tuberculosis of the kidney or seminal vesicle. It begins in the globus minor, spreads to the entire organ, and may involve the testicle. The invasion is usually insidious, producing a slow, gradual enlargement without pain. There is a tendency for fluctuant areas to develop which may break down and form permanent sinuses. Because of the failure of response to conservative treatment, excision is usually indicated as soon as the diagnosis is made, providing there are no contraindications.

Spermatocele. Occasionally a collection of cloudy fluid containing spermatozoa collects about the epididymis but does not invade the testis. Such a cystic swelling is called a spermatocele. Very few symptoms are present, but the lesion may be confused with chronic epididymitis or tuberculosis of the epididymis.

TESTICLE

Undescended Testicle (Cryptorchidism). The testicles descend during the latter months of fetal life, but cryptorchidism is noted in about 15 per cent of babies at birth. The testicle may lie within the abdominal cavity but more frequently is present in the inguinal canal. Descent of the testicles will occur, however, in a large percentage of these infants within a year or two after birth. The main cause of the lack of descent usually appears to be shortness of the blood vessels of the vas; abnormalities of the inguinal canal may also exist. In view of the effect of antuitrin therapy, the primary cause appears to be hormonal imbalance.

It is essential that cryptorchidism be treated sometimes during childhood, since it has long been known that the increased temperature in the abdominal cavity over that in the scrotum is sufficient to inflict serious damage to the spermatogenic function of the testicle, which develops at puberty. Patients with bilateral cryptorchidism are usually sterile. Many observers have reported a greater incidence of malignancy in undescended testes than in descended testes, but there is not agreement on this point.

Treatment. During recent years the gonadotropic hormone of pregnancy urine (antuitrin S) has been used with varying results in the treatment of cryptorchidism, but on account of frequent recurrence and damage to the testicle, it is being abandoned by many physicians. Operative correction, preferably between the ages of eight and twelve years, is again becoming the procedure of choice. A hernia is usually present along with the undescended testicle and should be repaired at the same time.

Operation consists of opening the canal, finding the testicle, dissecting away the short

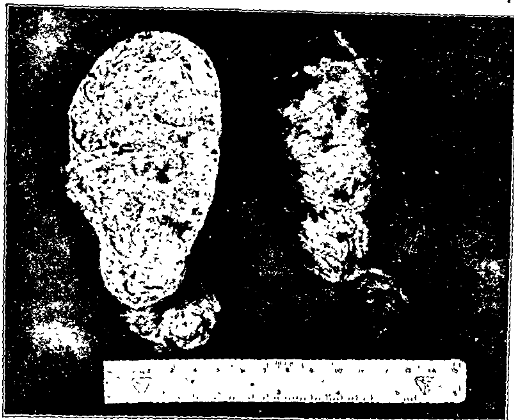

Fig. 16. Teratoma of the testicle in a man, aged 28. Enlargement of the testicle was first noted four months previously. The Aschheim-Zondek test was positive; two weeks after operative removal of the tumor it was negative.

fibrous tissue strands connecting the tortuous vessels, freeing the vas, and anchoring the testicle to the fundus of the scrotum (Bevan) or to the subcutaneous tissue of the thigh (Torek). The latter procedure requires a minor operation several weeks or months later to separate the attachment to the thigh.

Torsion of the Spermatic Cord. Because of a weakened gubernaculum associated with maldescent, the testis may be suddenly pulled upward by the cremaster muscle in such a manner as to allow twisting of the cord. This rarely occurs in children. The blood supply may be completely strangulated, in which case gangrene of the testis occurs, terminating in an abscess or atrophy of the testis or both. *The pain associated with torsion of the cord* is intense. Nausea, vomiting, and mild shock may be present. *Unless reduction can be attained within an hour after development of the torsion, operation (orchidectomy) is advisable.*

Miscellaneous Diseases of the Testis. As a tertiary manifestation, *syphilis* may affect the testis either as an *interstitial orchitis* or as a *gummatous degeneration. The swelling* is insidious and associated with no pain or inflammatory signs. Antiluetic treatment produces *a retrogression* of the swelling.

There are a few diseases, among which mumps is the most important, which may be associated with *orchitis.* During the acute process the testis may be swollen and tender, but atrophy later develops. *Tuberculosis of the testis* may be encountered in association with tuberculous epididymitis, but is a rare lesion; orchidectomy will usually be strongly indicated.

Tumors of the Testis. With the exception of a few benign tumors, such as fibroma, most tumors of the testis are *malignant. They may be divided into two major groups:* 1. teratomas (Fig. 16) and 2. seminomas. *Teratomas arise from the sex cells but contain many* different types of tissue, including muscle, cartilage, and fat. They occur in young adults, *are very malignant, grow rapidly, and metastasize* to the lumbar chain of lymph nodes as well as to the nodes in the retroperitoneal *portion of the upper* abdomen. Reference has

already been made to the relation of malignant tumors to cryptorchidism. It should be mentioned that tumors of the testicle frequently develop insidiously, the patient being entirely unaware of their presence. Even if he consults a physician, the enlargement may be passed up. In a few instances a relatively small tumor may metastasize and produce manifestations of epigastric enlargement before the patient is aware that there is anything wrong with his testicle. In teratomas, the amount of *chorionic* hormones in the urine is increased, whereas in seminomas the amount of *hypophyseal* hormones is increased; the former gives a positive Aschheim-Zondek test, but the latter does not.

TREATMENT. As soon as the diagnosis is made, orchidectomy should be performed unless metastases are obvious and growing so rapidly as to threaten life within a very short time. Dissection of lymph nodes at the time of the orchidectomy does not appear to increase the chances of a cure. Radiotherapy is effective in seminomas but only occasionally so in teratomas. Ultimate results from the standpoint of five-year cures are very poor in teratomas and fair in seminomas.

PENIS

Phimosis. Frequently, the orifice of the prepuce is congenitally too small to allow retraction behind the glans (phimosis). This allows accumulation of smegma which may be the source of considerable irritation. This irritation may at times be associated with considerable infection of the glans and prepuce (balanoposthitis). Adhesions between the glans and prepuce are frequently present. If the preputial orifice is large enough to allow retraction, these adhesions may be separated readily in children without resorting to operative procedures.

Circumcision is strongly indicated in all instances when there is an actual phimosis and is advisable when the prepuce is redundant. It may be performed at any age. Local or general anesthesia may be used, depending upon the age of the patient. A dorsal slit is made backward to within 0.5 cm. of the sulcus. Excision of the prepuce is carried forward on each side with a scissors until the incisions meet in front of the frenum on the ventral side. A generous amount of skin must be left on the ventral side near the frenum so as to prevent deformity of the penis during erection. All bleeding points must be carefully ligated. The cut edges are then approximated with interrupted sutures of 000 catgut.

Paraphimosis. When the prepuce is tight and becomes retracted, it is occasionally difficult or impossible to reduce it because of the edema which rapidly develops. The prepuce distal to the line of constriction becomes very edematous. The glans may be cyanotic and painful; if the constriction is complete enough to block all circulation, gangrene will develop. Reduction should be attempted, but not until the edema of the glans and prepuce distal to the constriction has been squeezed out by digital compression. If this can be accomplished, reduction may be possible. However, if reduction is impossible, and necrosis of tissue seems imminent, it is advisable to cut across the constricted prepuce in a longitudinal direction on the dorsal surface and treat the patient by bed rest and local irrigation until the edema subsides. After the edema and inflammation subside, circumcision may be performed in a routine manner.

Carcinoma of the Penis. Rarely indeed is carcinoma of the penis encountered in a patient who has been circumcised, suggesting that in this instance irritation is an important factor in the development of the tumor which usually appears on the unexposed surface of the prepuce. The tumor is of the squamous cell type and metastasizes slowly to the inguinal lymph nodes (Fig. 17).

The type of treatment required depends upon the size of the carinoma. If small, it may be excised locally, and after a dissection of the inguinal lymph nodes has been performed, x-ray therapy should be given over the penis and groins. If the tumor is large, amputation is advisable. Since these tumors are of the squamous cell type, they usually recede favorably after x-ray therapy.

Congenital Anomalies. Very few of the anomalies of the penis are common unless phimosis, as already discussed, is considered to be congenital. An abnormally small urethral meatus is, however, fairly frequent.

HYPOSPADIAS. This lesion, consisting of the location of the urethral meatus on the *ventral* surface of the penis, proximal to its normal

Fig. 17. Squamous cell carcinoma of the penis. A, appearance of the lesion six month after onset; B, low power photomicrograph from a section of the excised specimen; note that the hyperplastic epithelial growth is invading the subcutaneous tissue.

position, is in reality just as much an anomaly of the urethra as the penis. There are three types: 1. balanic, in which the meatus is located at the junction of the glans and shaft; 2. penile, in which the meatus is located at the penile-scrotal angle; and 3. perineal, in which the meatus is located just in front of the triangular ligament. A downward and backward curve of the urethra, noted particularly upon erection (chordee), is usually present because of an atrophy or absence of the corpus spongiosum and the presence of a fibrous band along the ventral surface of the shaft.

Treatment is operative and is usually confined to the penile type because treatment is less satisfactory in the other types.

Innumerable operations have been devised to correct the anomaly. The urethra is constructed by skin grafts of various types taken from the thigh, prepuce, or scrotum. Scar tissue on the ventral surface must be excised. Furthermore, to prevent deformity upon erection, it is necessary to construct a long urethra.

Epispadias. This anomaly, consisting of the location of the urethral orifice on the dorsal surface of the penis, is less common than hypospadias. The defect which represents a cleft, may extend through the entire length of the shaft and even be associated with exstrophy of the bladder.

Herpes Progenitalis. Single or grouped blisters may arise on the glans penis or skin and a few days after onset the blisters may rupture, after which infection frequently occurs. This lesion is seen frequently and is often ushered in with considerable pain which disappears as soon as the vesicles appear. Treatment consists of cleanliness and dusting powders.

MISCELLANEOUS LESIONS

Hydrocele. There are different varieties of hydrocele (Figs. 18, 19), most of which are congenital in origin. A few appear to be

Fig. 18

Fig. 19

Fig. 18. Hydrocele in a boy, aged five. The swelling was first noted two years previously.

Fig. 19. Hydrocele in a man, aged 55. The swelling was first noted six months previously. All of the fluid was removed by aspiration three weeks previously, but, as is usually the case, reaccumulated rapidly.

caused by infections or by operative procedures. The vaginal type of hydrocele (fluid in the tunica vaginalis) is said by many observers to be the most common, but the fact that most hydroceles extend so far upward along the cord suggests that patency of the distal cord of the funicular process exists at least to a slight degree in most instances.

There is usually a history of a slowly growing mass in the scrotum which, with the exception of the congenital hydrocele, is irreducible. They are pear or oval shaped and may attain an enormous size, containing several hundred milliliters of fluid. The mass is dull to percussion. No impulse is noted over the mass upon coughing except when a hernia is also present and projects downward against the apex of the hydrocele. The mass transmits light except in the rare instances when a chylous hydrocele (containing shimmering cholesterol crystals) is present. The fluid contained in the sac is usually clear and straw colored, but may be colorless and opalescent.

Treatment. The mass may be reduced readily by aspiration, but fluid always reforms, except in infants when multiple aspiration may be curative. Injection of sclerosing substances may at times be successful. There are two types of operative procedures: 1. The bottle operation consists of making a small incision in the apex of the sac and inverting the testicle through the hole in the sac. This is a simple procedure quickly done, but is occasionally followed by a tender mass which may have to be excised later. 2. Excision of the hydrocele sac along the margin of its attachment with the testis and cord probably results in a greater percentage of cures than other procedures. On account of the delayed tendency for the tiny vessels on the cut surface of the sac to stop bleeding, it is essential that a running suture of fine catgut be taken along the cut edge to prevent postoperative hemorrhage, which is a serious complication from the standpoint of obliteration of the blood supply to the testis with resultant atrophy.

Varicocele. Dilatation of the spermatic veins is a common anomaly and is probably of congenital origin. It is usually located on the left side because the left spermatic vein has no valves and empties into the vena cava at right angles. Standing for long periods of time and strenuous exercise are probably secondary etiologic factors. The dilated veins are tortuous and rarely associated with tenderness or pain. Occasionally mild discomfort in the scrotum is complained of, but this is usually relieved satisfactorily if the scrotum is supported with a suspensory. Excision

MILITARY SURGERY

Frank B. Berry

History reveals that with each successive war of any magnitude the problems of military care become more complex because of the increasing number of people involved; the increasing variety and lethality of the weapons and the counter measures used against them; the broader scope and greater mobility of warfare with resulting diversity of geography and climate; and, finally, the increasing medical knowledge, its tools, and its elaborate equipment. In World War II the large numbers of civilian casualties from the bombing of cities brought many new problems which, although incident to war, are not strictly within the field of military surgery; hence, a discussion of them and a plan for their care will be omitted.

As we face the present we are confronted by a new and terrifying force: the thermonuclear (fission) weapons, bombs or guided missiles, fired from the air, land, ships, or submarines. With rocket propulsion these already carry for hundreds of miles with a considerable degree of accuracy. Therefore, we must consider military medicine and surgery under two widely different situations:

1. That concerned with the conventional type of warfare, which will be considered first.
2. That concerned with a major catastrophe or disaster occurring from a sneak attack, delivered simultaneously on many targets with thermonuclear bombs from the air and guided missiles from submarines or more distance bases. This is truly "survival" medicine and surgery and will form the subject of the second part of the present chapter.

Military Surgery, per se, may be defined as the surgical care of the personnel of the Armed Forces, and of others entrusted to their care, in time of war. It is a part of a closely coordinated and highly integrated organization which may be called upon to operate efficiently and simultaneously, under vastly different conditions, in all parts of the world. Such an organization must be flexible and mobile; it must establish long lines of evacuation for its sick, wounded, and disabled; and it must so phase the necessary procedures that the lines of evacuation are always kept open with minimal strain upon them. This requires a high degree of professional judgment so that lightly wounded men who are, or may soon again be, of use in a given combat zone may be held there, while those who are seriously ill or wounded may be evacuated promptly. This prevents confusion in that it not only keeps open the lines of evacuation, but it also prevents unnecessary crowding and muddle in the rear areas and thus lessens the load in replacement centers and in the flow of personnel to the front.

Military surgery has to do largely with a group of comparable individuals, for the most part young, healthy males, who are the recipients of wounds and trauma produced by similar types of weapons, objects, and vehicles. Because of these causative agents similar patterns of injury often appear: "mine" or "deck feet," "trench foot," "desert sore," "frostbite"; identical patterns in flash burns; characteristic wounds caused by high explosives and high velocity missiles; and burns and radiation injury from the use of nuclear weapons. Wounds of major arteries and joints are somewhat analogous and are amenable to standardized forms of treatment. Finally,

of the varicose veins will rarely fail to relieve the symptoms but is not often indicated.

prompt the surgery may be, truly lethal wounds will always be fatal because of their very nature. Hence, the earlier the wounded arrive in the hospitals, the greater will be the hospital death rate, no matter what is done, but there will be a corresponding lowering of the killed in action (KIA) rate and the diminution of the KIA:WIA (wounded in action) ratio. This is a fact not commonly recognized, and it is erroneously thought by some that the farther forward surgery is performed, the greater will be the percentage saved. There is an optimum point for the most forward surgical installation beyond which the law of diminishing returns operates with increasing rapidity, and at the same time such hospitals are exposed to increasing risk of capture, destruction, or damage, plus a progressive inability to function properly. The majority, probably over 95 per cent, of those listed as "killed in action" die from head wounds, by being literally blown to pieces by exploding shells or bombs, or as a result of hemorrhage from extensive wounds of the heart or great vessels. There is no salvage in the first two groups, and that in the third is extremely small but, barring such wounds as these, the wounded usually live, including even a large number with wounds of the heart and great vessels.

THE NATURE OF MILITARY WOUNDS

Inasmuch as the military surgeon must, perforce, be primarily concerned with the wounded soldier, he should be cognizant of the common causative agents and the nature of the wounds they produce. In the production of weapons and ammunition careful studies and tests are made so that the effects produced within given areas and under given conditions are known with astonishing accuracy, i.e., the number, size, distribution, and damaging effect of fragments of shell casing that may be expected from the burst of each shell or bomb, or the pattern of damage caused by a land mine or booby trap. Less accurate studies have been made as to the relationship between causative agents and wounds. According to such data as are available, however, approximately 70 per cent of the wounds in World War II in the Army were caused by artillery and mortar fire, but the mortality from bullets was slightly greater. The direct aim possible with small arms probably accounts for this. In World War I explosive missiles were responsible for 50 to 80 per cent of all wounds, the rate being highest when battle conditions were most stabilized. A parallel condition existed in the European Theater in World War II in that after the German resistance was broken and the tactics were those of pursuit, the proportion of bullet wounds rose.

Causative Agents. Although weapons are employed in various manners in different tactical situations, the injuries inflicted are the same and fall under the headings of explosives, bullets, secondary missiles, violent displacement, exposure to elements, heat and fire, and radiation of varying intensity. Bayonet wounds are rare, and neither chemical nor biological warfare was employed in World War II.

TABLE 1. Causative Agents of Wounds
An Army (U.S.), World War II
September 1944—May 1945

BULLETS		
Unspecified	4,790	
Rifle	5,882	
Machine Gun	1,774	
Total	12,446 =	24.8%
HIGH EXPLOSIVES		
Unspecified	28,130	
Shell (artillery)	5,389	
Mine	1,868	
Booby Trap	81	
Blast Concussion	1,711	
Grenade	22	
Bomb	557	
Total	37,758 =	75.2%
Other	0	
Total Wounds	50,204 =	100.0%

1. The explosives: artillery and mortar shells, bombs, grenades, rockets, land mines, booby traps, anti-aircraft flak
2. Bullets: rifle, machine gun, small arms
3. Fire: flame-throwers, cordite, incendiary bombs, flash (gasoline), phosphorus
4. Bayonets
5. Secondary missiles: masonry, armor, dirt, etc.
6. Crashes: aircraft, glider, vehicle
7. Exposure to elements: frostbite, trench foot
8. Thermonuclear weapons
9. Chemical warfare: gases
10. Biological warfare

common patterns in disease and infection also appear: malaria, amebic dysentery, neuropsychiatric problems, and wound infections due to the clostridia or *C. diphtheriae*.

In order to provide the best and safest treatment for illness and trauma, occurring as they do in war in such a steady and at times almost overwhelming flow, certain measures of standardization are essential. It is not at all the desire to bar individual initiative nor to restrict the ability and skill of the more expert, but rather to stimulate them and direct their effort into the most effective channels and at the same time to assist and instruct the less experienced. Letters and directives are issued, therefore, as necessary sources of advice and information and for the purpose of simplifying, expediting, and improving the surgical care of the wounded, so that those working in the field may be kept informed at all times of new developments, changes in and evaluation of the procedures employed, and their phasing.

The functions of every medical installation from the company aid post to the hospitals in the Zone of Interior, together with the duties of the surgeons in them, should be carefully delineated so that the mission of each is clear. This done, then personnel of proper skill and professional qualifications must be so apportioned among these units as best to accomplish these different missions. Each procedure must be timed in relation to the whole problem involved; otherwise, even though performed with the greatest expertness, it may be entirely wasted if undertaken at the wrong time or in the wrong place. Thus different types of hospitals have been provided, staffed, and equipped for surgery of varying urgency, magnitude, and duration of convalescence. The Field or Mobile Army Surgical Hospital unit (MASH)* is small, highly mobile, and well equipped to care for a relatively few cases of the most urgent surgery by supplementing its intrinsic staff temporarily with expert surgical teams from auxiliary surgical groups. But to enlarge it so as to care for patients who can safely tolerate further travel or to extend its scope of surgery destroys its mobility and clogs its beds. As the MASH unit takes care of the Priority I surgery, so the Evacuation Hospital takes care of the next group, which might be termed Priority II. The primary function of both of these hospitals concerns *Initial* surgery. The MASH unit concerns itself only with resuscitation and immediate surgery necessary to preserve life and limb and correct grave physiological disturbances. Depending upon the tactical situation the Evacuation Hospitals will perform necessary surgery upon such patients as will probably return to duty within a week or ten days. The surgeons will perform careful débridements and reduction of fractures and apply plaster casts for transportation to the rear for the fracture group and those with extensive débridements; and they will perform the initial surgery, which may be definitive, for wounds of the abdomen, chest, and central nervous system.

* Has now been redesignated, similar to platoons of a Field Hospital.

CONVENTIONAL MILITARY SURGERY

Battlefield care forward of the most advanced battalion aid station is itself of first importance in saving the lives of a small group of men, such as those who perhaps might die of hemorrhage from a large vessel of an extremity or asphyxiation of obstructed airways, both of which can be corrected on the battlefield by the aid man or at the advance aid station by trained personnel. The importance of this small zone is not generally realized.

The closer a hospital is to the front lines, the higher will be its case mortality rate. This is because the farther forward it is, the greater the number of wounded it will receive who would ordinarily die on the battlefield. As a rule only a small proportion of the wounded are operated upon within six hours of their injury. This is due to the time required first, to remove them from the field, second, to evacuate them to the hospital, and third, to prepare them for operation. Some of the surgeons working in the field hospitals in World War II, because they had always been taught that six hours was the "golden period" for wound surgery, expressed concern over the fact that the mortality in the zero to six hour group was as high as it was in those receiving surgery in from six to twelve hours, or higher. Here a distinction must be recognized between the surgery of *wounds* and of *lethal wounds;* no matter how perfect, skillful, and

GENERAL ORGANIZATION FOR TREATMENT

Priorities in Treatment. Under ordinary civilian conditions, there is little or no priority in the treatment of the injured inasmuch as there are usually sufficient time and facilities to care for all of them. In combat or during extraordinary civilian catastrophes, the number of injured may be so great as to require triage, or sorting, of the casualties with a definite and prearranged system of priorities of treatment. Proper triage demands experienced professional ability and full understanding of the existing tactical situation; hence, a triage team should consist of surgeons of mature judgment and capable of prompt decision. Hard and fast rules cannot be laid down, and decisions must obviously be governed by such considerations as available personnel, amount of supplies, transportation facilities, and the exigencies of the military situation, which in general supersede other considerations since they are more directly connected with the immediate aims of warfare and the protection of the healthy and intact fighting forces.

In the United States Army, triage of casualties occurs in the Combat Zone in five medical installations in the chain of medical evacuation: 1. Battalion Aid Station; 2. Collecting Station; 3. Clearing Station; 4. Mobile Army Surgical Hospital (MASH), or platoon of the field (surgical hospital); 5. Evacuation hospital. Depending upon the given situation, these may leap-frog each other rapidly, extend laterally, or be temporarily located with relatively long intervening distances. The Collecting Station may be bypassed entirely, and at times the Mobile Army Surgical Hospital may be located in close proximity to an evacuation hospital, or with temporary expansion may indeed serve as one: hence the flexibility of this type of evacuation. The important features to be emphasized are that it is *flexible* and also provides a functional three-point system: a first aid station, triage center (the clearing station) with a hospital for the nontransportable severely wounded very close by, and a larger hospital within a relatively short distance to the rear or lateral.

Emergency Medical Treatment. First aid treatment is administered by the soldier himself or by a fellow soldier, who is usually one of the Company Aid men. The care of the wounded begins *here* on the field. The Aid men arrest external hemorrhage, apply snug sterile dressings, put on temporary splints, administer morphine for pain, and arrange for the transport of the patients to the Battalion Aid Station either by litter, by small or improvised field ambulances if possible, or with assistance to the wounded who can walk. In wounds of the extremities, the tourniquet may be life saving when applied. Its purpose is to *stop* bleeding. When hemorrhage cannot be controlled by pressure and a firm bandage, a tourniquet is applied proximal to the wound and drawn tight until all bleeding has ceased. Only after this purpose has been attained is the dressing applied and the limb immobilized. The trained enlisted personnel of the Armed Forces' Medical Services are efficient in their knowledge and use of first aid measures. "The U.S. Army Medical Department soldiers, the 'medics,' accompany all of our troops into battle and accord our wounded first aid care and probably more rapid evacuation and finer individual care than are accorded the wounded of any other army." (3).

The Battalion Aid Station. Here the medical officer applies or rearranges dressings and splints when necessary and removes tourniquets if he considers them unnecessary. If morphine has not already been given, this may be done now if deemed necessary by the medical officer. A booster dose of tetanus toxoid is administered as is an initial dose of antibiotics. It is here that the first real steps in resuscitation are taken by assuring arrest of hemorrhage, immobilization and traction of fractures of the long bones, airtight dressings for chest wounds or relief of tension pneumothorax, a free airway, and administration of plasma (expander), which may be continued during transport. Occasionally whole blood may be provided in a Battalion Aid Station when this is possible and conditions warrant. Often this is impossible because of difficulty in supply and refrigeration. The prime objective is to keep the aid station clear and patients at a minimum so that the patient may reach a hospital where more effective resuscitation is possible and initial

Missiles of low velocity do not penetrate deeply and exert their effects mainly by contusion and laceration, and the initial velocity of shell, bomb, grenade and mine fragments, though very great at first, decreases rapidly. Secondary missiles are earth, stones, armor, masonry, bone, etc., liberated and dispersed by the primary explosion. Large or small missiles of very high velocity from shells, mines, grenades, or bombs,

in the first portion of their flight, and rifle bullets within the first mile of their flight, produce "explosive" wounds, with the wound of exit larger than the wound of entrance. Shape and velocity remaining the same, doubling the weight of the missile doubles its wounding power. Shape and weight remaining the same, doubling the velocity quadruples its wounding power, since it quadruples its energy. When weight and velocity remain the same, increase in sectional area either regularly or irregularly, as in a bullet with flattened point or one with the deformity of a split jacket, produces additional wounding capacity, and especially its "shock" effect, which cannot be stated mathematically since it will vary so greatly, with the character of the tissue affected (1).

With the rapid decay in the velocity of shell fragments, much of their damage is due to the tissue damage caused by their size and weight, the dirt and clothing carried in by them or by secondary missiles set in motion by them.

"The wounding effects of a bullet depend on (*a*) the amount of energy it transmits to the tissues, (*b*) the velocity of the transmission, (*c*) the direction of the transmitted energy, and (*d*) the density of the tissues" (1). High velocity bullets travel at over 2,000 feet a second and rotate on their long axes at about 3,000 revolutions a second. The muzzle energy is about 2,400 foot pounds and the rotatory energy about 12 foot pounds. If a missile does not emerge from the body, its entire force is absorbed by the body. If it emerges, obviously all of its energy has not been expended. When a high speed missile, even a smooth pointed rifle bullet, enters the body, it may cause terrific damage at some distance from its line of passage because the energy of the bullet is transmitted all along its path at oblique angles. Particles of clothing or dirt are scattered in like manner through the path along these lines of force and the tissues are blown apart momentarily as though by an internal explosion. In homogeneous tissues all particles move together in a wave-like manner, the motion varying with the density of the tissue involved. When varying densities are encountered, however, as when a bone is shattered, irregular stresses are developed and the bone fragments become so many secondary missiles.

Three zones have been described in wounds caused by high velocity missiles: first, the innermost zone, the wound channel, filled with necrotic tissue, old blood, and debris; second, the zone of direct traumatic destruction with cauterization of tissue, which varies in width and forms an excellent culture medium for bacteria; and third, an outer zone of tissue of greatly reduced vitality, likewise suitable for bacterial growth (2). If this concept of the high velocity missile wound is understood, the objective of adequate careful débridement will be better comprehended.

Blast. The effects of blast were studied after World War I and again early in World War II. Injuries from bomb blasts are sustained from: 1. the fragments of the bomb itself, 2. secondary missiles such as flying debris and falling masonry, 3. falling or being thrown, and 4. the concussion of the blast wave. The blast wave consists of a shell of air traveling initially at about 3,000 feet per second in all directions but falling away rapidly. The injury is occasioned by the impact of the wave on the body, like a sudden blow. The ear drums may be injured, but the damage to the lungs is the chief effect. This consists of subpleural and intrapulmonary hemorrhages with possible rupture of the alveolar walls. In the abdomen, there are sometimes subserosal hemorrhages in the intestines or even rupture at times. In the central nervous system, it is not entirely clear how much of the injury is from the blast itself or how much may be due to concussion subsequent to sudden displacement of the head by the blast.

Explosions of mines or depth charges in water produce a single high pressure wave. Both lungs and intestines are affected, but the peritoneal injury predominates and ruptures of the intestines, especially the colon, are frequent.

thighs, extremity wounds with severe vascular injuries or evidence of anaerobic infection; 3. major traumatic amputations and compound fractures of the long bones with extensive soft part damage. In order to preserve maximum mobility and assure the best care for their patients, these small hospital units of 50-60 beds should hold as few patients as possible for actual operative surgery. After observation, adequate resuscitation, arrest of hemorrhage, and other necessary procedures, further triage can be made of this group of casualties so that about 40 per cent may be evacuated to the Evacuation Hospitals for definitive treatment or for further care and operation before transfer to a General Hospital.

Special Hospitals. In order to conserve as many men as possible who may be potentially able to return to duty within 48 hours, holding stations or "platoons" for special types of patients may be established well forward, usually in the vicinity of Clearing Stations or only slightly to the rear. As a rule, in combat, there are two of these: 1. for venereal disease, and 2. for acute neuropsychiatric disorders due to battle fatigue, where patients may be rested and observed for 48 hours, after which many are frequently able to return to their units. These patients live under full field conditions, require minimum treatment for this initial period, and lighten the load in the hospitals further to the rear where beds are so much in demand. With modern therapy the patient with venereal disease does not need any prolonged hospitalization and is soon fit for duty again. The soldier with exhaustion or battle fatigue may respond rapidly to rest and sedation, and it has been found in all wars that it is far better to keep such patients near the front because once they are evacuated to the rear, it becomes increasingly difficult to return them to active duty.

The Evacuation Hospital. All patients not requiring first priority surgery in the MASH units (and all medical and venereal cases) are sent directly to the Evacuation or Special Hospitals from the Clearing Station, and in addition the Evacuation Hospitals receive the small groups of patients from the MASH units, as mentioned above. Here again all patients are triaged on admission and labeled according to priority. This triage is usually performed in the admission tent by one or more senior surgeons, and priority is established for resuscitation and place on the operative schedule. Either different colored tags are used, or different wards are provided for first and second priority cases. Sometimes, if the load of admissions is unusually heavy and transport facilities are good, still another group of patients is selected for immediate evacuation. This group consists of those, both ill and wounded, for whom it is believed that initial definitive treatment may safely be deferred, and those who can stand transport and who will receive earlier attention at another hospital than they will if they have to await their turn where they are, because of the existing backlog of untreated patients.

In the foregoing paragraphs, an outline has been given of the various medical installations through which a wounded soldier passes on his way to a general hospital in the Communication Zone. Criticisms at times have been made that this system is too complicated, necessitates too much handling of the patient, and encourages delay. But the treatment of badly wounded soldiers, not singly but in large numbers, is itself complex, and a well planned organization is required to accomplish it so that: 1. the best possible care is provided; 2. this care ensures safety and is within the capabilities of the available medical personnel at all points; 3. the lines of evacuation are always kept open; and 4. facilities are provided at the most forward point possible to which nontransportable patients may be carried without delay to receive expert surgical care. At this place, there must be water, heat, light, shelter, and space to hold patients so that sufficient facilities may be provided for the care of this group. It is not practicable to establish such an installation farther forward than the Clearing Station. Even here, it is sometimes forward of the Division artillery. But the small unit, the MASH operating close beside the Clearing Station, fulfills the requirements of the three-point system described by Jolly (5): triage point, an adjacent small hospital for the nontransportable, the larger hospital farther back from the others, which thus makes possible selective and highly expert surgical care with minimum delay. Each unit along the way from

surgery and other treatment may be instituted without delay.

The emergency medical tag (EMT) should be started if this has not already been done by the Aid man, and the following information is of the utmost importance, requires little time, and should be stated on the tag as fully as possible. Quite apart from the name, serial number, and unit, *how, when,* and *where* wounded should be stated and any therapy noted. "How" is the type of missile if known; "when," the day and hour; "where" means primarily the geographical area where the man was when wounded, although of course the parts of the body involved should also be stated. If tourniquet is used, it should be clearly stated. Administration of morphine, tetanus toxoid, antibiotics, initial dressing, and intravenous therapy are of great importance and should be so recorded. Any special warning as to urgency of evacuation, treatment, or surgery is also noted.

From the Battalion Aid Station the wounded are evacuated to the Collecting or Clearing Station by ambulance, jeep, helicopter, or even by litter carry. The responsibility of evacuation always rests with the rear unit; thus, the responsibility for evacuation of the Battalion Aid Station rests with the Regimental Medical Company or the Division Medical Battalion, using ambulances or helicopters. Here the responsibility of evacuation rests entirely with the Division. The Army is responsible for evacuation of the rearmost Division installations such as the Clearing Station or the Mobile Army Surgical Hospital. The Communication Zone in turn is responsible for evacuating the Army installations, and finally, evacuation from the Communication Zone is furnished by the Zone of Interior.

The Clearing Station. The Battalion Aid, Collecting and Clearing Stations service the Division. Casualties passing to the rear of this zone are cared for by the Army. The Division is an extremely mobile unit; hence, its medical installations are similarly organized so that only those patients with trivial wounds or minor illness can be retained in them.

Clearing is the process of disposing of the casualties of a division or comparable unit. It consists of sorting all casualties of the unit, returning to duty such as are immediately fit for full duty, and transferring all other, except the dead, who are the responsibility of the Graves Registration Unit, to a medical unit of a higher echelon [Field Army. Ed.]. It is not to be confused with hospitalization.

In other than combat situations, if a clearing unit be organized and equipped for the purpose, it may undertake limited care and treatment of such sick and injured as will be fit for duty within a short time (4).

To what extent a Clearing Station can perform this second function in time of war depends upon its location and the tactical situation. In actual combat its function is largely that of triage and urgent resuscitation, and it holds only the slightly ill and those with very minor wounds. Whole blood is available in the Clearing Station.

Of the wounded and injured to be evacuated further a certain proportion will be nontransportable. A "nontransportable" casualty is a patient who cannot be evacuated further without real danger to life. Such a patient is transferred immediately to the Mobile Army Surgical Hospital, which should be, as a rule, within "hand-carry" distance from the Clearing Station. All other wounded are sent on back to the Evacuation Hospital except as noted above.

Evacuation by helicopter commonly begins at the Clearing Station, although in favorable instances helicopters may be sent forward to the Battalion Aid Station or even onto the field itself; this means of evacuation of the wounded is rapid and the most comfortable.

Mobile Army Surgical Hospital. The MASH units supporting the Clearing Stations are small, complete surgical hospitals of fifty beds each equipped to care for nontransportable casualties. These are: 1. those suffering from grave, life-endangering physiological disturbances such as hemorrhage, severe shock, cardiorespiratory imbalance from wounds of the heart or pericardium or large sucking wounds of the chest, intracranial pressure, and certain maxillofacial or neck wounds in which there is obstruction to respiration; 2. a group of impending fulminating infections including all thoraco-abdominal and abdominal wounds or wounds in other areas that may have penetrated the abdomen, such as wounds of the buttocks and upper

scalpel, but are equally dangerous to the patient if used without expert precision. One of the major responsibilities of the military surgeon is to make full use of these and similar measures and at the same time to avoid the dangers that may attend their usage.

a. The ever present necessity for evacuation of the wounded to the rear is in fundamental conflict with ideal surgical management of the individual patient. To minimize this conflict, *close coordination between the functions of administration and professional services is required.* It is the responsibility of the medical officer charged with the surgical management of the patient to place technical procedures properly, both in time and in space, with due regard to the tactical situation on the one hand and to the welfare of the patient on the other. Unless the surgeon visualizes his position and the function of his hospital in relation to other surgeons and other hospitals, he may become confused in the mission he is to perform. Although some needed operation may be performed correctly, the military effort may be impeded and unforeseen harm done to the patient if the operation is done at the wrong time or in the wrong place.

b. *It is the responsibility of administrative officers* charged with the establishment of evacuation and hospitalization policies to adapt the schedules of movement of patients to the maintenance of highest standards of surgical treatment. Priority of movement must be accorded to patients with certain types of injuries just as the duration of hospitalization in a given zone must be differentially adjusted to the urgent surgical needs of the patients. The term "nontransportable" as relating to the unfitness of battle casualties for interhospital transfer must, when military necessity permits, be extended beyond actual danger to life by a consideration of the likelihood of deformity, ultimate disability, and delay of recovery when these hazards exist (6).

Timing of Surgery. In war the timing of surgical procedures is of primary importance. It must be realized that the wounded soldier may pass through many medical installations before his final disposition—frequently as many as four to eight in the theater of operations. Treatment must be definitely planned in advance, therefore, and a clear conception of the type indicated in the various echelons must always be kept in mind. Only by such proper staging of surgery and the keeping of careful records can the best care be provided. There is nothing hit or miss, but the efforts of an expert surgeon may be entirely wasted if they are applied improperly as to time and place. Churchill has divided war surgery into the initial, the reparative, and the reconstructive phase. The first two belong in a theater of operations, the last belongs to the Zone of Interior (7).

Initial surgery is such surgery as is necessary to save life and limb, to correct physiological disturbances, and to prevent and treat infection. It includes resuscitation and the treatment of surgical shock, which of itself accomplishes two purposes: 1. it makes the patient transportable; and 2. it makes surgical intervention possible. The initial surgery itself is not intended to be definitive in any sense of the word, although at times it may be. Included in both are the control of hemorrhage; establishment of a good airway; temporary correction of cardiorespiratory disturbances with tracheostomy when necessary; surgery of the abdomen; clean débridement of wounds and of penetrating wounds of the joints with installation of antimicrobial and closure of the joint capsule; completion of traumatic amputations; transportation immobilization of fractures. When circular plaster is used, both it and any encircling bandages must always be cut before the patient is evacuated. When the spinal cord is involved and there is paralysis of the bladder, a suprapubic cystostomy should be performed. This is safer and less troublesome than the insertion of an indwelling catheter. Tracheostomy may be lifesaving but should not be undertaken lightly as it must be realized that such a patient may require considerable care during the first few hours following this operation.

Records. The emergency medical tag (EMT) should be carefully noted and corrected when in error. It should be placed in a field envelope together with the hospital record, which is started in this installation. This must state briefly what has been done, date and hour of accomplishment, medication given, any special or unusual features. If plaster has been used, a rough diagram should also be drawn on the cast over the site of injury with the date. Added sedation and amount of intravenous therapy, blood, plasma or expanders should likewise always be noted.

the front line to the hospital in the Zone of Interior has a perfectly definite mission to perform. Deviation from this mission at any point interrupts the whole pattern designed for the care of the wounded with resulting deterioration of this care. The system itself is elastic and may be telescoped or expanded to meet particular situations. With temporary modifications, the same plan provides the same high quality of care in desert, jungle, island, amphibious, urban, or rural warfare. When each unit carries out the mission for which it is designed, both it and the units in front of and behind it develop confidence and trust in each other with the result that each is ready and able at all times to do what it is supposed to do, and there is consequent improvement in continuity of care of the wounded.

Transportation. During World War II and in Korea, the United States Forces never compromised the principle of first priority surgery for the most severely wounded. This was made possible by great elasticity in organization for transport and evacuation of the wounded, flexibility in the utilization of the various medical units and hospitals, and use of auxiliary surgical teams. These teams were employed in all echelons from the Beach Clearing Station in amphibious operations to the General Hospital in the Communication Zone. Their chief employment, however, is in the MASH units, where they are entirely responsible for the surgery, and in the Evacuation Hospitals, where they supplement the surgical staffs.

In addition to the intrinsic transport of the Divisions and their Medical Regiments, separate Ambulance Companies from the Field Army are assigned as needed. These establish loading points all the way from forward of the Collecting Station to the Evacuation Hospital, which, depending upon the rapidity of the combat movement and terrain, may be located anywhere from near a Clearing Station to 60 to 70 miles to the rear, although the usual distance is 10 to 15 miles behind the front line. The Ambulance Control points are in contact with the Evacuation Hospitals as well as the Clearing Stations and MASH units so that the incoming load may be estimated and properly distributed. From the Evacuation Hospitals patients are evacuated to medical holding units for transport by air, to railheads, or even directly to General Hospitals.

The nontransportable group of patients do not tolerate transportation until after resuscitation and initial surgery; hence they are held in the Mobile Army Surgical Hospitals until adjudged safe to travel. Most head wounds, however, stand transportation very well, as do also the properly splinted fractures, soft part wounds, and some of the maxillofacial and chest cases.

Air evacuation of patients, a development of World War II, was greatly expanded in the Korean conflict. It is rapid, comfortable, and safe. Patients may be evacuated from the forward hospitals to hospital centers several hundred miles to the rear with speed and without transfer through other units. In especial situations, moreover, such as prevailed at Anzio, planes may be used for evacuation of even the freshly wounded to General Hospitals in the Communication Zone. Furthermore, the most forward airfields may be made available as soon as they are established for a plane carrying supplies of fresh whole blood from the Base for use in the MASH and Evacuation Hospitals.

WAR WOUNDS — GENERAL CONSIDERATIONS

Of the many articles that have been written about the management of war wounds, perhaps the best summation of the problem is expressed in the opening paragraphs of the War Department Medical Bulletin on the *Care of Battle Casualties:*

> The care of the wounded must always be modified by conditions and circumstances that govern the tactical situation at the moment. It is erroneous, however, to assume that the surgery of war is entirely molded by concessions to the need for haste and confusion of caring for overwhelming numbers of patients. Military surgery is not to be regarded as a crude departure from accepted surgical standards, but rather as a development of the science of surgery to carry out a specialized and highly significant mission. Modern surgical treatment employs many adjuvants to operative techniques, such as chemotherapy, fluid replacement therapy, the transfusion of whole blood and fractions of blood employed as substitutes, potent anesthetic agents and narcotics, [and antibiotics. Ed.]. These tools are as important to the military surgeon as his

and not as definitive therapy in patients who have suffered extensive hemorrhage. The patient who has been in poor condition because of blood loss, with low blood volume and possibly low hematocrit, often will be seriously endangered if his blood (and effective vascular) volume is increased by plasma without hemoglobin being added. Such a patient may superficially appear to be prepared for anesthesia and surgery. The blood volume has been restored and the meager quantity of hemoglobin available diluted. A small further loss of hemoglobin from renewed bleeding or during surgery may be critical and sudden disaster occurs (8).

(c) *Albumin.* The action of albumin is almost identical with that of plasma. Its chief advantage is its small bulk. When it is used, however, intravenous saline solution must also be given to overcome the dehydration that is almost always present and is accentuated when concentrated albumin alone is used, inasmuch as its effect depends on drawing fluid from the tissues into the vessels.

(d) *Expanders.* Plasma expanders such as dextran, PVP (Polyvinylpyrrolidone), and others such as oxypolygelatine may be used in limited amounts probably up to 2,000 ml. as a temporary measure. The only advantage these have over glucose, however, is that they remain in the circulation somewhat longer. Obviously they are not as useful as hepatitis free plasma or albumin or, of course, blood.

(e) *Blood.* Whole blood is the basic therapy in resuscitation and preparation for surgery of patients suffering from hemorrhage or traumatic shock. Evidence of hemorrhage, the pulse, color and temperature of the skin, the facies, and the blood pressure are all important guides to the patient's condition. Both the blood pressure and pulse are deceptive, however, in the early stages of shock; both may be unstable, so much so, in fact, that marked change may occur even on change of position. On arrival at a hospital after a long ambulance ride, the patient may appear to be in bad condition. After a short period of rest in the Trendelenburg position, however, the pulse may return, the blood pressure rise, and the color improve. The most important favorable clinical signs are a steady pulse and a warm, dry skin with prompt return of color on blanching—evidence of adequate capillary circulation. Unfavorable signs are falling blood pressure and rising pulse rate, clammy, cold, and dusky extremities, and restlessness. Treatment should never be delayed pending the result of laboratory examinations.

The speed of administration and the amount of blood to be used depend upon the condition of the wounded man. Although ideally blood of the same type as the patient's should be used, this is seldom possible or practicable and requires the services of the laboratory for grouping and cross matching; the avoidance of such delay may be vital at times. Therefore low titer (iso-agglutinin titer 1:64 or less) type "O" blood is used, as indiscriminate administration of high titer "O" blood may cause considerable destruction of red cells in some recipients of other blood groups (9). In the more serious cases, it will be necessary to give the first 500 to 1,500 ml. rapidly, perhaps even under pressure and by two or more veins. While the first transfusion is running, the patient's blood can be grouped and cross matched for future needs. When the blood pressure begins to rise, the speed of the transfusion can be decreased. After it has reached 80 mm. Hg, the rate of flow should be definitely slowed to 500 ml. every 30 to 60 minutes. This is particularly important in chest and head cases, which should always be kept a little on the "dry side," so as to prevent cardiorespiratory difficulties with pulmonary edema, or increased intracranial pressure. With a blood pressure of 80 to 85 mm. Hg, the patient is ready for surgery. In fact, surgery may be an integral part of resuscitation in the arrest of internal hemorrhage, the repair of ruptured hollow viscera, or the reduction of large eventrations. If surgery must be delayed because of a backlog, the blood pressure should be held at about this level, provided the patient looks well clinically, rather than an attempt made to raise it still further. Added transfusions will do more good during operation and postoperatively, and the risk of starting hemorrhage afresh will be averted. Should the patient's condition begin to deteriorate, surgery should be undertaken forthwith.

Transfusion of whole blood should not be undertaken lightly nor its dangers neglected; it is an exact procedure and should always be

Resuscitation. Resuscitation includes all measures used for the relief of shock in restoring a patient to a relatively normal "equilibrium" so that he reaches a moderately stable condition. This "equilibration" should not lead the resuscitation officer or the surgeon astray, however, as urgent surgery may be too long delayed. The resuscitation ward should be in charge of officers well trained for this work, should be of convenient location to the x-ray and operating wards, and should be thoroughly equipped with all modern apparatus for this most important phase of initial surgery. The resuscitation officer and one of the senior surgeons should maintain constant control of the patients, the amount and timing of plasma (expander) and blood replacement, and the timing of the necessary surgery.

Shock as seen in battle casualties is of three varieties: 1. hemorrhagic and traumatic, which are practically the same and accompanied by similar phenomena; 2. that caused by severe infection, as in overwhelming peritonitis or clostridial invasion; and 3. that accompanying burns. In the first variety there is hemodilution and reduction of the circulating blood volume, whereas in the last two there is hemoconcentration. Blood, plasma and plasma expanders are used for all types of shock, but as in civilian practice, blood is by far the most important. Preparations of norepinephrine should also be available. At times this medication may prove invaluable and even lifesaving as an adjuvant to intravenous therapy.

In burns there is a greater need for plasma to supply early plasma volume deficiency, but whole blood is still essential because of the red blood cell destruction and the resulting anemia. Resuscitation thus begins at the Aid Station with a combination of the measures just outlined. At the Clearing Station the decision is made whether or not the patient can withstand further travel to the Evacuation Hospital. If not, he is carried immediately to the adjacent MASH.

Here a full appraisal of the patient's condition is made and a complete physical examination performed *with good light.* The amount of morphine he has already received is noted as this may be an important factor if he is semicomatose. More than 0.015 gram is rarely necessary, and our present morphine substitutes, such as methadon, are equally as effective. There may be poor absorption from the capillaries in a person in shock, particularly in cold weather, so that if added dosage is given, the combined amount may be suddenly absorbed and signs of poisoning appear. Except for abdominal wounds and some fractures most patients do not have much pain and require relatively little sedation.

The patient is placed in the Trendelenburg position with the foot of the litter elevated twelve inches, unless difficulty in breathing is caused by it. Frequently this alone will bring about considerable improvement. If there is a wound of the thorax, the chest is aspirated of blood and air, the intercostal nerves above and below the wound are injected with 5 to 10 ml. of 1 per cent procaine, and the trachea aspirated if it is obstructed with blood and mucus. If external bleeding has not already been arrested, this is done, and splints are inspected as to their efficacy. The patient is kept warm, but external heat is applied with great care as it is far better that he should be a little cool than too warm.

Fluid. Most injured patients are thirsty. If surgery is imminent, however, it is obvious that water should not be given by mouth and it is, of course, contraindicated with abdominal wounds. Furthermore, if the patient is sensitive to, or has received, morphine, water will probably make him vomit. Gastric dilatation is common in these patients, and there is often much undigested food in the stomach; lavage should be performed, preferably with a large tube.

Intravenous Therapy. (a) *Saline and Glucose.* These solutions are good for dehydration, but they are in no way substitutes for whole blood. They are useful in maintaining the bare needs of fluid equilibrium only if there is to be a prolonged delay before surgery. They may increase intracranial pressure or precipitate or increase pulmonary edema. An already dilute blood is further diluted, and such fluids soon leave the circulation and enter the tissues.

(b) *Plasma.* In seriously wounded patients,

plasma gives more time to get whole blood into the patient. It should be considered as a stop-gap

and not as definitive therapy in patients who have suffered extensive hemorrhage. The patient who has been in poor condition because of blood loss, with low blood volume and possibly low hematocrit, often will be seriously endangered if his blood (and effective vascular) volume is increased by plasma without hemoglobin being added. Such a patient may superficially appear to be prepared for anesthesia and surgery. The blood volume has been restored and the meager quantity of hemoglobin available diluted. A small further loss of hemoglobin from renewed bleeding or during surgery may be critical and sudden disaster occurs (8).

(c) *Albumin.* The action of albumin is almost identical with that of plasma. Its chief advantage is its small bulk. When it is used, however, intravenous saline solution must also be given to overcome the dehydration that is almost always present and is accentuated when concentrated albumin alone is used, inasmuch as its effect depends on drawing fluid from the tissues into the vessels.

(d) *Expanders.* Plasma expanders such as dextran, PVP (Polyvinylpyrrolidone), and others such as oxypolygelatine may be used in limited amounts probably up to 2,000 ml. as a temporary measure. The only advantage these have over glucose, however, is that they remain in the circulation somewhat longer. Obviously they are not as useful as hepatitis free plasma or albumin or, of course, blood.

(e) *Blood.* Whole blood is the basic therapy in resuscitation and preparation for surgery of patients suffering from hemorrhage or traumatic shock. Evidence of hemorrhage, the pulse, color and temperature of the skin, the facies, and the blood pressure are all important guides to the patient's condition. Both the blood pressure and pulse are deceptive, however, in the early stages of shock; both may be unstable, so much so, in fact, that marked change may occur even on change of position. On arrival at a hospital after a long ambulance ride, the patient may appear to be in bad condition. After a short period of rest in the Trendelenburg position, however, the pulse may return, the blood pressure rise, and the color improve. The most important favorable clinical signs are a steady pulse and a warm, dry skin with prompt return of color on blanching—evidence of adequate capillary circulation. Unfavorable signs are falling blood pressure and rising pulse rate, clammy, cold, and dusky extremities, and restlessness. Treatment should never be delayed pending the result of laboratory examinations.

The speed of administration and the amount of blood to be used depend upon the condition of the wounded man. Although ideally blood of the same type as the patient's should be used, this is seldom possible or practicable and requires the services of the laboratory for grouping and cross matching; the avoidance of such delay may be vital at times. Therefore low titer (iso-agglutinin titer 1:64 or less) type "O" blood is used, as indiscriminate administration of high titer "O" blood may cause considerable destruction of red cells in some recipients of other blood groups (9). In the more serious cases, it will be necessary to give the first 500 to 1,500 ml. rapidly, perhaps even under pressure and by two or more veins. While the first transfusion is running, the patient's blood can be grouped and cross matched for future needs. When the blood pressure begins to rise, the speed of the transfusion can be decreased. After it has reached 80 mm. Hg, the rate of flow should be definitely slowed to 500 ml. every 30 to 60 minutes. This is particularly important in chest and head cases, which should always be kept a little on the "dry side," so as to prevent cardiorespiratory difficulties with pulmonary edema, or increased intracranial pressure. With a blood pressure of 80 to 85 mm. Hg, the patient is ready for surgery. In fact, surgery may be an integral part of resuscitation in the arrest of internal hemorrhage, the repair of ruptured hollow viscera, or the reduction of large eventrations. If surgery must be delayed because of a backlog, the blood pressure should be held at about this level, provided the patient looks well clinically, rather than an attempt made to raise it still further. Added transfusions will do more good during operation and postoperatively, and the risk of starting hemorrhage afresh will be averted. Should the patient's condition begin to deteriorate, surgery should be undertaken forthwith.

Transfusion of whole blood should not be undertaken lightly nor its dangers neglected; it is an exact procedure and should always be

surrounded with every precaution. When there is time, and except in emergency, cross matching should be performed. If there is any question in the cross match, even when low titer "O" blood is used, the donor blood should also be grouped, as the possibility of human error is always present. Although the Rh-factor is not of the same importance as it is in civilian surgery, it should not be neglected, as occasionally Rh negative individuals are encountered for whom special precautions must be taken. In time of war, hospitals of a Field Army should be relieved of the necessity of drawing the blood required and should be able to call upon the Blood Bank for their entire supply. Sometimes, however, Evacuation Hospitals can maintain blood banks of their own and, when this is possible, donors may be readily obtained from nearby Service Troops and from their own slightly wounded patients or those with minor illnesses.

Time Required for Resuscitation. If the patient fails to show any response, or shows only a very transient one, after 1,000 to 2,000 ml. of blood or after two to three hours spent on resuscitation, something is obviously wrong. The causes for this failure to respond are usually: 1. continuing hemorrhage; 2. massive infection, particularly peritoneal or clostridial; 3. incomplete major traumatic amputation or large eventration of viscera; 4. extensive intracranial damage; or 5. blast injury of the lungs or heart. If any of the first three of the above are suspected, immediate surgery is indicated with continued transfusion, as resuscitation cannot be complete until such necessary surgery is performed. With the last two conditions, it is better to proceed with whatever operative treatment is required than to procrastinate and continue to pour in blood and plasma because in such cases as these, continued intravenous therapy will precipitate increased intracranial pressure or cerebral edema, or cardiac dilatation with pulmonary edema. As to the proportions of blood and plasma used in preparation for and through surgery, the ratio is about two or three 500 ml. units of blood to one unit (500 ml.) of plasma; the more severe the wounds and the shock, the greater will be the amount of blood required.

Anesthesia. The advances in anesthesia have been very great during the past quarter century, so that instead of playing a distinctly ancillary role to surgery, in World War II it assumed an important position and increased considerably the possibilities of surgery. Quite apart from the many difficult technical problems with which he is confronted, the anesthesiologist is also responsible for the training and supervision of his nurse and corpsmen assistants, usually administers all regional and sympathetic nerve blocks, and may be in charge of resuscitation and the preoperative preparation of the major cases.

In the forward hospitals, many problems arise in conjunction with the severely wounded which tax the skill and resourcefulness of the anesthetist; hence, most of the best anesthetists should be in these installations, although some supervision and training must be maintained in the rear areas. A number of variables influence the choice of anesthetic agent: (*a*) type and condition of patient, (*b*) type of injury, (*c*) volume of work and tactical situation, (*d*) personnel available, (*e*) equipment and location, and (*f*) previous medication:

(*a*) The patient is a young, healthy male when wounded; he is well fed and well trained and has enormous powers of recuperation even from most severe trauma.

As opposed to these favorable factors, he may be gravely wounded and suffering from exhaustion, long exposure, and severe shock and hemorrhage. The wounds are frequently multiple, and extensive infection may already be present. These unfavorable factors are almost always encountered in the MASH units, less often in Evacuation Hospitals.

The *condition of the patient* in regard to loss of blood, shock, disturbed physiology, etc. is also important.

(*b*) Each type of injury presents its own problems. The *location of the wound* or wounds has its own indications or contraindications regarding the agent to be used.

(*c*) The *volume* and *pressure* of work and the extent of the surgical backlog, along with the existing military situation as to the needs of evacuation or possible impending move of the hospitals—all these must be considered.

(*d*) What *personnel* are available to give anesthesia and with what agents and technics are they familiar? This alone may be the governing factor in the choice of the anesthetic.

(*e*) The *equipment* available and *location* of the hospital will also influence the choice: ether is excellent in temperate climates but is almost useless in the tropics without a closed circuit because of the great evaporation.

(*f*) Finally the choice of anesthetic is affected by *previous medication*, particularly morphine, as occasionally it is necessary to resuscitate a patient from the effects of morphine given initially. Most wounded soldiers require comparatively little preoperative sedation. They are exhausted and may also be in varying degrees of shock or are weakened from loss of blood and as a rule respond to induction with little resistance.

Before any general anesthetic is administered, the stomach should be emptied for frequently there is much undigested food present, which should be removed by lavage or induced vomiting when feasible. Oxygen may be more effective in quieting a restless patient with badly disturbed cardiorespiratory physiology than morphine. Atropine should always be given before anesthesia to diminish secretions and, when pentothal is used, to prevent laryngeal spasm. Scopolamine is contraindicated in forward surgery because of its amnesic and hallucinatory properties.

The anesthetic agents most suitable for use in forward surgery are: (*a*) procaine and pontocaine, (*b*) nitrous oxide, (*c*) ether, (*d*) sodium pentothal, (*e*) vinyl ether at times, for short anesthetics or induction. In most forward areas nitrous oxide will be dispensed with because of the logistics problem created by the weight of the tanks.

(*a*) *Procaine* and pontocaine or cocaine topically are used for local or regional anesthesia or the local blocking of nerves, as in intercostal nerve block in chest injuries and sympathetic blocks for wounds or thromboses of the major arteries. The use of local anesthesia is limited to those areas that are readily anesthetized, to short and relatively limited procedures, and to head cases, when the patient is usually semicomatose. It has a limited value, in skilled hands, for epidural anesthesia. There is no place, however, in the forward surgery of the wounded and injured for *spinal anesthesia*, for these patients are already frequently in shock with the effective circulating volume of the blood reduced, they may have to be moved by ambulance following surgery, and the incidence of annoying, or even serious, complications is greater following spinal anesthesia than it is with other agents. *In quiet periods it may be used for* routine surgical procedures, and in hospitals in the Communications Zone its indications are the same as in any civil institution.

(*b*) *Nitrous oxide* is useful alone for very short procedures. Its chief values are that it is an induction agent for ether, it can be administered with sodium pentothal and 50 per cent oxygen, thereby reducing the amount of pentothal required, and it is noninflammable. It is the least essential of the agents used in forward hospitals and may be readily sacrificed when transport is at a premium and supply difficult.

(*c*) *Ether* is still the most useful of all anesthetic agents. It is the safest, packs and transports readily, is administered easily, and is the best agent at present for patients suffering from shock or hemorrhage, for those with thoracic, abdominal, or extensive wounds, and also for many with head and maxillofacial injuries. Nitrous oxide, pentothal, ethyl chloride, vinyl ether, or chloroform may be given for induction, or ether itself may be used for this purpose in the severely *injured. The anesthesia may be* perfectly controlled at any plane, and a high percentage of oxygen, which is so necessary in shock and wounds of the head, chest, and abdomen, may be provided throughout. Endotracheal administration is particularly valuable for this same group of patients, with the added advantage of better aeration, control of respiration, and aspiration of the trachea and primary bronchi. There is no respiratory depression and patients react promptly, which is important for the patient and in greatly facilitating nursing care.

(*d*) *Intravenous anesthesia* has certain limitations but numerous advantages. In the early days of our participation in World War II, sodium pentothal was used indiscriminately—almost as routine by some; the mor-

surrounded with every precaution. When there is time, and except in emergency, cross matching should be performed. If there is any question in the cross match, even when low titer "O" blood is used, the donor blood should also be grouped, as the possibility of human error is always present. Although the Rh-factor is not of the same importance as it is in civilian surgery, it should not be neglected, as occasionally Rh negative individuals are encountered for whom special precautions must be taken. In time of war, hospitals of a Field Army should be relieved of the necessity of drawing the blood required and should be able to call upon the Blood Bank for their entire supply. Sometimes, however, Evacuation Hospitals can maintain blood banks of their own and, when this is possible, donors may be readily obtained from nearby Service Troops and from their own slightly wounded patients or those with minor illnesses.

Time Required for Resuscitation. If the patient fails to show any response, or shows only a very transient one, after 1,000 to 2,000 ml. of blood or after two to three hours spent on resuscitation, something is obviously wrong. The causes for this failure to respond are usually: 1. continuing hemorrhage; 2. massive infection, particularly peritoneal or clostridial; 3. incomplete major traumatic amputation or large eventration of viscera; 4. extensive intracranial damage; or 5. blast injury of the lungs or heart. If any of the first three of the above are suspected, immediate surgery is indicated with continued transfusion, as resuscitation cannot be complete until such necessary surgery is performed. With the last two conditions, it is better to proceed with whatever operative treatment is required than to procrastinate and continue to pour in blood and plasma because in such cases as these, continued intravenous therapy will precipitate increased intracranial pressure or cerebral edema, or cardiac dilatation with pulmonary edema. As to the proportions of blood and plasma used in preparation for and through surgery, the ratio is about two or three 500 ml. units of blood to one unit (500 ml.) of plasma; the more severe the wounds and the shock, the greater will be the amount of blood required.

Anesthesia. The advances in anesthesia have been very great during the past quarter century, so that instead of playing a distinctly ancillary role to surgery, in World War II it assumed an important position and increased considerably the possibilities of surgery. Quite apart from the many difficult technical problems with which he is confronted, the anesthesiologist is also responsible for the training and supervision of his nurse and corpsmen assistants, usually administers all regional and sympathetic nerve blocks, and may be in charge of resuscitation and the preoperative preparation of the major cases.

In the forward hospitals, many problems arise in conjunction with the severely wounded which tax the skill and resourcefulness of the anesthetist; hence, most of the best anesthetists should be in these installations, although some supervision and training must be maintained in the rear areas. A number of variables influence the choice of anesthetic agent: (*a*) type and condition of patient, (*b*) type of injury, (*c*) volume of work and tactical situation, (*d*) personnel available, (*e*) equipment and location, and (*f*) previous medication:

(*a*) The patient is a young, healthy male when wounded; he is well fed and well trained and has enormous powers of recuperation even from most severe trauma.

As opposed to these favorable factors, he may be gravely wounded and suffering from exhaustion, long exposure, and severe shock and hemorrhage. The wounds are frequently multiple, and extensive infection may already be present. These unfavorable factors are almost always encountered in the MASH units, less often in Evacuation Hospitals.

The *condition of the patient* in regard to loss of blood, shock, disturbed physiology, etc. is also important.

(*b*) Each type of injury presents its own problems. The *location of the wound* or wounds has its own indications or contraindications regarding the agent to be used.

(*c*) The *volume* and *pressure* of work and the extent of the surgical backlog, along with the existing military situation as to the needs of evacuation or possible impending move of the hospitals—all these must be considered.

(*d*) What *personnel* are available to give anesthesia and with what agents and technics are they familiar? This alone may be the governing factor in the choice of the anesthetic.

(*e*) The *equipment* available and *location* of the hospital will also influence the choice: ether is excellent in temperate climates but is almost useless in the tropics without a closed circuit because of the great evaporation.

(*f*) Finally the choice of anesthetic is affected by *previous medication*, particularly morphine, as occasionally it is necessary to resuscitate a patient from the effects of morphine given initially. Most wounded soldiers require comparatively little preoperative sedation. They are exhausted and may also be in varying degrees of shock or are weakened from loss of blood and as a rule respond to induction with little resistance.

Before any general anesthetic is administered, the stomach should be emptied for frequently there is much undigested food present, which should be removed by lavage or induced vomiting when feasible. Oxygen may be more effective in quieting a restless patient with badly disturbed cardiorespiratory physiology than morphine. Atropine should always be given before anesthesia to diminish secretions and, when pentothal is used, to prevent laryngeal spasm. Scopolamine is contraindicated in forward surgery because of its amnesic and hallucinatory properties.

The anesthetic agents most suitable for use in forward surgery are: (*a*) procaine and pontocaine, (*b*) nitrous oxide, (*c*) ether, (*d*) sodium pentothal, (*e*) vinyl ether at times, for short anesthetics or induction. In most forward areas nitrous oxide will be dispensed with because of the logistics problem created by the weight of the tanks.

(*a*) *Procaine* and pontocaine or cocaine topically are used for local or regional anesthesia or the local blocking of nerves, as in intercostal nerve block in chest injuries and sympathetic blocks for wounds or thromboses of the major arteries. The use of local anesthesia is limited to those areas that are readily anesthetized, to short and relatively limited procedures, and to head cases, when the patient is usually semicomatose. It has a limited value, in skilled hands, for epidural anesthesia. There is no place, however, in the forward surgery of the wounded and injured for *spinal anesthesia*, for these patients are already frequently in shock with the effective circulating volume of the blood reduced, they may have to be moved by ambulance following surgery, and the incidence of annoying, or even serious, complications is greater following spinal anesthesia than it is with other agents. In quiet periods it may be used for routine surgical procedures, and in hospitals in the Communications Zone its indications are the same as in any civil institution.

(*b*) *Nitrous oxide* is useful alone for very short procedures. Its chief values are that it is an induction agent for ether, it can be administered with sodium pentothal and 50 per cent oxygen, thereby reducing the amount of pentothal required, and it is noninflammable. It is the least essential of the agents used in forward hospitals and may be readily sacrificed when transport is at a premium and supply difficult.

(*c*) *Ether* is still the most useful of all anesthetic agents. It is the safest, packs and transports readily, is administered easily, and is the best agent at present for patients suffering from shock or hemorrhage, for those with thoracic, abdominal, or extensive wounds, and also for many with head and maxillofacial injuries. Nitrous oxide, pentothal, ethyl chloride, vinyl ether, or chloroform may be given for induction, or ether itself may be used for this purpose in the severely injured. The anesthesia may be perfectly controlled at any plane, and a high percentage of oxygen, which is so necessary in shock and wounds of the head, chest, and abdomen, may be provided throughout. Endotracheal administration is particularly valuable for this same group of patients, with the added advantage of better aeration, control of respiration, and aspiration of the trachea and primary bronchi. There is no respiratory depression and patients react promptly, which is important for the patient and in greatly facilitating nursing care.

(*d*) *Intravenous anesthesia* has certain limitations but numerous advantages. In the early days of our participation in World War II, sodium pentothal was used indiscriminately—almost as routine by some; the mor-

tality attributable to it was 1:450. As its limitations became appreciated and its contraindications accepted, more judicious selection of cases was made, with the result that it soon became recognized as a most important agent for anesthesia in forward surgery, and its mortality rate dropped to one out of every 5,500 cases in which it was used (10). Pentothal abolishes the normal CO_2 mechanism of stimulation of the respiratory center and throws the whole burden on the response of the carotid sinus to anoxia. It is a marked respiratory depressant, and when it is given, high oxygen content of the blood is essential and oxygen rather than CO_2 must be used to bring about improvement in respiration. As pentothal may also produce laryngeal spasm, premedication with atropine is mandatory and the dose should be repeated intravenously if spasm occurs.

Sodium pentothal in 2.5 per cent solution is ideal for operations of not over 45 minutes. If longer anesthesia is required, it should be combined with nitrous oxide-oxygen, 50 per cent each, or a shift made to ether. It is contraindicated in severe shock or extensive hemorrhage, in cases of anaerobic myositis, in abdominal and intrathoracic wounds, in conditions involving the neck and mouth because of its action on the carotid sinus, and in intracranial operations because of its tendency to anoxia. For these last three groups of cases, as well as for many wounds of the neck and face, endotracheal ether is the anesthetic of choice.

(*e*) See ether (*c*).

A sampling of 44,530 anesthetics given in Seventh U. S. Army hospitals from November 1, 1944, to April 30, 1945, is typical of the differences between the field and evacuation hospitals. All of the former were working adjacent to the Division Clearing Stations and so received only the nontransportables and most severely wounded (11).

Basal anesthesia with avertin or paraldehyde and rectal ether have no place whatsoever in military surgery in forward hospitals.

Operative Treatment. The concept of war surgery has been clarified by Churchill (7), each phase defined and its mission explained.

> Wound management may be divided into three phases—initial, reparative, and reconstructive. The first two are concerns of an overseas theater. The latter is the mission of the Zone Interior. . . .
>
> The initial wound operation is directed toward the prevention of infection by a complete excision of tissue devitalized by the missile. Procedures such as closure of a sucking wound of the chest or suture of a perforation of a hollow viscus restore physiologic equilibrium as well as arrest the dangers of infection. Recognition of all devitalized tissues is oftentimes impossible, particularly in a massive wound or one complicated by skeletal injury. Disturbances of blood supply and subtle changes that indicate impending death of tissues may not be detectable. In a certain number of these cases mixed anaerobic infection of residual dead tissues is the inevitable sequella. Others will develop invasive infection spreading from the wound to involve normal tissues. To minimize the incidents and hazards of infection, primary closure by suture is strictly avoided. Exact maintenance of the reduction of fractures by precise methods is precluded by the necessity for evacuation to the rear, so temporary or transportation splinting, usually with plaster of Paris, is employed (7).

So important is the initial débridement that the whole future course of the wounded

TABLE 2.

	(MASH) FIELD	EVACUATION
Inhalation	2,148—86.2%	9,762—23.2%
Field Blocks	45—01.8%	4,904—11.6%
Miscellaneous Regional	117—04.6%	558—01.3%
Spinal	11—00.4%	383—00.9%
Sympathetic	44—01 8%	319—00.8%
Sodium Pentothal (intravenous)	71—02 9%	22,363—53.1%
Intravenous Combined	56—02.3%	3,849—09.1%
Total	2,492	42,138
Endotracheal (Evacuation Hospitals)	3,042	(31.1% of inhalations)
Endotracheal (Field Hospitals)	1,782	(82.9% of inhalations)

soldier may well depend on the care and the completeness with which this is performed. The literal translation of *débridement* is *incision*. The French describe the trimming of excision of wounds as *épluchage* and *parage*. In our comprehension of the term, however, débridement of a wound means complete excision as far as possible of all damaged or devitalized tissues, and removal of all foreign bodies, dirt, and small, completely unattached bone fragments. The initial incision must be bold and ample and the fascia split widely in a longitudinal direction. Good lighting, free retraction, and a dry field are essential. Compromise must be made, of course, with major nerves and arteries. Particular attention should be given to muscles and fascial planes, and less to skin, which requires minimal excision, and bone ends should be thoroughly cleaned and rongeured, if necessary. All recesses are opened and explored. Bleeding vessels should be ligated carefully with only the smallest amount of tissue included in the ligature and fine ligatures used and the ends cut short. The tissues, already traumatized, are handled with great gentleness. The wound is left unsutured and dressed with a layer of *fine-mesh* plain gauze, which is not stuffed or plugged in but merely laid over the edges to the depth of the wound. When plain fine-mesh gauze is used, the wounds appear fresher and drier at the first dressing than when petrolatum gauze has been used. A properly débrided wound is dry and bleeds readily, its muscle appears red and contracts normally, it appears clean and contains no hidden pockets. If a cavity in the tissues is left, as around the site of a fracture, and puddling seems likely, counterincision at the most dependent point should be provided at the time of débridement so as to permit drainage of the wound secretions. If the wound is extensive, even though no fracture is present, immobilization in plaster of Paris should be provided.

Just as plasma is not a substitute for whole blood in resuscitation, neither are sulfonamides and penicillin [antibiotics—Ed.] substitutes for the surgical excision of devitalized tissue. Chemotherapeutic agents cannot sterilize dead, devitalized, or avascular tissues nor do they prevent the septic decomposition of contaminated blood clot (7).

Local use of antimicrobials in wounds is not recommended, except in joints. A combination of penicillin and streptomycin or a broad spectrum antibiotic has probably already been given at the Battalion Aid or Clearing Stations. This medication is continued at the hospital throughout the surgical and early postoperative period. In most instances antibiotics are preferable to chemotherapeutic agents because: 1. they are more effective against the common types of wound infection; 2. they produce no renal complications; 3. they do not interfere with the appetite; 4. they do not add to an already present anemia. Sensitivity must be considered, particularly with penicillin. One of the soluble sulfonamides is indicated, however, when an indwelling catheter or suprapubic cystostomy has been necessary. The antimicrobials used in conjunction with exact and complete débridement add to the possibilities of initial surgery but are in no way a substitute for it.

The magnitude of the surgical problems that confront the forward surgeons when supported by adequate resuscitation therapy is difficult to visualize by one not having a firsthand acquaintance with their work. Highest standards of precision must be maintained if the potentialities of surgery are to be realized to full advantage. This precision must be attained in the use of adjuncts to surgery as well as in operative technics. Initial surgery cannot be carried on as a hasty, slapdash and bloody spectacle, with rapid evacuation of the patient to the rear if satisfactory *results are to be achieved* (7).

Postoperative. In the Mobile Army Surgical Hospitals, except for the resuscitation ward, there is no special area designated as a postoperative ward. All of the patients in this hospital, when it is utilized properly, are seriously ill in the immediate postoperative period and are under the constant supervision of nurses and highly trained corpsmen, with the members of the medical staff likewise in constant attendance. Each ward is equipped for postoperative emergencies with adequate suction, provision for intravenous medication, oxygen equipment, tracheotomy sets, water, and heat and good light. In Evacuation Hospitals, postoperative wards are established where the patients are held as long as possible following operation and where

such special care and equipment as outlined above are always available.

Reparative Surgery. This is carried out in the General and Station type Hospitals in the Communication Zone to which patients are evacuated from the Field and Evacuation Hospitals of the Field Army. "A highly significant and far reaching advance in military surgery has taken place in the base hospitals with the development of what may be called *reparative surgery*. Wounds left unsutured at the initial operation are routinely closed by suture, usually at the time of the first dressing" (7).

If the original débridement has been properly performed and the patient promptly evacuated, the initial dressings are removed in the operating room of the base hospital between the fourth and tenth day. If the wound appears clean and without sign of infection, it is sutured without any freshening of the edges or cleansing of the wound other than the gentle removal of fresh blood and clots. Or the closure may be staged, with closure of muscles and fascia as the first stage, as in very large wounds of the back and shoulders, and skin closure deferred to a later date. Tension and strangulation of tissues must be avoided; otherwise, failure is inevitable. Later than ten days the skin margins will have to be freed and the ends of the wound may be extended with curved or "Z" incisions and flaps formed. With simple closure no added therapy is required, but with the more complicated procedures parenteral antibiotics may afford protection from infection. If at the first dressing there is redness or evidence of foreign bodies or slough, moist dressings are applied for a few days or the wound is redébrided and moist dressings applied.

The same principles apply to the more extensive wounds. When these patients are received in the base installations, their secondary anemia is corrected by transfusions and their casts removed and fractures reduced so as to obtain good alignment and healing. If débridement of these compound fractures and joint wounds is incomplete, the wounds are explored and all dead and infected tissue, foreign bodies, and sequestra of bone and cartilage are removed under the protection of antibiotics and transfusions as necessary. If good healing is obtained, such wounds may be reopened safely in two to three weeks for the suture of nerves or internal fixation of fractures.

In wounds of the chest, attention has been focused on restoration of the normal physiology with immediate re-expansion of the lungs and repeated aspirations or water seal drainage to maintain it. As these patients reach the base hospitals and centers, the procedures already initiated are continued and supplemented by drainage, or later by complete decortication of the lung. With transfusions and antimicrobials, radical surgery may be performed in from three to six weeks with the expectation of primary healing and complete lung re-expansion. In a series of 870 penetrating chest wounds treated by Burford in a chest center, 752 were accompanied by hemothorax and 111 of this group became infected. Only four of these patients were returned to the Zone of Interior for further treatment of their empyemas. The others were either returned to duty within the theater or required evacuation to the Zone of Interior for other reasons (12).

Patients with abdominal wounds usually reach the base within about two weeks after their initial surgery and frequently present most difficult surgical problems. Anemia and electrolyte and fluid imbalance have to be overcome and small intestinal fistulae closed. A certain number of these patients develop early intestinal obstruction. Some need revision of colostomies, and in some the colostomy may be safely closed with the expectation of a return to duty in the theater.

Although reconstructive plastic surgery belongs in the Zone of Interior, it should always be remembered that skin is the best dressing there is. Any area, therefore, that cannot be closed by suture or sliding flaps should be covered as early as possible with split thickness grafts even though later revision may be required. The early closure of wounds by suture or graft not only diminishes hospitalization but reduces the deep scarring and fibrosis that will otherwise occur, and it also makes possible the early return of thousands of troops to duty, who otherwise would be returned to the Zone of Interior.

Infection. All wounds are contaminated, but the transition between contamination and

infection is an ill-defined borderland. In the past an empiric period of six hours has been stated as the "golden period" during which infection need not be considered as an important factor in a fresh wound, but after this time wounds should be considered to be frankly infected. While this may be true with the majority of wounds, it does not apply to those of the trachea, mouth and hollow viscera, which are infected from inception.

To understand the nature of wound infection, it is necessary to distinguish between bacterial growth limited to the tissues that were devitalized by the injury and invasive infection that starts in the wound and extends to living tissues. The former may be termed surface infection with injury necrosis; the latter, invasive infection (13).

The common pathogenic and saprophytic bacteria are present in wounds and take part in the natural processes of proteolysis and digestion, which lead to the separation of dead tissue, sequestra, and the extrusion of foreign bodies. Mechanical, chemical, and biologic aids are frequently used to assist in this process: physiologic saline irrigations, sodium hypochlorite or Dakin's solution, urea, enzymes such as streptokinase and streptodornase and perhaps some of the collagenases. Antiseptics used to "sterilize" and stimulate wounds, while they may kill surface bacteria, also kill tissue. If the slough is thick, there will be no penetration of the wound at all by these chemical agents, and hence the desired antiseptic action will be nil. But, on the other hand, if the "antiseptic" really helps to separate the slough, it also comes in contact with viable tissues and "stimulates" them into a fresh layer of slough by its necrotizing action, or, by its irritant effect, increases wound secretions. Such agents should always be used purposefully to attain a specific end, not just on the general principle that it is good to kill all bacteria.

The almost inherent urge to place some agent, with hopeful healing and anti-infective properties, in a wound seems to be deep-seated in the human breast and is as difficult to control as the better recognized human impulses. Time and experience have repeatedly demonstrated the inefficacy of such agents. Perhaps some day such an agent will be found but the search seems futile when it is realized that the key to wound infection in traumatic wounds is dead tissue, a fact which Botallo recognized almost four centuries ago, and which Lister fully appreciated (14).

Years ago Lister taught that:

> All the local inflammatory mischief and general febrile disturbance which follow severe injuries are due to the irritating and poisonous influence of decomposing blood or sloughs (15).

In the presence of dead tissue and tissue with an impaired blood supply, anaerobic bacteria are predominant, and the most important of these are the *Clostridia perfringens* (*Welchii*), *oedematiens*, *septicum* and *sordelli*, and anaerobic streptococci. Infection with these organisms may be local and limited to the area of the wound, or in deep wounds local pockets may be formed in the wound track or in nearby fascial spaces, which sometimes contain gas under pressure, the "gas abscess." This type of infection is apt to occur in wounds in which initial surgery has been delayed.

Invasive infection starts in the same manner and spreads by direct extension into muscles, along fascial planes, and along vascular sheaths. Lymphangitis and involved regional lymph nodes are seldom seen; metastatic infection and septicemia originate from infected thrombi or from erosion into a damaged vessel.

The anaerobic infections that are limited to the fascial planes and connective tissue have been designated anaerobic cellulitis. The patient may appear acutely ill with high temperature and other signs of absorption of toxins. The pulse is usually disproportionately low in comparison with the temperature, however, and there is not the overwhelming prostration noted in clostridial myositis. There may be signs of localization or evidence of extensive progression of the infection. Anaerobic cellulitis usually responds well to wide incision and drainage and excision of all necrotic tissues along with parenteral antibiotic therapy.

Gas Gangrene. When the clostridia invade the muscles themselves, the picture is quite different and is one of true "gas gangrene." This term has been replaced by the more specific term *clostridial myositis*. The infection appears in two forms, the dry and the wet. The dry form is usually associated with *Cl. perfringens* and the wet with *Cl. oedematiens*

or *sordelli*, but frequently there is a mixed flora of these bacteria along with anaerobic cocci and the common pyogens. Compound fractures of the long bones and wounds or thrombosis of the major arteries of the extremities are important predisposing factors, and the lower extremities are most commonly the site of infection.

The best preventive against clostridial myositis is early and adequate débridement with nonsuture of wounds; this means free skin and fascial incisions so as to prevent the development of tension in the wound. There must be *no* circular or constricting dressings. Whenever the patient complains of sudden onset of pain in his wound, the wound should be redressed at once, as sudden pain is the most common symptom of the onset of clostridial myositis. Other early symptoms and signs are loss of appetite, personality changes, and prostration and hemorrhage from the wound. The condition often makes its appearance with dramatic suddenness and profound prostration and runs a fulminating course. Contrary to its character in anaerobic cellulitis, the pulse is disproportionately high in relation to the temperature, and the toxemia is profound, with rapidly developing anemia and signs of shock. There is marked swelling, there may be color changes and crepitation, and in the wet form the tissues are wet and soggy. The treatment is surgical and consists of wide incisions and excision of all involved muscle bellies. Amputation is necessary only when the circulation is so impaired that survival of the limb is doubtful, or if there is so much bone or muscle destruction that the limb will be useless anyway.

Penicillin is recommended in dosage of 1 million units intramuscularly every three hours, or tetracyclines are used in dosages of 0.5 grams intravenously every eight hours, or 0.2 grams every six hours intramuscularly. Antigas serum as presently developed or hyper-immune serum is of questionable value; primary reliance must be placed upon adequate surgery and control of the accompanying aerobic infection with antimicrobials.

Statistics on anaerobic cellulitis and clostridial myositis are confusing and not too reliable, particularly because the two conditions have not been well differentiated. In World War I the incidence of gas gangrene was 1.7 per cent (1.08 per cent for wounds of soft parts only and 6.26 per cent in cases complicated by fracture) and the mortality was 46.6 per cent. The Seventh Army in reporting 46,600 U.S. battle casualties from November 1, 1944 to April 30, 1945, in France and Germany, had 152 clostridial infections with 90 amputations and 38 deaths; the incidence in this series was 0.3 per cent of all wounds and the mortality 24 per cent.

Tetanus. Due to the increasing widespread inoculation with tetanus toxoid in early childhood with booster doses continued, tetanus is no longer the major problem it once was. Nevertheless, an occasional neglected patient is admitted to the medical services with this dread disease. If the patient is a member of the armed services or is otherwise known to have had tetanus toxoid previously, a booster dose is immediately given when he is first received in a medical facility. If he has never had tetanus toxoid, then he should be tested for sensitivity and a large dose of tetanus antitoxin given. The usual prophylactic dose of 1,500 units is useless in war wounds. This should be raised to the level of 6,000 to 9,000 units initially, and at the same time the wound should be thoroughly débrided, or excised if possible (16). Once the disease has established itself, therapy has little more to offer today than it did many years ago. It is largely supportive in nature, with sedation and adequate alimentation by vein or by gavage. After prompt testing against horse serum and desensitization if necessary, very large doses of tetanus antitoxin intravenously should be given, such as 60,000 to 100,000 units initially and 50,000 to 75,000 units at 24-hour intervals.

Recent experiments with small animals suggest that large doses of the tetracyclines may also be of distinct benefit in treatment.

Bactericidal and Bacteriostatic Agents. These have already been referred to and the basic principles underlying their use stated. All hark back to 1870, when Lister suggested that the skin be washed thoroughly with a 1:20 aqueous solution of phenol, all bleeders tied, no sutures used, and the wound covered with dressings soaked in a 1:5 solution of phenol in oil, which was changed the following day to a 1:10 phenol in oil dress-

ing and then to a 1:20 dressing (17). In World War I the surgeons still sought the ideal antiseptic, hence Dakin's solution of the exact pH so that injury to living cells would be minimal, but the solution itself is too unstable to attain this objective. Because a correctly performed Carrel-Dakin dressing is almost impossible of proper execution in a mobile hospital, where numbers of open wounds require daily dressings under this treatment, other antiseptic dressings in the form of pastes were advocated. Only toward the end of the war was it fully realized that the primary requisite for wound healing was the initial removal of all dead tissue so that a clean wound was left.

In the early stages of World War II, great hopes were placed in the sulfonamides, but it soon became apparent that they were of no avail per se in preventing infection in the presence of dirt, sloughs, dead tissue, and sequestra. And so it was again with penicillin. It became evident, however, that these antimicrobial agents might be used singly or in combination, and when so employed they extended the scope of surgery considerably, especially when initial surgery had been long delayed. When employed in this manner, they are particularly valuable in the field of reparative surgery but have no place in encouraging a "safe" period of delay.

The more thorough the débridement and the necessary surgery, the more helpful will be the antimicrobials. They are always an adjuvant, never a substitute or a cure in themselves. They should always be administered knowingly and with judgment and should be terminated as soon as possible because of real dangers associated with them. Unfortunately, penicillin at times creates sensitivity which may be most serious and even threaten life itself. The action of streptomycin on the intestinal flora and the *Escherichia coli* is of short duration with prompt escape of the bacteria from its control. Neomycin when administered orally and used in conjunction with streptomycin enhances the action of both. It cannot be given parenterally, however. Some of the broad spectrum antibiotics may occasionally induce agranulocytosis and also, by limiting the growth of the customary intestinal flora, may encourage the growth of intestinal monilia, with most distressing symptoms and a condition that at times does not yield readily to treatment. Perhaps one of the gravest of all the complications of our present widespread use of the antibiotics is the persistence of a resistant coagulase positive hemolytic staphylococcus. This is a highly virulent pathogen, and these infections, of which the most common are pneumonia, septicemia, and necrotizing colitis, are most difficult to treat.

Dressings. Dressings should be done infrequently, gently, and carefully, and one should never hesitate to transport a patient to the dressing tent or operating room if he can be moved and the dressing can be better performed there. Under ideal conditions the first dressing will be performed and the wound sutured in the operating room between the fourth and tenth days; the second dressing will be 10 or 12 days later when the sutures are removed. Masks should be worn for all dressings, even in the most forward hospitals; this precaution is a most important preventive of droplet contamination, which may of itself lead to wound infection.

Convalescence. Convalescence and rehabilitation are integral parts of military surgery. The greater the number of men who can be restored to duty within the Army area itself, the higher will be the morale of the troops. This is achieved by means of convalescent hospitals. Forward (Army) hospitals have a three-fold function: 1. to provide expert care for the wounded; 2. to provide for and keep clear the chain of evacuation so that they are able at all times to receive the oncoming load from the front; and 3. to hold as many as possible of the ill and minor wounded so as to assure their return to their own units with a minimum of delay and confusion. At times of great stress, such as an amphibious operation or the first phase of an offensive, it may be necessary to evacuate almost every one who is transportable. Again, during periods of quiet such as usually occur in winter, many can be held for two or three weeks in the forward hospitals. Various ancillary hospitals are employed to expand such a holding policy. These have a double action: first, more beds are provided; and second, by segregating similar groups of patients, the morale of these particular

groups as well as the morale of the others is improved. Thus we have the convalescent hospital, with skeleton staff and minimum equipment. When it is broken up into sections, the small units can move rapidly and act independently or be temporarily attached to an Evacuation Hospital. These units have reconditioning programs and provide for the care of some of the ill and minor wounded for 20 to 30 days after they have been discharged from one of the active hospitals. Likewise, venereal disease and neuropsychiatric centers are established by an army operating in the field so that these important groups may be immediately segregated and the patients in the other forward hospitals protected from the destructive effect of these cases on their morale. Simultaneously, by the establishment of these centers, professional care is concentrated and economized, with the result that the patients are much better cared for than if dispersed. One U.S. Army reporting for the period from September 1, 1944, to May 7, 1946, in France and Germany showed a return to duty of 40 per cent of all admissions in its own forward installations: 56 per cent of the "disease," 36 per cent of "injuries," and 16 per cent of "battle casualties" (11).

COMBAT ZONE SURGERY

General Considerations. Prior to consideration of the various types of war wounds individually, one should understand that this section deals entirely with the forward surgery of the wounded, where the primary goals are: 1. arrest of hemorrhage; 2. correction of grave physiological disturbances; 3. prevention of infection. These accomplished, the patient is transported out of the forward area as soon as his condition permits. The greater and more rapid the dispersion of patients to the base, the sooner reparative surgery can be instituted and the better the chances for recovery with good function and minimum deformities. In certain instances, as in abdominal and chest wounds, the initial surgery may of itself be definitive. Thus, the measures listed below must be considered with understanding of the above: the colostomy, the suprapubic cystostomy, and various other procedures recommended such as nonsuture of tendons, nonclosure of amputations, thorough and complete débridements, nonsuture of nerves, the immobilization rather than the perfect reduction of fractures, the initial treatment of major burns by the closed method. Although these measures may seem incomplete, they are those that have been tested by time and experience and have been proved to be the best procedures for this initial surgery.

Surgery in forward areas can always be expanded depending upon the tactical situation at any given period of time. This decision must be made by the Army and the Theater Surgeons, and the various medical installations in turn must abide by it.

Extremities. War wounds of the extremities, which comprise 61 per cent of the body area, account for about 65 to 70 per cent of all wounds. These wounds are simple or complicated depending upon whether they involve only the soft parts or include also bone, major arteries or nerves, joints, or communicate with other regions of the body. All combinations occur. The principles of complete débridement, with splinting when necessary, apply explicitly to the uncomplicated soft part wounds. With early delayed suture this is the largest group of casualties that may never require evacuation from the Army area.

The wounds of open (compound) fractures are débrided and dependent drainage established, when indicated, to prevent pooling of secretions. The object in the forward installations is not to reduce the fracture but to immobilize it promptly and completely in a plaster of Paris transportation cast. Skin-tight plaster is never used and all casts, and circular bandages under casts, are split after application. A rough diagram is drawn on the cast showing the fracture, the size of skin defect, and the date of application of the cast. Internal fixation is used in the forward hospitals at the time of initial surgery *only* when there is danger of impingement of the bone ends on major vessels or nerves, and in some fractures entering into joints when early reduction and fixation are essential to preserve the joint. Débridement of compound fractures of the femur is facilitated by insertion of a pin through the tibia and suspension of the leg, with the knee flexed at 90 degrees, to a frame over the operating table.

These patients are listed as first priority

for evacuation so that they may reach the fixed installations in the Base as early as possible compatible with their ability to withstand travel. Here the condition is appraised and adequate transfusions are given to restore the hemoglobin and hematocrit to normal limits. Casts are removed, wounds sutured or redébrided preparatory to suture, and fractures reduced by whatever means are deemed advisable.

Peripheral Nerves. War injuries to peripheral nerves include contusion and division, with or without loss of substance. Damage from the concussion effect of missiles, with resulting palsies, may occur though no gross evidence of the injury may be seen at the time of operation. When nerves are found divided, no attempt to approximate the ends by suture is made at the original operation, even though in certain instances this would appear to be the ideal procedure. The reasons are that at the time of initial surgery: 1. one cannot determine the extent of possible added nerve damage due to concussion; 2. as little foreign material as possible should be left in the wound; and 3. the frequent necessity of leaving sutured nerves under tension and uncovered in débrided wounds courts further disaster. One of two methods is, therefore, employed at the initial operation: 1. the nerve ends are simply stitched separately beneath adjacent muscles, without tension, or 2. the nerve ends are brought together loosely with a single suture and then protected by overlying tissues. By using wire sutures, the position of the nerve ends can be determined by x-ray, and the size of the gap to be closed can be demonstrated. The extremity is properly splinted, and a careful record of the procedure is made. In the fixed hospital in the Base secondary suture of the wound is done, and two or three weeks after it is fully healed, definitive nerve suture may be performed. At this time degenerative changes will be fully apparent, and an appropriate amount of the nerve can be resected.

Arteries. Major vascular injuries probably complicate about 0.9 to 1.5 per cent of *all* wounds, and between 1.4 to 2.7 per cent of extremity wounds. They seriously complicate (7, 11) the surgical problem in that they threaten the viability of the limb itself, they favor clostridial infection, and, later, they may lead to aneurysms, which usually become the problem of the reconstructive phase of military surgery.

Few of these wounds are simple; the great majority are complicated by comminuted fractures and extensive tissue damage. The wound of the vessel itself is often extensive, and there may be extensive thrombosis already present when the patient is first seen. Sometimes in the absence of an open arterial wound due to contusion, there may be damage to the vessel wall with thrombosis.

Numerous procedures have been advised and devised to circumvent these difficulties and furnish a new arterial segment or to provide temporary circulation until the collateral system can take over. But no amount of reconstruction will avail if the limb distal to the point of injury is already dead. Unfortunately, since most of the injuries are extensive and there is often no choice other than a graft of some sort or ligation of the artery, the injuries suitable for arterial suture and those in which prostheses or grafts may be employed are relatively few, for two reasons: 1. the extent of the damage itself, and 2. the time factor, as it is rarely possible to save the limb by restoring its circulation after eight to ten hours have elapsed from the time of wounding. Every effort should be made, however, to obtain a primary suture or the use of vein graft, or an arterial graft if such is available. If a vein segment is used, this should be reversed so that its valves do not impede the arterial flow. Just as we have blood banks, it is now possible to have blood vessel banks or to use artificial prostheses, such as those made out of nylon, dacron, or similar materials. While successful for large vessels, these have not proved as successful for the smaller. Perhaps the best of these artificial prostheses at present is the Edwards-Tapp, of crimped nylon. Again here the tactical situation and the type of warfare play an important part. This surgery may or may not be possible in the Mobile Army Surgical Hospital, for in war, one must never lose sight of the fact that in the initial surgery of the wounded, the saving of limbs is always secondary to the saving of life.

If the popliteal artery is ligated, 70 to 75 per cent of these patients will require amputation, and about 50 per cent following liga-

tion of the superficial femoral artery (11, 18, 19).

Sympathetic block or sympathectomy has its greatest value when the limb has been ischemic for a period of time and shows very slow recovery after repair of the vessel. After ligation of a major artery, the question of ligation of the accompanying vein arises. Wounds are so different and so complicated, it has been impossible to make any comparison in similar groups where the accompanying vein has been ligated with groups where it has not. If it is ligated, however, it should be cleanly divided after ligation.

Amputations. Closely associated with vascular lesions is the problem of amputations. The great majority will be performed for extensive trauma and are really the completion or temporary revision of traumatic amputations or the removal of limbs attached by only a few shreds of tissue.

"There are three major reasons for amputation—a hopelessly mangled limb, infection and vascular insufficiency" (13). In World War II vascular insufficiency was the reason for amputation more often than infection, or infection and vascular insufficiency combined. Everything is done to preserve as much stump length as possible, prevent infection, and render later revision easy should it prove necessary. These objectives are best attained by the modified circular amputation, which should present a slightly concave open cross section of the extremity at completion. A circular incision is made through the skin and the skin is allowed to retract; the fascia is then incised at this level and the superficial layer of muscles cut and permitted to retract; finally, the deep layer of muscles is cut at this level and the periosteum of the bone is incised, but not stripped, at the level of muscle retraction, and the bone cut through. Skin traction is applied with the original dressing. Continued skin traction of about five pounds is most important in the postoperative period to preserve maximum length, prevent retraction of muscles and skin, and provide a firm covering of fibrous tissue for the end of the bone.

Joints (20). The principle of débridement applies with particular emphasis to joints. They are poorly vascularized structures, their cartilage is prone to infection and necrosis when injured, and drainage of suppurative processes in them is very unsatisfactory. By thorough débridement, bad results can be prevented in the vast majority of cases. All penetrating wounds of joints or compound fractures communicating with joints should be widely explored, with good retraction, so that the joint may be completely visualized. The joint is irrigated with saline solution, all blood clots, loose bone and cartilage fragments, and foreign bodies are removed, and ragged areas of cartilage are pared smooth. The joint capsule is then closed and antimicrobials in saline or water instilled; the skin is not sutured. Plaster immobilization is provided. For the knee joint this means a low spica, as a simple long leg cast does not provide sufficient immobilization. After 48 hours the joint is reaspirated and the antimicrobial agent again instilled, and the process repeated at 48-hour intervals until there is no significant accumulation of fluid. Even though a joint is suppurating when first seen, careful débridement and the treatment decribed should be carried out, for frequently even already infected joints will respond to this therapy provided they are first rendered physically clean. Two Evacuation Hospitals reported 227 arthrotomies for penetrating wounds of the knee with only two residual infections, one 10 and one 14 days old when received by them and both well established at that time (11). The knee of all the major joints is one of the most commonly injured and one of the most successful to treat.

The same principle of débridement applies to wounds of the hip joint. If these wounds are not properly débrided and the joint closed, a severe debilitating infection usually occurs, with eventual osteomyelitis and destruction of the joint if the patient recovers. The best approach to the joint is either by the usual anterior Smith-Peterson or a posterior approach. The joint is exposed and a thorough débridement is performed. Inasmuch as the blood supply comes in through the posterior capsule, this should not be disturbed unless badly damaged itself.

Although the results with the hip joint are inferior to surgery of the knee, nevertheless thorough débridement and installation of an antimicrobial agent will probably prevent a suppurative arthritis and the septic

complications that so often occur with this type of injury. Even if later the head of the femur undergoes an aseptic necrosis or traumatic arthritis, the problem in reconstructive surgery is far less and the outlook better than when incomplete initial surgery is performed.

Craniocerebral Injuries. The head, face, and neck comprise 12 per cent of the body area, and approximately the same percentage of wounds will be found in these regions. The craniocerebral group alone forms about 8 per cent of all wounds. Inasmuch as the vast majority of these injuries are of the penetrating variety, a decompression is often already present when the patient is first seen, and the problem of intracranial pressure is, therefore, of considerably less moment than it is in civilian practice. Furthermore, most of the patients stand transportation extremely well prior to surgery but not at all well in the early postoperative period. It is of the utmost importance that the initial surgery be complete in these patients; hence, they should be sent to installations where facilities, time, and provisions for postoperative care are available. Initial surgery may be safely delayed even up to 72 hours. Following operation, however, they should not be moved for a week or ten days. When débridement is performed, great care is exercised to remove all devitalized tissue, spicules and fragments of bone, and all foreign bodies, especially those other than metallic, although these, of course, are removed also whenever feasible. Every effort is made to close the dural defect, by fascial or preserved dural graft if necessary, and the wound is closed by primary suture. These wounds form one of the few exceptions to the dictum that wounds should never be closed primarily, because, unless primary closure is accomplished, infection and cerebral fungi are prone to occur with ensuing cerebritis. The majority of infected wounds and brain abscesses seen later in the Neurosurgical Centers in the Base are due to the presence of foreign material, particularly retained bone fragments.

Spinal Cord Injuries. This is an extremely difficult group of injuries for treatment, particularly as to laminectomy. In one series of 113 patients operated upon, the mortality varied from 0 to 33 per cent in different hospitals, while in a nonoperative group of 69 patients, the mortality varied from 0 to 66 per cent. Operation itself, therefore, does not appear to be a factor in the mortality. Improvement was noted following laminectomy performed as late as 17 days after injury in a patient who had shown no prior signs of recovery (11).

When patients with spinal injuries are received in the forward hospitals, suprapubic cystostomy should always be performed if bladder paralysis exists. In active warfare, suprapubic cystostomy is the procedure of choice because it is the safest device, requires least care, and is the most foolproof, all of which are essential in ensuring safe and comfortable transportation for the wounded soldier.

Eyes. Wounds involving the eyes frequently require the combined skill of the ophthalmic, maxillofacial, and neurologic surgeons. Fortunately they are not numerous, probably under 5 per cent of all wounds. A local anesthetic applied topically in the Aid Station, the use of atropine, a bland ointment, and immobilization of both eyes by pressure pads and bandages ensure safe transportation to the hospital. Only those eyes that are obviously irreparably damaged should be removed in forward installations. The use of conjunctival flaps is sometimes of great benefit until the patient reaches the Base.

Maxillofacial Injuries. Maxillofacial wounds account for about 4 per cent of all wounds. After thorough débridement and saline irrigations, wounds involving the mouth and face should be sutured with careful approximation of the parts when possible. Great ingenuity is often demanded in the initial surgery so as to prevent infection and conserve tissue, both vital for later repair. Fractures of the jaws should be maintained by wiring, and elastic bands used to hold the wired jaws together, as they are readily removed in case of vomiting. If there are bony defects or the fracture is extensive, contour may be preserved by internal fixation apparatus or a double pin external fixation apparatus. Assurance of an airway must be provided, and tracheostomy may be necessary. Dependent drainage is advisable, and moist dressings help in controlling possible infection. Parenteral antibiotics are of great value

for these patients, and comfort and control of the mouth infection are obtained by strict attention to oral hygiene and warm irrigations of saline and sodium bicarbonate. Even within the forward areas, special hospitals may be designated to receive these patients so that the best use may be made of the available personnel.

The Thorax. The chest occupies 16 per cent of the body area whereas wounds of the thoracic region itself account for only about 10 per cent of all wounds. This is in large part attributable to the fact that, like wounds of the head and abdomen, many of them cause immediate death on the battlefield. Penetrating wounds of the thorax present two principal problems: disturbance in the respiratory or cardiorespiratory systems, and infection. The first may be insignificant and hardly noticeable or it may be accompanied by severe hemorrhage and shock and a gaping pneumothorax. Early correction of the disturbed physiology minimizes the dangers of infection later.

Open pneumothorax is treated on the field or at the Aid Station with a snug occlusive dressing which is not disturbed until a suitable hospital is reached. Here, after necessary resuscitation, the wound is débrided and the opening into the thorax closed; the skin is left unsutured. Débridement of a wound of the thorax consists of removal of all damaged tissue and bone fragments, careful hemostasis, complete aspiration of the pleural cavity, and inspection of the intercostal or internal mammary vessels. The lung is expanded, the muscles are closed, and an occlusive dressing is applied. When there is danger of a pressure pneumothorax, a catheter is inserted through the second interspace anteriorly and underwater drainage estabtablished for a few days. In the more severe injuries, tracheostomy may be advisable.

There has been considerable discussion as to the advisability of primary formal thoracotomy at the time of the initial operation. In our experience, however, this is unwise. The only indications for primary thoracotomy, either by extension of the wound or by a new incision at a site of election, are: 1. continuing intrapleural hemorrhage, 2. evidence of injury to the trachea or larger bronchi, 3. evidence of large retained intrapleural foreign bodies, 4. evidence or suspicion of damage to mediastinal viscera, 5. evidence of involvement of the *diaphragm and abdominal* cavity. Unless one of the above indications exists, there is no indication at this time for a formal thoracotomy. Foreign bodies in the lung parenchyma can be removed at some later date with less risk and less chance of empyema.

Postoperatively the chest is aspirated as often as required to keep it dry and encourage re-expansion of the lung, which will also decrease the liability to infection. The problem of foreign bodies in the lung, clotted hemothorax and empyema belong to the reparative phase of surgery in the fixed hospitals of the Communication Zone where there are thoracic centers with surgical and medical specialists skilled in handling these conditions.

The Abdomen. Only about 4 per cent of wounds seen in Army hospitals are abdominal, and another 1 per cent will penetrate both the thorax and abdomen, although the abdomen comprises 11 per cent of the body area. The discrepancy is readily explained. The battlefield mortality of these wounds is high, and also the position of the advancing soldier offers a certain degree of protection to the abdomen. The closer a hospital is to the front, the greater the number of patients with abdominal wounds it will receive and the higher will be the mortality figures. The principal difficulties that confront the surgeon are hemorrhage, severe shock, and infection. The great majority of these patients are properly taken to the MASH units, and a smaller number of the less severely wounded to the Evacuation Hospitals. Because of the impending or established infection, the time lag to initial surgery should be as short as possible. If there is active hemorrhage, resuscitation cannot be complete until this is stopped by operation. Not over two to three hours should be spent in resuscitation; if there is no response to adequate blood replacement therapy, the failure is generally due to continuing hemorrhage, extensive soiling and peritonitis, or massive evisceration.

In the preoperative preparation of these casualties, the stomach should always be emptied. The anesthesia is preferably endo-

tracheal gas-oxygen-ether and a long midline incision is the one of choice. Small intestinal wounds are repaired individually when possible. If the damage is too extensive, however, or the repairs seem likely to cause obstruction, resection and an end-to-end anastomosis is performed. Large intestinal wounds should be exteriorized without tension. If this is not possible, then they should be closed in two layers and a proximal colostomy provided, usually with complete division of the gut, although at times a simple loop colostomy may be sufficient. The colostomy should always be brought out through a separate incision to prevent sepsis in and rupture of the large exploratory incision.

Wounds of the *rectum*, both intraperitoneal and extraperitoneal, and wounds of the anus demand sigmoid colostomy. Drainage of the perirectal space, in extraperitoneal rectal wounds, must also be provided at the time of the original operation by perirectal incisions through the fascia propria into the areolar tissues about the rectum. Removal of the coccyx occasionally may be required to accomplish this. In all wounds of the buttocks and flanks penetrating the abdomen, it is wiser to do the débridement first and the abdominal exploration second as these patients do not tolerate the prone position well after laparotomy.

Wounds of the *solid viscera* are treated according to usual civilian standards. Frequently nothing need be done to the liver if bleeding has ceased. If it has been extensively damaged, however, loose fragments should be gently removed and hemorrhage controlled by suture or a pack inserted with just sufficient pressure to control the bleeding. All liver wounds should be drained to prevent accumulations of the bile within the peritoneum. If the wound of the liver is not packed, the subdiaphragmatic space should be drained and great attention paid to insure a proper repair of the diaphragm. If subdiaphragmatic drainage is not established, the chances are great that there will be a collection of bile with or without perforation into the thorax.

The *kidneys* are treated with great conservatism, and only those irretrievably damaged are removed, but in every instance the opposite kidney should always be palpated. The patients should be carefully followed, however, as the possibility of a functionless, or "dead," kidney, which may necessitate removal at a later date, is real. Suprapubic cystostomy is provided after repair of wounds of the bladder, and if there is urethral damage as well, an indwelling catheter is also maintained in place.

General Considerations in Abdominal Wounds. Transfusion and plasma therapy are continued during the operation and in the postoperative period and careful attention given to the fluid and electrolyte balance. These patients must not be drowned or waterlogged by the overenthusiastic administration of parenteral fluids. If large amounts of blood are required, it is wiser to use identical type blood because of possible renal depression. Since these patients do not stand transportation well, every effort should be made to hold them in the original installation for 10 to 12 days.

An analysis of 55,000 battle casualties received in its forward hospitals as reported by a U.S. Army in the European Theater is given below; the mortality rates are also shown:

TABLE 3.

Classification	Battle Casualties (MASH) Field	Battle Casualties Evacuation	Mortality (%) (MASH) Field	Mortality (%) Evacuation	Mortality (%) Total
Abdominal	1,299—26.0%	906— 1.8%	24.6	11.5	19.2
Thoraco-abdominal	264— 5.3%	187— 0.4%	26.5	15.0	21.7
Thoracic	1,875—33.6%	2,645— 5.3%	8.7	3.3	5.4
Maxillofacial	111— 2.2%	3,211— 6.4%	2.7	0.7	0.8
Head	188— 3.8%	3,163— 6.3%	18.6	8.6	9.1
Spine	49— 1.6%	371— 0.7%	20.4	8.1	9.5
Upper Extremity	285— 5.7%	14,174—28.3%	5.0	0.3	0.5
Lower Extremity	860—17.2%	21,044—42.0%			
Other	266— 5.2%	4,393— 8.8%	8.5	0.7	1.1
Total	5,197	50,094	13.2	1.4	2.5

The higher mortality figures in the Field Hospitals reflect clearly the type of patients these units treated: they were the nontransportables, among whom the mortality is bound to be high. Nor is there the diluent of the many slight wounds in all parts of the body that make up a large part of the work in Evacuation Hospitals.

Hand Injuries. Even at the start of World War II, damaged hands were generally carefully splinted without thought as to future reconstruction; in fact, they were often splinted with traction and full extension or flexion, instead of in the normal relaxed position of function. In dealing with wounds of the hands in forward echelons, several basic principles should be kept in mind. First, the hand should always be loosely immobilized in its natural position of relaxation and function. Second, no tendons or nerves should be sutured. Hands should be carefully débrided and loosely sutured so as to provide for a minimum of scar tissue and as clean healing as possible. At the same time such procedures will cover exposed tendons and nerves. If there has been large loss of substance, an attempt should be made, if feasible, to bury the hand in an abdominal or thigh flap: in other words, try to get the open surfaces and exposed tendons covered with the hand in position of relaxation and ready for transportation to the Base, where true reconstructive surgery may be instituted.

Genital Injuries. As regards the genitals, there is little to add to what has already been said. As to wounds of the *bladder,* these of course must be sutured and suprapubic drainage temporarily established. If the *urethra* is damaged, a temporary splint should be inserted such as a catheter, probably Foley type, and it may be necessary to insert this in a retrograde fashion. If the scrotum has been avulsed and the testes exposed, it is essential that débridement be carefully performed and the skin loosely closed. If there has been loss of substance, the testicle can be readily buried temporarily in the thigh and the remains of the scrotum stitched loosely to the thigh so as to prevent retraction. The patient is now safe for evacuation, and the extravasation of urine has been prevented.

Burns. In World War II, burns presented no major problems in the Army because the incidence was low. They were commonly caused by explosions and fires within tanks during tank warfare, by phosphorous shells or bombs, by bombs and scattering of flaming liquid or incendiary material, by bursting of steam pipes on ships in naval warfare, and by explosions and fires in areoplanes, and by propellants. There are also the many flash burns incident to the extensive use of gasoline by a mobile army. Chief among these are those burns resulting from minor explosions and flares associated with the use of field ranges. The same principles of treatment apply as are practiced in civilian surgery. The initial care consists of a minimal cleansing by gentle means and the application of uniform pressure dressings with the added protection of a plaster cast as indicated for comfort or to assure immobilization. Plasma and transfusion therapy is governed by the estimated extent of the burn, the needs of the patient, and his hemoglobin and hematocrit levels. The strictest asepsis and masking should be practiced whenever the dressings are changed, and granulating areas should be covered with split thickness grafts as soon as the sloughs separate. Patients with extensive or severe burns present the same nursing and feeding problems as they do in civil life; hence, they should be evacuated from the forward hospitals to the base as early as is compatible with their safety. In severe burns of the face and the neck, tracheostomy may be life saving.

In most instances of major burns, closed treatment is indicated. In the event of mass casualties, however, this may not be possible and even those with minor burns would have to aid in the rescue work. Pain in most burns diminishes greatly or ceases within about thirty minutes. Wherever possible, a simple dry dressing should be used. If cleansing is necessary, one of the modern surgical detergents is best employed. These are less irritating, less macerating, and far more efficient than ordinary soap.

When damage to the lungs is suspected, oxygen is needed and the amount of plasma and blood administered should be limited so as not to overload the cardiorespiratory system.

New problems are presented with thermo-

nuclear missiles. In the initial effects, there will be large numbers of burns (40 to 60 per cent) of all degrees of intensity. Many patients will also suffer from the explosive effects of the bomb or from flying or falling objects. In addition to the explosion and the terrific heat generated, there is likewise an enormous amount of radioactivity liberated, which penetrates and extends over a varying distance, and also in the fallout area, so that those in the path of the radioactivity will exhibit effects ranging from alopecia and mild delayed burns to sterility, marked agranulocytosis, blood destruction, and death. With the ordinary high air bursts, except for the initial damage by the liberated radioactivity, there is little added danger from this source inasmuch as the radioactive cloud soon blows away. This condition, however, is quite reversed in ground or water bursts, in which cases the radioactivity persists. There are three general classifications of radiation injury: 1. the very severe; almost all of these patients will die within the first two or three days no matter what is done for them. 2. The moderately severe radiation effect; in these instances radiation illness will appear within several days, although there may be an initial wave of nausea or slight diarrhea; then the signs of anemia and leukopenia will appear with multiple hemorrhages, nausea and bloody diarrhea. Some of these patients will be saved by prompt hospitalization, transfusions and adequate diet and good care. 3. The third group consists of those with minor radiation effect; almost all of these patients will recover. The appearance of the illness will be delayed and their blood counts will show relatively minor damage. The lethal initial dose is in the neighborhood of 600 r whereas in the moderately severe cases the dosage may be between 200 and 400 r.

Cold Injury (21)—Trench Foot. This is the term generally applied to a condition resulting from prolonged exposure of the feet to cold and moisture, usually, though not necessarily, associated with dependency and immobility and with constriction of the limbs by shoes and other clothing. It is closely related, though not precisely similar, to immersion foot and shelter foot.

Important factors in the development of trench foot are:

1. Temperature. The incidence increases as the temperature drops below 55° F.
2. Length of exposure. This may vary from hours to weeks.
3. Dependency and immobility. Men who sit or stand in trenches and who crouch in foxholes for long periods of time are particularly likely to develop trench foot.
4. General chilling. This results in general vasoconstriction and circulatory stagnation.
5. Footwear. Constricting footwear, and that which does not afford adequate warmth and protection or does not permit evaporation, predispose to trench foot, although keeping the feet dry is considerably more important than is the factor of evaporation.
6. Age. Men under 17 and over 40 years of age are more susceptible to trench foot than those within these age limits.
7. Previous environment. The experience of the Hawaiian-Nisei groups in the Mediterranean and European Theaters in World War II suggests that individuals accustomed to a warm climate have a lower resistance to the combination of cold and wet environments than do those accustomed to colder climates.
8. Trauma.
9. General nutritional deficiency.
10. A history of previous trench foot of moderate severity, or peripheral vascular disease.

Pathology. During the period of exposure and hypothermia, there is peripheral vasoconstriction, chiefly of the arterioles but sometimes also of larger arteries. The resultant ischemia causes anoxia, which results in increased permeability of the capillaries, exudation, and edema. These changes may be accentuated by existing arterial disease, tight shoes or leggings, prolonged exposure to cold, and trauma incurred from walking on the damaged feet.

Immediately after exposure to warmth, a marked inflammatory hyperemia of the part occurs with excessive vasodilation. This is accompanied by swelling and edema, which, though due chiefly to increased permeability of the damaged capillaries, are caused in part, also, by mechanical factors. Thus a vicious circle is established, in which transudation increases the already existing oxygen deficiency. There may likewise be peripheral nerve changes as evidenced by the paresthe-

sias, anesthesias, and sudomotor disturbances present.

CLINICAL MANIFESTATIONS. The clinical manifestations vary, and depending upon the length of exposure and degree of tissue damage, the lesions may be classified as mild, moderate, or severe. The mild type exhibits erythema, slight tingling or paresthesias, and little edema, if any. In the moderate cases there are pitting edema, blebs, and ecchymosis. In the severe form the symptoms and signs are accentuated, with bullae, extravasations of blood, and incipient or actual gangrene.

The earliest symptoms consist of coldness and numbness of the feet and sometimes tingling or aching. The most prominent symptoms, however, are numbness and a heavy wooden feeling. Walking is clumsy, as if "on blocks of wood." If the shoes are removed, the feet will be found to be cold and partially anesthetic to pain, touch, and temperature. Swelling usually is not marked and the skin, at first red, soon becomes white, waxen, or mottled blue. Later, blisters appear. Frequently at this stage, when the shoes are removed for the purpose of resting, drying, or rubbing the feet, the patient discovers that he is unable to put them on again because of swelling.

After several hours as the symptoms progress, there will be increased swelling, mottling, and areas of anesthesia, most commonly about the toes, plantar, and lateral aspects of the feet. At first the peripheral pulses may be absent. As the feet grow warm, swelling increases rapidly and a severe burning pain begins; this marks the beginning of the second or hyperemic stage.

This stage may persist for days or weeks and the feet become hot, red, and dry and the pulses full and bounding. Blebs and patchy ecchymosis appear, with the damage greatest about the toes and distal part of the foot. Actual gangrene may be present in severe cases. The anesthesia is replaced by paresthesias and an intense burning pain relieved by cold and made worse by heat. The affected parts may ache and throb, there are scattered areas of hyperesthesia and paresthesia, and there is anhydrosis. In severe cases, the edema may extend all the way to the knees. After four to six days, all the symptoms begin to subside. If the injury has not been great, the skin assumes a normal color after some exfoliation. Occasionally, however, the feet become cold, blue, and sweaty. The usual complications are phlebothrombosis and infection, localized or spreading. Rarely, transient hematuria and albuminuria, enlargement of the liver, and mild fever may be noted.

In the posthyperemic stage, the condition apparently progresses to complete recovery in the milder cases. Symptoms may persist for a long time, however, in the most severe forms, and are aggravated by walking, standing, or exposure to cold. Deep-seated pain, stiffness in the joints, and osteoporosis may persist, and there may be a residual hyperhydrosis of the feet and an excessive sensitivity to cold.

PREVENTION. Prophylactic measures consist, first, in the provision of adequate warm and protective footwear and clothing and the avoidance of unnecessarily prolonged exposure; and, second, in a campaign of instruction to officers and men in the prevention of trench foot. The formulation of the prophylactic routine is the responsibility of the surgeon, but its implementation is the responsibility of the military command itself. *Unit commanders must be interested in and assume responsibility for the care of the feet of their troops.* The incidence of trench foot will rise or fall in direct ratio to the cooperation of all elements of the command.

Measures of Major Importance. 1. Loose-fitting waterproof or water-resistant boots are essential. They should be equipped with removable inner soles and should be large enough to accommodate two pairs of woolen socks (one light and one heavy) so as to provide sufficient insulation, ventilation, and absorption. The insulated type boot and the shoe-pac with rubber foot piece and leather top seem to be the best type of footgear except on rough or mountainous terrain. Troops must be instructed *not* to lace the boots tightly.

2. Proper clothing and gloves should be worn. They should be wind and water resistant and of good insulating properties. Constriction by all clothing, particularly leggings, socks, and garters, must be avoided.

3. An abundant high-caloric, high protein diet should be provided; whiskey and

other alcoholic beverages are to be avoided.

4. Every effort should be made to keep the feet dry. A compulsory daily sock exchange may be arranged, to be operated by the company mess section, and drying shelters and tents can be provided.

5. Prolonged immobility should be avoided.

6. The boots should be removed at least once daily, the feet dried and massaged, dry socks put on, and inner soles replaced. Under good foot discipline, men are assigned in pairs, each one being responsible for the daily care of the other's feet.

7. Weekly foot inspections should be held.

8. Whenever it is at all possible, there should be frequent relief of front line units in cold weather.

The incidence of trench foot can be sharply reduced by such a program, but no matter what is done nor how good the foot discipline in any unit, when that unit goes into the line in cold, wet weather, its trench foot curve will rise, such rise depending upon the feasibility of carrying out the above measures.

TREATMENT. Treatment consists of rest, elevation of the feet, prevention of infection, and ambulation as early as possible.

Initially the patient should not be permitted to walk. His wet clothes should be removed and his feet gently cleansed with white soap and water and then thoroughly dried. He should be kept warm, but his feet should be left exposed to the air and elevated on pillows, with especial care to avoid pressure on the heels.

Cooling at room temperature is usually adequate provided the temperature does not exceed 70° F. If ice bags are used, the foot must be well protected by pledgets of cotton between the toes and sterile cotton batting wrapped around the foot so as to protect the tissues.

In the early prehyperemic stage, when vasospasm is still present, whiskey may be given. Sympathetic block is seldom indicated, as its effect is too prolonged and the pain of the hyperemic stage is aggravated.

Massage is contraindicated in the prehyperemic and hyperemic stages.

Measures to prevent infection, including tetanus, should always be instituted. Blebs are ordinarily left alone, but if they are to be opened it should be done with a sterile needle under aseptic precautions. Areas of necrosis and gangrene are treated conservatively and amputation should be delayed as long as possible, for generally the actual tissue destruction is not as great as would appear, even after careful examination.

After the edema and hyperemia have subsided, graduated vascular exercises, gentle massage, warm baths, and passive movements should be started, and the patient then allowed out of bed after a week.

If intractable pain and edema persist, compression dressings or elastic bandages may be cautiously employed and sympathetic block may be tried. Lumbar sympathectomy is indicated only when test blocks have given relief or when manifestations resembling Raynaud's disease develop and persist.

Frostbite. The injury in frostbite is not dissimilar to that of trench foot with ischemia, vascoconstriction and sludging of the blood in the capillaries. Unless the circulation can be re-established, there will be destruction of the skin and deeper tissues proportionate to the duration and extent of the injury. The treatment consists in moderately rapid warming by gentle massage or rubbing with alcohol if the tissues are intact. The temperature of the room should be in the nature of 65° to 70° F. and the injured member slightly depressed. A small infusion of alcohol and novocain is given at once to bring about a vasodilatation. Not more than one sympathetic block is indicated to assure abolition of all vascular spasm. Treatment then consists of protection of the damaged part from infection, a rather cool temperature, and the institution of anticoagulant therapy. Even though the injury may be 48 hours old, anticoagulants may still be of value; heparin may help relieve the pain, and in addition the area of gangrene and final loss of tissue may be lessened by their use. The anticoagulants need not be used to the same extent as in the treatment of venous or arterial thrombosis, and a safe level should always be maintained. Amputation should be avoided as long as possible as in many in-

stances what appear to be irretrievably damaged parts will recover with proper expectant treatment.

CHEMICAL WARFARE (22)

The scope of chemical warfare is broad because it aims at whole groups of people and large areas of terrain rather than at individuals. It may be used to start fires, to make land untenable and water undrinkable, to produce casualties, and for purposes of concealment.

Agents. Chemical warfare agents may be classified according to their physiologic action, their persistence, and their tactical use:

(a) *Physiologic Action.*

1. Lung irritants, whose primary damage is to the respiratory tract
2. Vesicants, which injure the eyes, produce erythema and blisters on the skin, and damage the respiratory tract when inhaled: mustard, lewisite
3. Lacrimators or tear gases, which act primarily upon the eyes, causing tears and temporary pain
4. Irritant smokes or sternutators (vomiting gases), which irritate the eyes and throat and cause temporary prostration
5. Systemic poisons, which stop essential physiological processes: nerve gases

(b) *Persistence.* Persistence varies greatly. Mustard is an example of a persistent agent and phosgene is nonpersistent.

(c) *Tactical Use.*

1. Agents that injure or kill personnel—mustard, nerve gases
2. Harassing agents, to force the wearing of masks and to impede operations—irritant smokes
3. Screening agents to produce dense smoke—white phosphorous
4. Incendiaries

From the standpoint of actual warfare, the two most important groups of these chemical agents in the production of casualties are the nerve and mustard gases, against both of which gas masks are effective. It is extremely difficult to detect nerve gas, however, and its action is exceedingly rapid, with very high mortality. The only remedies we have against it at the present time are large doses of atropine and oxygen administration. The atropine should be repeated after five minutes if no relief is obtained. Nerve gas attack can decimate large areas with great rapidity.

The nerve gases act on the respiratory center by interfering with the metabolism of acetyl choline so that this substance accumulates and the formation of cholinesterase is inhibited. This results in respiratory paralysis. The treatment is immediate hospitalization, oxygen therapy, and large doses of intravenous atropine, which should be repeated at intervals until the respiratory mechanism is well established.

The mustard group includes mustard, nitrogen mustard, lewisite and some others. The effects of these are primarily upon the eyes and the skin; when inhaled there is damage to the respiratory tract; and when they are absorbed they cause systemic poisoning. The eyes may be permanently affected. Persons contaminated with the vesicants endanger those who come in contact with them, and both they and everything they touch must be decontaminated. Those in contact with these casualties should wear protective masks and impermeable gloves and aprons, or protective clothing if the area is contaminated. The agents persist from hours to days, particularly in cold, damp weather and in dark, poorly ventilated places. The best treatment for any of these gases is thorough washing with soap and water and irrigation of the eyes with water or 3 per cent sodium sulamyd solution, which should be instilled every four to eight hours and sterile petrolatum applied to the lids. The eyes must not be bandaged. For nitrogen mustard and lewisite, BAL solution and ointment should be used early. Although extremely irritating to the normal skin and eyes, they give prompt relief to the blepharospasm, erythema, and blisters caused by the lewisite. The lesions caused by these gases require weeks to heal; thus these agents are ideal for the purpose of disabling large masses of people, who in turn will require others to care for them.

Biological Warfare. Biological warfare presents itself in several phases: 1. bacteria in bombs or aerosol mists, 2. viruses, 3. food poisonings and toxins such as botulinus, 4. destruction of crops by spraying or implantation of disease molds or organisms, 5. epizootics and zoonoses by any of the above methods. From the standpoint of this résu-

mé, it is necessary only that one should be aware of the manifold methods in which this type of warfare can be waged. Biological warfare is of special interest to preventive and veterinary medicine and sanitary engineering. Like chemical warfare, it destroys neither the land nor the buildings as opposed to thermonuclear warfare. It may produce large numbers of casualties, with mortality varying with the agents used. Along with the casualties produced, it spreads panic and fear, and by its employment many of those who are unaffected will be required to care for the sick and also to till the soil so as to provide sufficient food in the event that biological agents are employed to destroy crops and dairy and food animals.

SURVIVAL OR DISASTER MEDICINE AND SURGERY

With our present weapons development offense has outrun defense for the time being, so that one country may deliver a massive attack upon another country, with resulting casualties of unimaginable numbers. The 300,000 wounded of the British Army in the Battle of the Somme in World War I over a period of two and a half to three months are infinitesimal in numbers compared to the casualties that would result from a single major sneak attack from the air or a combination of air and sea. Not only can such an attack result in millions of casualties occurring practically simultaneously, but at the same time there would be complete disruption of communications, food and water supplies, sanitation, and the whole economy of a nation. Following such attack, great conflagrations would occur, and there would probably be a heavy and extensive fallout pattern, to say nothing of the area itself, which might well be grossly contaminated with radioactive materials for a period of 10 to 14 days.

The transition from normal economy to one of national survival will occur within a few short moments. How can we plan to meet such a terrifying situation? To assume as many do today that, "It can't happen here" is false; rather, we know it can happen but we HOPE it will not. Nevertheless, there must be some sort of preparation.

Three departments of government* immediately assume paramount importance:

1. Office of Defense Mobilization
2. Department of Defense
3. Federal Civil Defense Administration

To show the function of this structure, the Office of Defense Mobilization would probably become the over-all governing agency for the apportionment of total resources, both human and material. Defense and Federal Civil Defense Administration would both be claimants to it. First, even before assessment of any damage, however, the needs of the sick and wounded present themselves immediately and medical care must be ready. With only slight delay, preventive medicine and sanitation come to the fore in order to minimize to as great an extent as possible the spread of epidemics. New disease patterns may arise, such as the appearance of hemorrhagic fever in Korea, dysentery, influenza, other infectious diseases, possibly even plague, zoonoses, and also starvation.

Quite apart from the federal groups concerned, each community must have its own medical organization in order. Studies have shown that about one-third of the major medical facilities are located in primary target areas and about 80 per cent of the medical, dental, nursing, and ancillary medical personnel are located in our large metropolitan centers. In other words, the ratio of casualties between (A) the medical and allied groups as compared to (B) the rest of the population would probably be about sixty to forty (A:B). Therefore, there will be an extreme shortage both of personnel and of facilities, and "hundreds of thousands of casualties who under normal circumstances would recover, will die due to the lack of trained personnel, adequate facilities and necessary supplies."

* Since the writing of this chapter the Office of Defense Mobilization and the Federal Civil Defense Administration have been combined into a single office, the Office of Civil and Defense Mobilization. Thus, this office now consists of two parts. It has become the over-all governing body but within it there is the suboffice of civil defense. This suboffice of civil defense administration and the Department of Defense would both become claimants in time of great emergency for apportionment of resources personnel, production, material, transportation, communications, food, medical facilities, and so forth.

stances what appear to be irretrievably damaged parts will recover with proper expectant treatment.

* Since the writing of this chapter the Office of Defense Mobilization and the Federal Civil Defense Administration have been combined into a single office, the Office of Civil and Defense Mobilization. Thus, this office now consists of two parts. It has become the over-all governing body but within it there is the suboffice of civil defense. This suboffice of civil defense administration and the Department of Defense would both become claimants in time of great emergency for apportionment of resources. personnel, production, material, transportation, communications, food, medical facilities, and so forth.

The problem of sanitation has been previously mentioned; one must also consider the problem of disposal of the dead. The Federal Civil Defense Administration will provide small hospitals and stockpile short lists of essential medical items. Limited emergency lists of medical items have already been accumulated by the Department of Defense, and work is progressing with somewhat encouraging results on preservation of whole blood or red cells for long periods of time. This could be stored in many places. The patterns of medical care and of medical materiel storage should be just the reverse of that which we follow in our peacetime economy. All of this storage of materiel should occur at points well dispersed from the major centers so that should such disaster ever occur, the problem will be not that of trying to salvage what might be left from the mountains of debris, but rather that of moving the much needed personnel and supplies from the periphery toward the damaged areas. Simultaneously the survivors in these areas with their own organization would be moving toward and establishing their treatment centers in the periphery or undamaged territory. There should be a neighborhood or block-type organization with neighbor taught to help neighbor and in addition, if confusion is to be prevented, there must be a system of local predesignated leadership established.

It is useless to talk about creating burn centers or any other kind of centers within our large metropolitan areas to care for casualties in such major disaster. These areas themselves will be destroyed. Our large metropolitan and industrial zones should therefore look to their periphery 50 to 60 miles away, where there should be previous stockpiling of materiel for assistance in case of such need.

Instead of assuming a defeatist attitude, the sensible way of regarding such an overwhelming catastrophe is to look upon it in three phases.

1. "*Survival.*" Aside from the immediate care of the wounded and dead, the major problem will be that of transport of food and water to prevent starvation, and, next, sanitation and preventive medicine to prevent and control epidemics. By these measures the ground work is laid for the resumption of industry and communication. During this period, both military and civilian would have to interdigitate very closely. Little effective support for the military could be provided from the civilian economy, and the armed forces would have to make maximum use of most of their own available resources to carry out their own mission and to prepare for phase two.

2. Depending upon the speed with which this can be accomplished, the second phase might be called "*Defensive-offensive.*" During this period, recovery and rehabilitation are underway and supplies may be reaccumulated. The lesser ill and wounded are now active again and our economy is recovering.

3. The third phase is "*Offensive.*" Now we are beginning to gather strength and reserves and can move forward once more.

Just as the area of the field of battle itself back to the Battalion Aid Station is of extreme importance in the saving of human life, the same will be true in the initial survival period. And how well and rapidly that survival is accomplished will depend upon our realization of the need of dependence on suburban and rural areas for human reserves and materiel supplies and their organization, stockpiling, and utilization. If one assumes the attitude that "It can't happen here" and relies upon the large centers, as we customarily do in peace, then we may well find that our house was built upon the sand, and it will fall.

GLOSSARY OF TERMS

A FIELD ARMY is the largest combat unit operating in the field.

COMBAT ZONE: The immediate area of combat. This area varies in depth and extent. It is directly under the control of the Field Army commander.

ZONE OF COMMUNICATIONS: This varies with the type of warfare and the area of battle. It extends from the rear of the Combat Zone to the points of debarkation in the United States.

ZONE OF INTERIOR: The boundaries of the United States.

BATTALION AID STATION: The first medical installation to which a wounded soldier or Marine is carried from the field of battle. This is a small sheltered area, manned by two Medical Officers, a Medical Service Corps Officer, and a small group of Medical Corps enlisted men.

COLLECTING STATION: A small station usually one to three miles to the rear of the Battalion Aid Station. Ambulances and helicopters are available here. Although this is a useful unit, it may frequently be bypassed or in certain instances temporarily eliminated and used to reinforce other units.

CLEARING STATION: This is the rearmost of the intrinsic medical installations of the division. It is usually five to seven miles behind the forward lines and has a small holding unit. Its primary function in active warfare is a triage center.

MOBILE ARMY SURGICAL HOSPITAL (MASH): A small unit of 50 or 60 beds. This should be within easy access, preferably hand carry distance of the Clearing Station, where all patients who cannot be evacuated further without danger to life are sent from the Clearing Station. This unit is reinforced by expert resuscitation and surgical teams and is equipped for major surgery. In World War II, small units or platoons of the field hospitals operated at this site. These have now been replaced by the MASH Unit.

EVACUATION HOSPITAL (EH): This is the major hospital of the Field Army. It may be a 400-bed unit or larger. All types of medicine and surgery are practiced here, with specialists on the intrinsic staff or reinforced by teams of specialists. These were usually allocated on the basis of one 400-bed EH to a division in World War II. Each two divisions and their 400-bed evacuation hospitals were further supported by one 750-bed EH.

THE AMBULANCE COMPANY: A company of ambulances. These are under the control of the Army Surgeon and temporarily attached to a Corps, or they are held under a Medical Group. They are always in contact with the collecting stations, clearing stations, and hospitals to which they evacuate.

THE MEDICAL GROUP: An independent organization, one of which operates with each Army, is assigned to a Field Army and directly under the command of the Army Surgeon. They assist him and reinforce the Army Headquarters and Corps staffs.

MEDICAL REGIMENT (BATTALION): This unit consists of an Administrative Headquarters and medical officers and troops. It is assigned to the Army. The Administrative Officers take care of their own administration and may assist the Field Army Surgeon as he desires. The medical officers, troops, and ambulances are at the disposal of the Army Surgeon in any manner as he may direct.

EMERGENCY MEDICAL TAG (EMT): A tag applied to each soldier, wounded or ill, either on the field of battle by the Emergency aidman or in the Battalion Aid Station. This accompanies him back to the MASH Unit or Evacuation Hospital where his field record is established from the information contained on the EMT and further history obtained from the patient.

MEDICAL ETHICS AND CONDUCT

Unethical Practices
Relationship of Physician to Physician
Relationship of Physician to the Patient
Responsibility to the Community
Malpractice and Medicolegal Aspects of Practice
Euthanasia
Relationship of Physician to Hospital

Physicians practicing medicine, regardless of their specialty, have a responsibility and an obligation to society for their conduct. Greater emphasis on conduct and ethics is perhaps necessary in surgery. Large fees for operation throw temptation into the path of the surgeon. Fee splitting is one of the major errors of conduct confronting the profession. The physician must maintain proper relationships with his colleagues, his patients, his hospital, and the community in which he practices. Problems of conduct and ethics will be discussed in detail after considering some of the historical aspects of medicine.

The Heritage of Medicine. Hippocrates said, "Medicine is of all the arts the most noble." We must appreciate that the medical profession is an altruistic one in which the physician is dedicated to service. Any student who enters medicine with the idea of making a fortune has chosen the wrong profession; while it may be possible to reach this objective, it is better that he change to another field of endeavor where financial gain may be greater. The true rewards of medicine lie in other directions and will be achieved only when our conduct, responsibilities, obligations, and ethics are fully understood. These will be discussed in this chapter. The business aspects of medicine are the subject of the splendid monograph by Truman (1). Details of medicolegal problems are ably discussed by Regan (2a) and by Long, in his recent book (2).

The physician receives his medical degree in a ceremony, during which he pledges himself to the following Oath of Hippocrates:

I swear by Apollo the physician, by Aesculapius, Hygeia, and Panacea, and I take to witness all the gods, all the goddesses, to keep according to my ability and my judgment the following Oath:

To consider dear to me as my parents him who taught me this art; to live in common with him and if necessary to share my goods with him; to look upon his children as my own brothers, to teach them this art if they so desire without fee or written promise; to impart to my sons and the sons of the master who taught me and the disciples who have enrolled themselves and have agreed to the rules of the profession, but to these alone, the precepts and the instruction. I will prescribe regimen for the good of my patients according to my ability and my judgment and never do harm to anyone. To please no one will I prescribe a deadly drug, nor give advice which may cause his death. Nor will I give a woman a pessary to procure abortion. But I will preserve the purity of my life and my art. I will not cut for stone, even for patients in whom the disease is manifest; I will leave this operation to be performed by practitioners (specialists in this art). In every house where I come I will enter only for the good of my patients, keeping myself far from all intentional ill-doing and all seduction, and especially from the pleasures of love with women or with men, be they free or slaves. All that may come to my knowledge in the exercise of my profession or outside of my profession or in daily commerce with men, which ought not be spread abroad, I will keep secret and will never reveal. If I keep this oath faithfully, may I enjoy my life and practice my art, respected by all men and in all times; but if I swerve from it or violate, may the reverse be my lot.

Although Hippocrates (460 to 370 B.C.) may be known as the father of medicine and

of medical ethics and conduct, the same feeling of honor and responsibility to the patient existed before his time. For example, in Babylon, a pride and sense of responsibility was expressed by the Code of Hammurabi (3, 4), dated about 1900 B.C., as follows:

> Concerning the wounds resulting from operations it is written: If a physician shall produce on anyone a severe wound with a bronze operating knife and cure him, or if he shall open an abscess with the operating knife and preserve the eye of the patient, he usually shall receive 10 shekels of silver; if it is a slave, his master shall usually pay two shekels of silver to the physician.
>
> If a physician shall make a severe wound with an operating knife and kill him, or shall open an abscess with an operating knife and destroy the eye, his hands shall be cut off.
>
> If a physician shall make a severe wound with a bronze operating knife on the slave of a free man and kill him, he shall replace the slave with another slave. If he shall open an abscess with a bronze operating knife and destroy the eye, he shall pay the half of the value of the slave.
>
> If a physician shall cure a diseased bone or a diseased organ, he shall receive five shekels of silver; if it is a matter of a freed slave, he shall pay three shekels of silver but if a slave, then the master of the slave shall give to the physician two shekels of silver.

Our scientific debt to our predecessors is great. This has been expressed so well by Barrett (5) that we quote directly from him: "A physician's debt to medicine can never be repaid in full. From the obscure country practitioner to the most renowned surgeon at the great medical center, each has received more from this, the oldest and noblest of professions, than the longest life can repay. From those who have received much, much is expected." The physician has been given much, a great part of which is the vast store of information which has been developed by his predecessors. In turn each of us has a duty to contribute to the great wealth of medical knowledge as well as to fulfill the obligation "to study and treat the ills of mankind, real and imagined, great and small" (5).

All of us know that tuition pays but a small part of the cost of medical education; each physician is financially indebted to society for the additional contribution made to his intellectual development. The physician partially repays society by his care of his patients. He devotes his ability and training to the solution of his patient's problem. Nobility of character develops during the process of serving mankind. The vast majority of our profession have conducted their lives so honorably as to justify the trust placed in them. For this reason the profession has risen to a high position of honor in contributing to the welfare of the people. We must see to it that this trust is not betrayed by the few who might be tempted to do so.

Whatever the field chosen by the young physician, he must realize that there is a need for continuing his education for the rest of his life. In the first place, this means a fundamental education in liberal arts. Too many physicians indeed are unable to write clear, readable papers or speak simply and understandably or even without obvious errors. Continued training can be achieved by many means, including attendance at medical meetings and graduate courses, reading medical books and journals, and personal contacts with other physicians. If the physician does not keep abreast of his field he rapidly becomes out-of-date, and his value to his patient lessens.

Physician's Fees. The young physician may have considerable difficulty in determining the size of his fees for services rendered. There are no rules for making a decision as to the amount of fees. In general, the amount is related to ability to pay, but this is by no means the only determining factor. Important also in determining the fee are the magnitude of the operation and the experience and judgment required on the part of the surgeon. Thus, the fee for an appendectomy should be less than that for a total gastrectomy for cancer even though both are celiotomies.

Regardless of the amount of the bill, the surgeon in most cases should discuss the matter with the patient before the operation, especially on request. This will eliminate much misunderstanding later. If more than one physician has been treating the patient, each should *send his own bill*, in proportion to the service rendered. Any method of fee-splitting is illegal and is condemned by the "Principles of Medical Ethics of the American Medical Association" (6), as discussed in detail under the next heading. If the patient

requests a combined, itemized bill, or there is some other legitimate reason why bills must be combined, each physician should send a receipt to the patient for the amount he receives. However, an exception is made in the formally organized clinics, where the physicians band together on a partnership basis even though each may receive a set salary or percentage of the total net income. Under such circumstances, it is entirely ethical to send a single bill, because the money collected is being distributed by the physicians themselves according to prearranged plan. As Hawley (7) remarks, this is not fee-splitting because there is no element of inducement. The method of payment by insurance companies for medical services rendered is irregular, and the recommendations of many companies are actually unethical, because they will pay only one physician even though two or more physicians may have treated the patient. This method of payment requires either a split of the fee or lack of payment to one of them. The American College of Surgeons is making a strenuous effort at the present time to have the insurance companies correct this error.

The ethics of paying surgical assistants has aroused some controversy. In any major operation, a first assistant is required who, of course, deserves to be paid, unless he is a resident or other full time physician. If a resident is not available, the surgeon must have another assistant; if he is not the referring physician, he may be paid by the surgeon, without discussing it with the patient. It is not ethical to employ the referring physician as assistant if residents are available, or if an assistant more skilled than the referring physician, is available. If there are several surgeons in a clinic, one should be designated as first assistant. In other words, the assistant's fee must not be used as an inducement for referral of the patient, nor fee-splitting disguised as an assistant's fee.

UNETHICAL PRACTICES

Numerous types of unethical practices exist in medicine. The profession must exert all possible effort to abolish them.

Fee Splitting. This is the most common of all unethical practices. It has been defined by the American College of Surgeons as

> the refunding of any portion of the total fee for the care of a patient to either the surgeon or referring physician. Moreover, when the surgeon or the referring physician submits a joint bill, itemized or unitemized, it shall be interpreted as fee-splitting, according to the principles stated by the Judicial Council, and approved by the House of Delegates of the A.M.A., in December 1952.

Rebates, or commissions from manufacturers, pharmacists, chemical companies, laboratories, ambulance companies, and x-ray laboratories are considered unethical. In eleven states, laws have been passed making fee-splitting a crime. In four states fee-splitting has been defined as any division of a fee even though the patient has knowledge of the division. In six states it has been defined as the secret division of a fee.

HARMFUL EFFECTS OF FEE-SPLITTING. Most of the ill effects of this practice are sustained by the patient. It actually is the factor responsible for many other types of unethical practices mentioned below; some are discussed later in more detail.

1. Fee-splitting results in overcharging; the patient actually pays for the act of being transferred from one physician to another.
2. It encourages unnecessary operations. Records show that in localities where fee-splitting takes place, the number of normal organs needlessly removed is high.
3. It results in immoral practice. The patient is used as a pawn, and the physician encouraged to place emphasis on his financial return, not the welfare of the patient.
4. Well-trained, honest young surgeons have difficulty starting practice in a community where fee-splitting is practiced. Patients are not referred to the young surgeon, despite his competence, because he does not split fees; the surgical patients will be sent to other surgeons who may or may not be competent but who offer the highest rebate.

MEANS OF PREVENTING OR ELIMINATING FEE-SPLITTING. Numerous means are available for correction of this evil, even though it is difficult to detect, since usually only two parties are involved in the practice. Some methods of prevention are enumerated below:

1. The surgeon should emphasize the importance of team work by telling the patient the importance of the initial care and establishment of the diagnosis by the referring physician.

2. The public should also be educated as to the value of the services of the referring physician and the justification of a fair fee for him.

3. The medical profession should publicly condemn excessive fees.

4. The medical societies, hospital staffs, and faculties of medical schools should impress upon students and medical trainees the evils of fee-splitting.

5. Medical societies should establish a method of punishment for fee-splitting, whether it be cancellation of membership or some other punitive measure.

6. Medical societies should establish Grievance Committees to which lay people as well as physicians may go for discussion of financial or other complaints. All physicians should be educated to the philosophy that fee-splitting is a serious evil.

7. Fees should be adapted to the patient's ability to pay. The surgeon should consult more freely with the patient or referring physician regarding the size of his fee in relation to the patient's ability to pay.

8. All physicians should be educated to tell the patient where the total professional fee goes, except in organized clinics, where such explanation is not necessary even though it is usually made.

9. If a hospital is having difficulty with ghost surgery, the patient may be required to sign an operative permit with the name of the operating surgeon thereon.

10. The hospital may ask all staff members to submit their financial books to an accountant.

11. Tissue Committees will minimize or eliminate needless surgery, and in this way will counteract fee-splitting.

Ghost Surgery. This term "is applied to an operation in which the patient is not informed of, or is misled as to the identity of the operating surgeon" (7). Under such circumstances the family physician permits the patient to believe that he is going to perform the operation, but instead employs another physician to do the operation without the patient's knowledge. The "ghost" surgeon usually does not meet the patient, but performs the operation and does not visit the patient postoperatively. He accepts the diagnosis without examining the patient and is told where to cut (8). The family physician collects the fee from the patient and splits it with the surgeon who performed the operation. The hospital records usually do not indicate that the operation was not performed by the family physician. In other words, fraud is perpetrated in a number of ways; the physician and hospital are both open to suit and collection of damages.

Payment of a Salary to Referring Physician. In an attempt to avoid the designation "fee-splitting," some physicians have organized a "clinic" and placed referring physicians on a salary which would be about equal to the amount due as refund for the split for fees collected from patients sent to the "clinic." These physicians are trying to hide under the cloak of the ethical procedure of employment by salary of physicians by a clinic. However, in the true clinic the physician is hired, usually full time, for care extended patients, regardless of the source of referral. Moreover, in the ethical clinic there is no element of inducement.

Abuse of First Assistantship Privilege. It is obvious that a surgeon must have a first assistant; he should be sufficiently well trained to perform this duty efficiently. In hospitals which are approved for the training of residents this duty or privilege is assigned to the resident. When a resident is not available, some other physician will have to be secured for operations which are of sufficient magnitude to require an assistant. The surgeon is expected to obtain the services of the best qualified physician or surgeon available. If the assistant is not the referring physician, he may send his bill to the patient, or he may be paid directly by the surgeon, even without the knowledge of the patient (9). If the assistant is the referring physician, he must be paid by the patient, and not by the operating surgeon. Under such circumstances the amount of the fee for assisting must be a fair charge equivalent to the amount paid the assistant when he is not the referring physician. It is entirely unethical for the surgeon to overstate the value of assisting to the patient so that he

will pay an exorbitant fee. If the referring physician should send a bill larger than a just one for service rendered, it is classified as an overcharge and actually is a form of fee splitting if part goes to the referring physician.

Unjustified Operation. This "is one in which either the indications were inadequate, or the procedure was one which is contrary to generally accepted surgical practice" (7). At times there may be a controversy as to just when an operation is justifiable, because error in diagnosis may be made by even the best of physicians. To pass judgment on the justification of a given operation, accredited hospitals have an audit, or tissue, committee to review the data. The greatest abuse is observed in removal of normal uteri and normal appendices. The terrible injustice to the patient of performing a needless operation needs no supporting arguments.

Excessive Fees. An excessive or exorbitant fee may be defined as one "greater than the patient is reasonably able to pay, or higher than justified by the service rendered" (7). Unfortunately, there is no prescribed way in which a standard fee can be set for an operation. The skill required to perform a certain operation may be greater than that required for the same operation in another patient; moreover, the ability of the patient to pay must be considered, because a patient with a low income should not be charged even the average fee. A surgeon of great experience may feel, and justifiably so, that his services are worth more than those of an inexperienced surgeon. The family physician often complains that the surgeon charged so much that the patient did not have enough money left to pay him; this may be a legitimate complaint, because the patient tends to pay the surgeon first, and to pay the referring physician if and when he accumulates money to do so.

RELATIONSHIP OF PHYSICIAN TO PHYSICIAN

There is no profession in which the members work in close contact with each other as much as in the medical profession. This intimacy makes it essential that the physician learn how to get along with his colleagues in the interest of the best care of the patient. The secret of the ability to get along with people is the application of the "Golden Rule." Allied to this philosophy is the axiom that one should not openly criticize his colleagues, but should make a constant effort to treat them with thoughtfulness as friends to be enjoyed and helped, rather than as competitors to be overcome or eliminated. When it is necessary for a physician to be out of town, it is customary to have another physician take care of his patients. The latter should, of course, return the patients to the former when he is again available.

During *consultations* certain important phases of conduct arise and should be clarified. In the first place, consultation is an important phase of medical practice and should be used more often. The knowledge available in medicine is so tremendous that no one person can possibly possess all of it; even the specialist in a comparatively narrow field cannot feel that he is completely informed in that subject. The old adage "two heads are better than one" certainly applies to medical problems. If the physician is in doubt about certain important phases of the patient's illness, he should ask permission to call in a consultant. If the patient appears unhappy and dissatisfied with the physician's advice and care, it is highly desirable to ask the patient if he would like to have a consultant see him. After the consultant has completed his examination, he should retire with the physician in charge to discuss the patient's condition. After they have had their conference, they should present the results of their deliberations to the patient or his relatives. It is customary for the consultant to do this in the presence of the physician in charge, since the consultant is actually employed by the patient. The consultant must not dishonestly agree with the physician in charge just for the sake of being friendly, if he feels the diagnosis or therapy is erroneous. On the other hand, the consultant should not criticize the physician in charge for inability to arrive at a solution to the medical problem, because often the solution is not apparent until all the data have accumulated. In most cases a common ground for therapy can be reached. An awkward situation might arise if the consultant and the physician calling for aid could not agree on a plan for further care. Usually in such circum-

stance a third physician is called in, or the first consultant withdraws after being given the opportunity to present his views to the patient or relatives in the presence of the physician in charge.

It should be emphasized that no patient "belongs" to the physician as a property right; *the physician is actually hired by the patient*, who may go to as many physicians as he likes. However, medical principles require that for the good of the patient he should not have two physicians at the same time when neither knows what the other is advising and prescribing. If a patient leaves one physician to go to another physician, that is his privilege. The second physician under such a circumstance has no obligation to send the patient back. Indeed, the first physician should cooperate by sending to the second physician on request any data he has.

RELATIONSHIP OF PHYSICIAN TO THE PATIENT

Certain professional characteristics are necessary for a physician's success. Two of them are very essential: 1. honesty, and 2. willingness to practice the "Golden Rule."

In his contact with the patient many of the physician's attitudes are related to his personal characteristics, others to medical activities. In the first place, he should be willing to listen to the patient and be considerate of his feelings; he must be sympathetic. He should be dignified, but friendly. It is essential that he get acquainted with the patient, but too frequent or close social contacts are undesirable for numerous reasons unless they have existed before. A physician must not drink alcoholic beverages during working hours. Excessive drinking after hours is likewise highly undesirable because the physician never knows when he may be called on an emergency; in fact, persistent heavy drinking will ruin the physician's career. The foul breath of excessive smoking is disagreeable to the patient and makes a bad impression.

The physician should be honest in his expressed opinions, yet he should not divulge knowledge which might be detrimental to the patient, particularly if the patient is overly apprehensive. The physician must not be guilty of making misleading and inaccurate statements about the patient's disease to create a good impression, or for any other reason, because discovery of inaccurate statements by the patient will lead to loss of confidence; *moreover, it is dishonest. Do not* criticize fellow physicians, since this amounts to a method of self-criticism, and is usually interpreted by the patient as a weakness in personality.

The physician must be willing to spend time with the patient. He should explain the patient's disease in terms which the patient can understand (Truman, 1). The physician *may demonstrate his knowledge* of a disease, but must not brag.

The physician should be a good psychologist so that he may detect diseases which are related to personal problems, because the patient, himself, may be entirely unaware of this relationship. Accordingly, the physician *must be sufficiently astute and intelligent* to suspect the influence of family or social problems on the disease or patient's complaints. It may be necessary to scrutinize the personal and social problems of the patient, and to determine the extent to which he has been worrying about family or financial matters. Moreover, the physician must try to evaluate the patient's sincerity; often through false modesty the patient will give misleading or dishonest answers to questions.

The physician must not lose his temper in his contact with patients. He must remember that the patient is ill, and the situation is comparable to an axiom in business, namely, "the customer is always right." This does not mean that the physician must bow to the patient's wishes, but implies that he must be tolerant. There are many ways of saying, "no," without being abrupt.

When the patient has a serious or perhaps incurable disease, such as cancer, numerous problems arise which require much diplomacy and tact.

Should the patient be told he has a serious or hopeless disease? The answers to such questions as how much the physician should *tell the patient* are exceedingly important, although difficult of solution. There is no categorical answer to the question, "Should you tell the patient he has a cancer?" If the patient is a busy *executive, who must have*

an approximation of his life expectancy to plan for future possible activities, he must be told he has a cancer or malignant disease. However, the doctor should be sure to tell the patient the truth. There is no excuse for telling a patient he is going to die in six months, or at any specified time, particularly since no one can predict the exact duration of life in the hopeless stages of cancer, heart disease, etc. Moreover, supposedly hopeless cancer may occasionally cease its growth and, in fact, spontaneously regress. If the tumor is inoperable, the physician can tell the patient the prospects are not good, but to be hopeful. If the tumor has been removed by surgical or other means, he can inform the patient that the outlook should be very optimistic. A business executive usually is sufficiently mature to accept news of this type without losing his equilibrium. He does not fear death nearly as much as a young person. Moreover, the problems with which an older individual has been confronted have hardened him to the sad facts of life. He can, accordingly, adjust rapidly and effectively.

If the patient is young and apprehensive, it may not be wise to tell him he has a cancer or malignant growth. If an operation is indicated, the physician can tell the patient he has a growth which must be removed. If he asks a pointblank question, such as, "Is it cancer?" the physician can give an indirect answer, saying he must wait for microscopic sections; however, one should remember that candor is the best policy. It is the way truth is told that is important. After the growth has been removed the physician can then tell the patient that the question of the degree of malignancy becomes of less importance since no more trouble is expected. As Elman (10, 11) has stated, when patients are being treated for tumors most of them will accept a reasonable explanation concerning their illness and not demand specific answers. If the medical student is asked by the patient whether or not he has cancer, the answer should be very cautious since the student may not have the experience and tact to discuss such a vital point with the patient.

RESPONSIBILITY TO THE COMMUNITY

One of the physician's first responsibilities when starting practice in a community is to join the local medical society and take part in its activities. He should make sure that the society exerts all possible effort to treat the public fairly. The medical society should have a Grievance Committee, or a committee of this type, the function of which should be to listen to patients' complaints, especially concerning fees. If the physician does not think the function of the medical society is being carried out correctly, he should not stay away from meetings and criticize privately; it is much more effective to attend the meetings and try to correct the erroneous thought or action openly.

The physician must always remember that people are justifiably interested in and curious about their health and medical problems. There can be no doubt that life is the most valued of a person's worldly possessions. Accordingly, our actions must be governed by that fact. The physician should attempt to satisfy this need not only by action but by word. He need not explain the disease or symptoms at great length; often a few simple sentences will suffice. But he must not adopt a policy of mystery or indifference. The public, as well as the medical profession, must realize that health is a responsibility of both. Mutual effort must be provided in improving circumstances related to health.

Medical insurance should be encouraged. The types of policies are improving from year to year, but, for some unexplained reason, the insurance companies have been very slow in writing and publicizing the most valued and important of all policies, namely, the one to protect the patient against a medical catastrophe. The failure to extend catastrophe insurance is partly responsible for the government's efforts to enter the medical insurance field.

MALPRACTICE AND MEDICOLEGAL ASPECTS OF PRACTICE

Suits for malpractice are increasing. Every physician should have malpractice insurance. To protect himself against possible suit, he should pay particular attention to the type of care given the patient. Everybody, including lay individuals, realizes the human body is so intricate that no physician is expected to know all its mechanisms of function in health and disease. Courts of law are aware of this,

and consequently not all errors are subject to suit. In general, the plaintiff must prove negligence or failure to use the average care, skill, and judgment exhibited in the practice of medicine in that community. Rarely is the wrong diagnosis sufficient to justify a suit, although there are such cases on record. Numerous phases of malpractice have been studied by the American College of Surgeons, and an important feature not sufficiently realized is pointed out by the following quotation from their publications (8):

> Yet the fact of the matter is that the malpractice claim, like charity, begins at home in many cases. It is in the surgeon's office or consulting room, and not in the hospital, that the seeds of malpractice claims are most commonly sown, for it is here that the doctor-patient relationship is established. The doctor-patient relationship is the soil in which dissatisfaction may take root and flourish or wither and die, depending on the surgeon's conduct.

Among the hazards often overlooked, the following factors have been emphasized by underwriters of the Professional Liability Insurance Program of the American College of Surgeons (12), and by malpractice authorities generally:

1. Carelessness or incompetence of office assistants
2. Destructive or unethical criticism of the work of other physicians
3. Improper conduct of physical examinations
4. The overoptimistic prognosis
5. Admissions of failure in connection with treatment
6. Failure to suggest consultation when results are unsatisfactory or when the patient shows signs of dissatisfaction or impatience
7. Office equipment that is obsolete or in poor working condition
8. Poorly planned or executed billing procedures, and excessive bills

Good records are very important in protecting the physician against suit. Accordingly, the physician must maintain detailed data in his office records and insist that data in hospital records be complete.

Nonunion and malunion of fractures are perhaps the most common causes of suit, even though the treatment rendered the patient may not have been erroneous or lacking in good judgment. Foreign bodies left in the wound at operation are likewise common causes for suit. Since, with few exceptions, the surgeon will have difficulty proving he has utilized average care under such circumstances, the verdict is apt to be favorable to the patient. Instruments left in a body cavity at the time of operation can be detected by x-ray. So also can sponges be detected by x-ray, since operating room sponges now are tagged with material impervious to the x-ray. The physician may be able to remove the sponge without knowledge of the patient, but with very few exceptions such action is not to be condoned, since the physician is then liable for fraud in addition to loss of the sponge in the wound.

It may be of slight comfort to know that the law will usually be on the side of the physician who has acted conscientiously and competently in fields in which he is qualified.

EUTHANASIA

Euthanasia may be defined as the planned destruction of life for what is called medically justified reasons. However, it is a dangerous practice which cannot be approved by the medical profession, even though it often appears cruel to allow a patient with a hopeless disease to live and suffer. There are numerous reasons for not approving destruction of life, even in circumstances in which recovery seems impossible (13). In the first place, a cure might be discovered at any time for what is a seemingly hopeless disease. In the second place, the practice of euthanasia inflicts a heavy blow on our moral responsibilities. The big question is: who is to decide what is hopeless, and who shall die? What is to prevent the physician from being influenced by ulterior motives, such as the hatred of a member of the family who no longer wants the patient to recover? Moreover, the courts have ruled that euthanasia is illegal. The physician who practices it does so with the possibility of a death verdict in court. This does not mean that adequate control of pain and suffering with the use of large and even sublethal dosage is not justified and even indicated. No patient should be permitted to suffer merely to prolong his life, already threatened by a fatal disease.

RELATIONSHIP OF PHYSICIAN TO HOSPITAL

Most hospitals permit only staff members to bring patients into the hospital. In determining the membership of its staff, the hospital is autonomous. However, to meet the approval of the medical profession, certain standards have been set. Years ago, the American College of Surgeons initiated a program by which hospitals could be accredited after meeting certain standards. As the number of hospitals increased throughout the country, this work became too complicated, and too expensive for one organization to execute. Accordingly, the Joint Commission on Hospital Accreditation was formed to attain this very important objective. This Commission is administered and supported by four major societies, American College of Physicians, American College of Surgeons, American Hospital Association, and American Medical Association.

Hospital accreditation is very important in the health of the community, because the welfare of the hospitalized patient depends to a great extent upon the standards maintained in that hospital. Accordingly, it is essential that the physician support the hospital in its efforts to support high standards, which are readily measured in terms of accreditation. If a hospital is not accredited, the staff must make all effort to improve the facilities so that it may be approved by the Joint Commission on Accreditation. Hospitals are inspected in various ways. Important are the administrative and professional organizations. The laboratory facilities, record room and other ancillary functions are investigated. Good medical records must be maintained by the medical staff. The services of a pathologist must be provided. All tissue removed at the operating-room table must be examined. The hospital must maintain a pharmacy, radiology department, and medical library. The staff must obtain an acceptable percentage of autopsies. A minimum attendance at hospital meetings is required.

As stated previously, the hospital itself is autonomous in that the Hospital Board has the primary authority in all appointments and details, so long as prerequisites mentioned above are met. However, certain problems not related to accreditation are important. One of these is the question as to who may have surgical privileges. It should be emphasized that neither the various Boards of Surgery nor the American College of Surgeons has made any statement whatsoever as to who shall operate in individual hospitals. That decision is up to the hospital itself. Often the hospital sets up various classifications in this regard; e.g., full operating privileges and limited operating privileges. The assignment of a house staff physician to either of these two groups is determined by a hospital committee. However, such a plan is far from ideal, since serious problems commonly present themselves at the operating table, although a simple operation was contemplated. For example, a physician may perform a celiotomy for appendicitis when the real cause of symptoms is a carcinoma of the right colon. Under such circumstances, the surgeon should be allowed to perform the correct surgical procedure and not have to subject the patient to two operations by closing the abdomen and having a competent surgeon do the definitive operation at a later date.
